or polygonal from mutual compression. Others are less malignant and retain their characteristic columnar form. Such growths have less tendency to transgress barriers (though they must do somewhere otherwise they would not be carcinomas) and are seen to be mainly intraductal. The invasive growths excite a greater or less degree of stromal reaction, both fibrous and cellular. A prominent feature of the histology is that in any one tumour there is usually an infinite variation in the pattern of the cancer cells, from the atrophic scirrhous with much fibrous tissue to the most cellular with little or none. Furthermore, while the breast lump may be an obvious scirrhous, the deposits in the lymph nodes may be highly cellular. It is possible, however, to distinguish those arising in the *nipple* (Paget's disease, p. 653), those arising in the *ducts* which are frequently papilliferous in form, and those arising in the *breast tissue* itself which are composed mainly of spheroidal cells with varying degrees of fibrous tissue response. A distinct type is the so-called *colloid* carcinoma where all the neoplastic cells are distended with colloid material. This tends to form a large growth but it is not highly malignant as might be expected.

THE SPREAD OF MAMMARY CARCINOMA

(*a*) **Local Spread.**—The tumour increases in size and invades other portions of the breast. It tends to involve the skin (fig. 711) and to penetrate the pectoral muscles, and even the chest wall.

(*b*) **Lymphatic spread** occurs in two ways: *by emboli*, composed of carcinoma cells, being swept along the lymphatic vessels by the lymph stream; and *by permeation*, that is, actual growth of columns of cancer cells along the lumina of the lymphatic channels. By these means the axillary lymph nodes and sometimes the internal mammary lymph nodes are involved comparatively early. Later, the supraclavicular lymph nodes, the opposite breast, and the mediastinum, are all possible resting places for itinerant carcinoma cells journeying by this route. Finally, they may be found in lymph nodes even farther afield.

(*c*) **Spread by the Blood-stream.**—It is by this route that skeletal metastases occur (in order of frequency) in the ribs, lumbar vertebræ, femur, thoracic vertebræ, and the skull, they are generally osteolytic pathological fractures occurring most often in a rib or a vertebra. In most instances it is by way of the blood-stream that metastases arrive in the liver, lung fields or brain from the breast, but secondary deposits may also be carried to the liver via the lymphatics within the rectus sheath and the falciform ligament. The adrenal glands and the ovaries are also common sites for blood-borne metastases.

Clinical Types of Carcinoma of the Breast.—It is difficult to give any one growth a distinct classification, and the clinical significance may be minimal. However, because the tumour may present in such a wide variety of ways, it is relevant to recognise certain clinical types. Commencing with the most malignant and (assuming that a diagnosis is made reasonably early) passing to the least malignant, the following clinical varieties are encountered:

Mastitis Carcinomatosa (2 per cent.).—Most of these cases occur during pregnancy or lactation. The diseased breast is often painful—an uncommon symptom in ordinary carcinoma of the breast. In 50 per cent. of cases there is retraction of the nipple. The reddened skin (fig. 709) feels abnormally warm and cutaneous œdema, which indicates blockage of the subdermal lymphatics with carcinoma cells, usually extends over a considerable area, i.e. over one-third or more of the breast. This galloping form of mammary cancer, which is the result of an unbridled proliferation

FIG. 709.—Mastitis carcinomatosa of the left breast.

of cancer cells with very little fibrous reaction, sometimes is mistaken for an abscess, and incised. The main distinguishing features between the two conditions are that in mastitis carcinomatosa there is (1) more widespread œdema, (2) (with few exceptions) an absence of pyrexia and leucocytosis, and (3) the 'inflammation' fails to respond to antibiotic therapy.

Treatment.—In many instances palliative treatment is all that is possible, and usually the patient is dead within a few months. Whether the pregnancy should be terminated is a great problem and each case has to be considered on its merits. Proof that benefit occurs is difficult to come by. If the pregnancy is terminated, oöphorectomy should be carried out as well.

Medullary (*syn.* **anaplastic**) **carcinoma** (17 per cent.) is usually found in women between twenty-five and thirty-five years of age with well-developed breasts (fig. 710). While presenting many characteristics of the scirrhous

FIG. 710.—Medullary carcinoma of the left breast. The nipple on the affected side is elevated. The breast contains an irregular firm mass. The axillary lymph nodes are impalpable.

FIG. 711.—Medullary carcinoma fungating through the skin.

variety, the epithelial element of the growth is in excess of its fibrous stroma. As a consequence the tumour does not feel so hard, and in advanced cases (fig. 711) it may present semi-solid areas due to degeneration of masses of ill-nourished cells. This carcinoma is not so malignant as one was often led to believe. Statistics from all clinics show that the survival rate after operation is no worse than that of scirrhous carcinoma, and when there is a pro-

nounced lymphoid reaction, it is strikingly better. Perhaps the relatively large size and rapid growth of the tumour impel the patient to seek relief earlier than in the case of scirrhous carcinoma.

Scirrhous[1] carcinoma (63 per cent.) is met with principally in middle-aged and elderly women. Owing to an abundance of fibrous tissue the lump feels very hard, while its contour tends to be irregular. The most important physical sign in breast cancer is attachment of the lump to the skin, underlying muscle, or to the nipple (fig. 712). The clinician must spare no pains to be certain whether the lump he is investigating has any such attachment (fig. 713). The importance of recent retraction of the nipple has been alluded to already (p. 634). *Peau d'orange* of the skin overlying the tumour is a late sign. In the early stages the axillary lymph nodes are impalpable, but they are invaded microscopically a considerable time before they can be felt clinically.

FIG. 712.—Scirrhous carcinoma of the left breast; Stage I. Nipple commencing to retract. (For staging of carcinoma of the breast, see p. 654.)

Untreated, the growth invades and eventually ulcerates through the skin and it may extend into the thorax (fig. 714), while dissemination via the lymphatic and bloodstreams finally determines the fatal issue.

If a breast containing a scirrhous carcinoma is cut with a knife so as to section the tumour, the following macroscopical characteristics will be noticed:

1. The growth cuts like an unripe pear, and may grate whilst being cut.
2. Usually *both* cut surfaces are found to be concave.
3. The colour of the cut surface is definitely grey (fig. 707), and its appearance has been aptly likened to the interior of an unripe pear. A most important gross finding is small granular whitish streaks within the tumour tissue.

FIG. 713.—Scirrhous carcinoma; Stage III. Nipple almost out of sight.

FIG. 714.—Stage III. Nipple submerged, skin involved by the growth which is adherent to chest wall.

[1] Scirrhous—from the Greek *skiros* = hard.

4. On viewing the periphery of the sectioned tumour it will be found that there is not the slightest indication of a capsule. True to its namesake, the crab, its claws have penetrated hither and thither into the breast tissue, and it is impossible to separate the tumour from the breast.

Atrophic scirrhous carcinoma (5 per cent.) is seen principally in aged, thin women with small breasts. The cellular element of the growth is comparatively sparse, its main constituent being the fibrous stroma. Although steadily progressive, the disease runs a very chronic course, perhaps taking ten years to ulcerate through the skin, after which it is inclined to grow somewhat more rapidly. Stilbœstrol (p. 660) may cause it to disappear.

Duct Carcinoma (8 per cent.).—As the leading symptom in both conditions is a blood-stained discharge from the nipple, it is often impossible to distinguish a duct papilloma from a duct carcinoma without the evidence of a biopsy or occasionally mammography. In the case of a duct carcinoma sometimes a small lump can be palpated behind the nipple or areola, and emerging from this there is usually a sector-shaped area of induration, viz.→

Obviously the cause of the latter is distension of those alveoli drained by the duct that is blocked by the growth.

Exploration in a Doubtful Case—On slitting up a lactiferous duct containing a duct carcinoma it is often possible to trace the main stalk of the neoplasm arising from the wall of the duct. From this stalk delicate tendrils, like fine seaweed, can be traced along smaller ducts, the latter and their corresponding alveoli being dilated into a fine sponge-work by the growth and blood-stained serous exudate.

The reason for the relative benignity of this form of carcinoma is that the lymph nodes are involved somewhat late in the course of the disease and, as a duct carcinoma gives rise to an alarming symptom (bloody discharge from the nipple) which impels the patient to seek advice early, the prognosis after mastectomy is usually good.

FIG. 715.—Intracystic papilliferous carcinoma. The breast is also the seat of fibroadenosis with multiple small cysts.

Intracystic Papilliferous Carcinoma (2 per cent.).—It is usually impossible to differentiate this condition from a simple cyst until its interior has been displayed or aspiration has revealed blood-stained fluid or a lump remains afterwards (p. 645.) Rapid recurrence of the cyst after aspiration is al so suspicious. Within the cyst there is a caul i-flower-like growth (fig. 715). The prognosis after early operation is good.

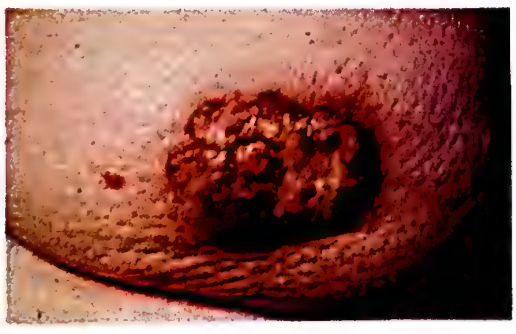

FIG. 716.—Paget's disease of the nipple. Note also the 'peau d'orange' due to the underlying carcinoma.

Paget's disease of the nipple (1 per cent.) is a persistent eczema-like condition that usually commen ces in patients over fifty years of age and does not respond to treatment. The nipple is eroded slowly and eventually disappears. As the disease progresses the areola becomes involved (fig. 716), and the erosion continues to spread peripherally until a carcinoma within the

Sir James Paget, 1814–1899. Surgeon, St. Bartholomew's Hospital, London. Described this condition in 1874.

breast becomes manifest. After many years of controversy it is now agreed that Paget's disease of the nipple is due to a slowly growing duct carcinoma that infiltrates the epithelial covering of the nipple.

Differential Diagnosis:

Eczema	Paget's Disease
Bilateral.	Always unilateral.
Lactation.	Menopause.
Vesicles.	None.
Responds to treatment.	Does not respond.

Microscopically the affected area is characterised by the presence of large vacuolated cells with small deeply staining nuclei in the epidermis. In the majority of cases an exhaustive microscopic search reveals the presence of malignant changes in the ducts. Sooner or later a carcinoma develops in the breast itself.

Treatment should always be mastectomy. As a rule the prognosis is extremely good. Naturally, if the patient has a palpable lump as well as nipple erosion, the prognosis is less favourable and is comparable to an invasive duct carcinoma without associated nipple change. On no account should patients with this condition be subjected to radiotherapy alone, as Paget's disease of the nipple is radio-resistant.

CLINICAL STAGING OF CARCINOMA OF THE BREAST

When the patient is first examined, instead of categorising the growth in such vague terms as 'early', 'moderately advanced', or 'advanced', it is highly desirable to have some conventional method of expressing, in an explicit manner, the stage which has been reached. Not only does this provide a reasonably accurate indication of prognosis but it also provides a basis by which results of treatment can be compared. It is a prerequisite of any staging method that it must be accurate, and symptomless metastasis must be searched for with all available methods. Full radiological survey is essential. Bone scanning by which the uptake of technetium or a similar isotope by the skeleton is examined using a gamma camera will detect occult metastases in the presence of normal X-rays and should be used if available. Liver function tests and a liver scan may also be helpful.

T.N.M. Classification.—The International Union against cancer has recommended a staging system known as T.N.M. (Tumour, Nodes, Metastases) (p. 48). This system is now accepted in most centres as the basis for defining stage on clinical grounds. As a result it is possible to define four stages very comparable to the original Manchester classification, i.e.

Stage I.—Growth confined to the breast. An area of adherence to, or ulceration of, the skin smaller than the periphery of the tumour does not affect staging. The tumour must not be adherent to the pectoral muscles or the chest wall.

Stage II.—Same as Stage I but there are affected *mobile* lymph nodes in the axilla of the same side. Clinical examination is notoriously inaccurate in assessing the significance of axillary lymph glands, for 26% of patients with no palpable glands have histological evidence of involvement and a rather greater percentage of patients with palpable glands have no evidence of tumour.

Stage III.—Skin involvement larger than tumour but still limited to the breast, lymph nodes mobile if palpable, tumour fixed to pectoral muscle but not to chest wall.

Stage IV.—Distant spread and metastases either blood borne or lymph borne; this includes the skin wide of the breast, fixed nodes in the axilla, palpable nodes in the supraclavicular fossa, involvement of the opposite breast, and deposits in bones and viscera such as lungs and liver.

PHENOMENA RESULTING FROM LYMPHATIC OBSTRUCTION IN CASES OF MAMMARY CARCINOMA

Peau d'orange is due to cutaneous lymphatic œdema. Where the infiltrated skin is tethered by the sweat ducts it cannot swell. The characteristic pitted appearance, so well likened to orange peel by French observers, has become a classical physical sign of advanced carcinoma of the breast. But it should be remembered that occasionally the same phenomenon is seen over an abscess, particularly a chronic abscess, of the breast.

Early Post-operative Œdema of the Arm.—Œdema may occur within a matter of days after radical mastectomy. Its cause is likely to be related to axillary vein occlusion, but it is wise to regard it as infective in origin and treat with a full course of antibiotics.

Late œdema of the arm (*syn.* elephantiasis chirurgens) is a frequent and troublesome complication of radical mastectomy. The swelling (fig. 717) appears at a time varying from several months to many years after operation and, although not inevitably the case, should be considered as evidence of tumour extension until disproved. Obese patients are specially susceptible to it. It may be associated with a local infection of the arm or hand and if any such is demonstrable, it must be vigorously treated with antibiotics. It is certainly more common when a radical mastectomy is followed by deep X-ray therapy. The only treatment of value is elevation with the use of an elastic armlet from the wrist to the axilla. Massage and exercises may give considerable benefit. In obese patients drastic reduction in weight is helpful. Various operations to enhance lymphatic drainage have been advocated (p. 176).

FIG. 717.—Late œdema of the arm following radical mastectomy three years previously.

Brawny arm can result from advanced neoplastic infiltration of unremoved or incompletely removed axillary or supraclavicular lymph nodes. The œdema, which is persistent and brawny (it does not pit), is due to lymphatic blockage, but in some cases venous obstruction is a contributory cause.

A forequarter amputation is merciful in selected cases, especially in order to relieve the intense pain caused by involvement of nerves in the axilla.

Cancer *en Cuirasse*.—Here, in addition to a brawny arm, the affected side of the thoracic wall is studded with carcinomatous nodules and the skin is so infiltrated that it has been likened to a coat of armour. Usually, but not necessarily, the condition appears in cases with local recurrence after amputation of the breast. It may also follow the distribution of irradiation to the chest wall and shoulder. Various palliative measures can be tried, but the main objective is to relieve pain and mental distress for the few remaining months of the patient's life, e.g. Mist. Euphoria (Chapter 60) is strongly indicated.

Lymphangiosarcoma has been recognised recently as a complication of post-mastectomy lymphœdema. Unless there is awareness of the condition, it is likely to be confused with recurrent carcinoma of the breast.

If considered humane and advisable, deep X-ray therapy may postpone the inevitably fatal course of this complication. The only alternative is to perform an interscapulo-thoracic (forequarter) amputation (fig. 718).

FIG. 718.—Lymphangiosarcoma developed 3 years after radical mastectomy. Patient well 6 years after forequarter amputation. *(R. P. Singh, F.R.C.S., Karchana, India).*

Serous effusion into the peritoneal or pleural cavities may be one of the terminal events in hopeless cases. The use of aspiration and replacement with a cytotoxin can alleviate symptoms in many of these patients.

METHODS OF TREATMENT OF CARCINOMA OF THE BREAST

At the present time there is no agreement as to the treatment of choice for early breast cancer. A variety of operations have been described and each has its advocates. They include segmental resection, simple mastectomy, radical mastectomy to remove the axillary lymph nodes, and extended radical mastectomy to include the internal mammary and/or the supraclavicular lymph glands. Each of these may be supplemented by radiotherapy or by chemotherapy. There is as yet no strong evidence that any of these methods is superior to the others and the main decision in an individual patient must be to define whether she is potentially curable or not. The presence of distant metastases whether occult or overt means that major mutilating surgery must be avoided, and it is held by authorities that local treatment for breast cancer should be directed to the ablation of the primary tumour (simple mastectomy) alone; more extensive resection (radical mastectomy) has as its objective the avoidance of unpleasant local recurrence rather than to improve overall survival. It must be said that the removal of axillary lymph glands and their subsequent histological examination means that metastatic deposits can be confirmed and thereby their effect on prognosis assessed. Some authorities believe that the presence of such deposits indicate disseminated disease and have advocated the use of prophylactic chemotherapy with cytotoxic drugs to eradicate these micro-metastases.

The advanced disease, Stages III and IV, the interests of the patient are best served by early palliation with surgery, radiotherapy and hormone control where appropriate.

Radical Mastectomy[1].—The breast and associated structures are dissected *en bloc*, and the excised mass is composed of:

1. The whole breast.
2. A large portion of skin, the centre of which overlies the tumour, but always includes the nipple. When there is much skin involvement more skin must be sacrificed.
3. The fat and fascia from the lower border of the clavicle to, and including, the upper quarter of the sheath of the rectus abdominis, and from the sternum to the anterior border of the latissimus dorsi.
4. The sternal portion of the pectoralis major and its fascial sheath.
5. The pectoralis minor and its fascial sheath.
6. The costocoracoid membrane.
7. All the fat, fascia, and lymph nodes of the axilla.
8. The fascia over, and a few of the superficial muscle fibres of, the anterior part of the external oblique, serratus anterior, the subscapularis, the exposed portion of the latissimus dorsi, and the upper part of the rectus abdominis (fig. 719).

During the operation every effort should be made to preserve:

1. The axillary vein.
2. The cephalic vein.
3. The long thoracic nerve of Bell (nerve to serratus anterior).

---

[1] William Stewart Halsted, 1852–1922, Professor of Surgery, Johns Hopkins University, Baltimore, was responsible for evolving the radical amputation of the breast as performed today. The operation is often known as ' a complete Halsted '.

Sir Charles Bell, 1774–1842. Surgeon, Middlesex Hospital, London, and founder of its Medical School.

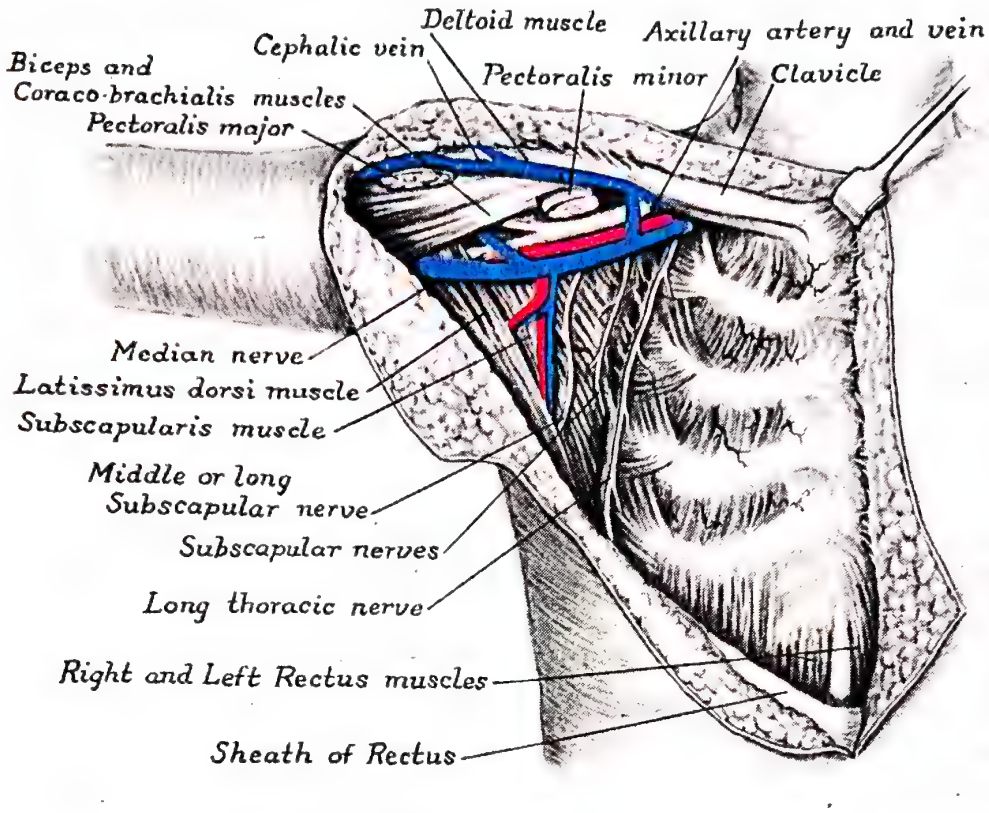

FIG. 719.—Radical mastectomy completed.

The middle or long subscapular nerve (nerve to latissimus dorsi) can be sacrificed without ill effect, and this should be done without hesitation if its division enables a more thorough dissection to be carried out.

During the operation the exposed chest wall must be protected by towels wrung out in hot saline. At the completion of the operation the wound is drained.

If a wide area of skin has been sacrificed, it may not be possible to approximate the skin edges completely. A deficiency is left which is treated by immediate or subsequent skin grafting.

After operation the arm is supported upon a pillow until the wound has healed, when early movement of the arm is encouraged. The movements of the arm after so extensive a loss of muscle are surprisingly good.

Extended Radical Mastectomy.—As about 50 per cent. of cases of carcinoma in the medial quadrants and 25 per cent. in the lateral quadrants of the breast show metastases in the internal mammary lymphatic chain, a small number of surgeons feel that the internal mammary chain should be included in a radical mastectomy.

Simple Mastectomy.—In this operation the excision of the breast is the same as the radical operation, but the pectoral muscles and fascia are not removed and the axilla is not disturbed.

Patey has described and practiced an extension of this operation in which the pectoral muscles are again spared but the axilla is cleared of its nodes. It is increasingly popular, because it combines the virtues of the Halsted procedure with a better cosmetic result.

THE RÔLE OF RADIOTHERAPY IN THE TREATMENT OF MAMMARY CARCINOMA

Post-operative irradiation is not indicated when the mastectomy specimen reveals no metastases in the axillary lymph nodes. It is usually given to patients who have axillary node involvement as soon as the wound has healed. The internal mammary, supraclavicular and axillary node areas are irradiated to a total dose of 4,000–6,000 rad. Present criticism of radio-

David Howard Patey, Surgeon 1899–1976. The Middlesex Hospital, London.

therapy is that it may interfere with the local lymphocyte immune response to the disease.

Treatment of Recurrences and Secondary Deposits.—Deep X-ray therapy causes disappearance or retards the progress of recurrences and secondary deposits in about one-third of cases. Examples are encountered where extensive metastatic deposits are so radio-sensitive that they melt away with this form of therapy, unfortunately only to return in the same, or another, site.

McWhirter's Method of Treatment.—Because either the supraclavicular or the internal mammary lymph nodes are implicated in 48 per cent. of patients with axillary lymph node involvement (p. 650), R. McWhirter considered that it was illogical to clear the axilla of its lymph nodes. He merely advised simple mastectomy to rid the patient of the primary neoplasm, and relied on radiotherapy for the treatment of axillary, supraclavicular and internal mammary lymph node involvement. The method is contraindicated in (1) very obese patients, (2) aged patients, (3) those with advanced arteriosclerosis, (4) those with tuberculosis, and (5) those with a primary neoplasm in the axillary tail of the breast.

RESULTS OF TREATMENT

Recurrence-free Rates (all forms of treatment)

Stage	5 *years*	10 *years*
I	68 per cent.	54 per cent.
II	40 „ „	25 „ „
III	15 „ „	4 „ „
IV	2 „ „	4* „ „

* Includes several patients treated earlier but not accounted for in the 5-year list. (*Statistics from the Royal Marsden Hospital, London.*)

Unlike some forms of malignant disease, where if the patient survives five years a permanent cure can be assumed, there is no such criterion in cases of carcinoma of the breast. Patients die of secondary mammary carcinoma (though rarely) as long as fifteen or even twenty years after operation. It is, however, abundantly clear that when the axillary lymph nodes are not involved, the prospect of many years of freedom from recurrence is much greater.

Screening for Breast Cancer.—Most authorities accept that the disappointing results which follow the treatment of breast cancer, regardless of the method used, are related to the dissemination that occurs in even early disease. It is less generally accepted that very early diagnosis and treatment materially influences the results. In some centres screening programmes which utilise clinical examination, mammography and thermography have attempted to diagnose tumours at a preclinical stage, and results are now becoming available relating to these patients. There is no doubt that the survival rates are significantly better than the hitherto accepted figures at comparable times after treatment but it is not yet possible to say whether this improvement will be maintained. It is possible, however, that population screening for high risk groups of women will be an accepted part of the management of breast cancer.

Robert McWhirter, 1904–1976. Director, Radiotherapeutic Department, Royal Infirmary, Edinburgh.

The effects of pregnancy after radical mastectomy for carcinoma are unknown but most surgeons advise against having children within 3 years of operation. Similarly the use of small doses of œstrogens for menopausal symptoms or in the contraceptive 'pill' may accelerate the growth of any remaining tumour tissue.

THE ENDOCRINE TREATMENT OF INOPERABLE AND RECURRENT CARCINOMA OF THE BREAST

1. **Hormone Responsive.**—About 30 per cent. of mammary carcinomas are hormone responsive; that is to say that their growth is controlled partly by one or more of the hormones involved in normal mammogenesis. When their hormonal milieu is altered to one that is disadvantageous to their continued growth they cease to proliferate or metastasise and many of their component cells perish. Unfortunately this regression following hormone deprivation is never permanent.

2. **Autonomous.**—The remaining 70 per cent. of carcinomas are composed of cells which require no hormonal stimulus to enable them to thrive, multiply and metastasise. Alteration of the hormonal status has an insignificant effect and usually no effect at all on tumour growth. Even if carcinomas belonging to group one are deprived of the hormone or hormones that stimulate them, after a varying number of months or years they, too, become autonomous.

Although the fact that some breast carcinomas are hormone responsive has been known for about seventy years, there is still no direct evidence as to which hormone or group of hormones is responsible. It has always been presumed that the term hormone responsive was synonymous with œstrogen responsive and that these cancers would cease to thrive if they were deprived of naturally occurring œstrogens. Indeed, most of the endocrine treatments for advanced cancer were aimed at those organs (i.e. the ovaries and adrenal glands) that are able to secrete œstrogens. During the past few years, however, since methods have become available for the accurate estimation of steroid hormones and their metabolites and of pituitary hormones it has become apparent that the problem is complex. Attempts to define hormone responsiveness in terms of the pattern of hormone levels in the blood or urine have so far been unhelpful. More recently methods of looking for œstrogen receptors in tumour cells or of examining the direct effect of various hormones on tumour cell cultures have been more hopeful in providing an answer. At the present state of our knowledge, however, treatment is still on an empirical basis, and although it has been found that certain combinations or sequences of drugs have a beneficial effect, we still do not know why this is so.

Oöphorectomy

This was the first treatment designed to affect the endocrine status of patients with advanced carcinoma of the breast. It was first described in 1896 by Sir George Beatson, of the Western Infirmary in Glasgow, who published an account of two cases treated in this manner. Oöphorectomy or ovarian irradiation is still used extensively as a treatment of recurrent or advanced breast cancer and is beneficial in approximately 20–30 per cent. of cases. It is of value only before the menopause and the remission so produced can last up to two years or longer.

Androgens

The administration of androgens probably accomplishes the same as an oöphorectomy although it could be argued that the former would also counteract the adrenal secretion of œstrogens. The remission rate and duration of remission are similar for

Sir George Thomas Beatson, 1848–1933. Surgeon, Western Infirmary, Glasgow, Scotland.

the two forms of treatment. Administration is usually by injection, either in the form of testosterone propionate, 100 mg three times a week intramuscularly or one of the anabolic steroids, such as Durabolin 50 mg once a week intramuscularly. The great disadvantage of this form of treatment is the incidence of virilisation which, if severe, can be most distressing. With Durabolin, which has a more powerful anabolic and weaker androgenic effect, the incidence of side-effects is greatly diminished, and only a problem in 10 to 20 per cent. of cases. Androgens can be administered to all age groups, but are usually considered the treatment of choice for patients who are pre-menopausal or within five years of the menopause.

Œstrogens

Although the prescription of œstrogens may seem contradictory to the theories of hormone responsiveness, it is perhaps the most efficacious treatment. It should not be given unless the woman is more than five years post-menopausal. The reponse to the drug increases with age and may reach 60 per cent. in women over seventy. Over-all the remission rate is approximately 40 per cent. Side-effects do occur however; nausea and vomiting may be troublesome in the early stages and usually subside in time. Fluid retention and vaginal bleeding are a more persistent problem and if severe may mean that the treatment has to be stopped altogether or an alternative type of œstrogen used. It is important that the drug is administered in sufficient amounts, as there is some evidence that small doses may actually increase the rate of growth of the tumour. Stilbœstrol is usually the drug of choice, and can be administered orally in doses up to 50 mg a day. An efficient substitute is ethinylœstradiol 0·5 mg daily by mouth.

Adrenalectomy[1] and Hypophysectomy

There can be little doubt that when successful these operations can give the greatest degree of benefit to a patient. Remissions for many years can be obtained, and patients are now living over ten years after one of these operations was carried out. In most series some 20 to 25 per cent. of patients have a really worthwhile objective improvement, and in a further 20 per cent. there will be relief of pain and subjective improvement.

Adrenalectomy is usually carried out as a one-stage procedure through a transverse abdominal incision (p. 629). This avoids the older and more painful two-stage operation where first the right and, after an interval of ten days, the left suprarenal is removed by an incision in the loin with removal of the eleventh or twelfth rib. In all cases bilateral oöphorectomy must be carried out. It is best to do this through a transverse suprapubic (Pfannenstiel's) incision.

Hypophysectomy.—This is usually done through a trans-sphenoidal or transethmoidal route. The pituitary is removed piecemeal after making a cruciate incision in the dura with diathermy.

Both procedures must be carried out under steroid cover and all patients will require to take cortisone as replacement for the rest of their lives. Usually 37·5 mg to 50 mg cortisone acetate a day by mouth with 0·1 mg fluorocortisone acetate every second day is sufficient. Nearly all hypophysectomy

[1] Charles Huggins of Chicago was the first to carry out adrenalectomy successfully.

Hermann Johann Pfannenstiel, 1862–1909. Gynæcological Surgeon, Breslau, Germany (now Wroclaw, Poland).
Charles Brenton Huggins, Contemporary. Professor of Surgery, Chicago, Illinois, U.S.A.

cases develop diabetes insipidus and it is necessary to prescribe pituitary snuff or injections of pitressin tannate in oil to overcome this. After about six months the condition spontaneously subsides.

The choice between adrenalectomy and hypophysectomy in any individual case probably depends on the facilities available. Surgical hypophysectomy gives the better response rate but requires the service of a skilled neurosurgeon if the operative mortality is to be kept within bounds, whereas adrenalectomy can be carried out by the general surgeon.

As an alternative to surgical hypophysectomy, pellets of Yttrium 90 can be introduced into the pituitary fossa by the transnasal route (Forrest). The early disadvantages of this procedure—of meningitis and blindness—seem now to have been overcome but the remission-rate is not as good as that from surgical hypophysectomy or adrenalectomy and, in many cases, probably not all the pituitary gland is destroyed. It may still be of value in very ill patients.

Cortisone and Ovarian Irradiation

It is known that most of the normal secretion of the adrenal gland can be diminished by the oral administration of large doses of cortisone. Some authorities believe that this may accomplish the same result as can be obtained by surgical adrenalectomy, providing it is accompanied by ovarian irradiation or oöphorectomy. The drug commonly employed is prednisone administered orally, in a dose of 5 mg three times a day. Few observers believe, however, that the response to this treatment is as good or as prolonged as can be obtained by surgical hypophysectomy or adrenalectomy. It has a place in advanced breast cancer in very old or very ill patients.

SUMMARY OF TREATMENT OF ADVANCED BREAST CANCER (J. L. HAYWARD) (IN ORDER OF PROCEDURE)

1. *Surgery.*—Localised lesions may be excised if solitary or causing symptoms.
2. *Radiotherapy.*—Especially for metastases in bone and skin.
3. *Hormones.*—(*a*) Up to menopause—ovarian ablation.
(*b*) Up to 5 years postmenopausal—ovarian ablation if there is evidence of continuing ovarian function followed by androgen therapy.
(*c*) After menopause plus 5 years—œstrogen therapy.
4. *Hypophysectomy* or *Adrenalectomy.*—For widespread metastases after hormone therapy has failed—corticosteroids if surgery not possible.
5. *Cytotoxins.*—Non-hormonal chemotherapeutic agents are used after hormone therapy and endocrine ablation has failed. The alkylating agent cyclophosphamide is the most frequently used single agent but recently combined treatment with up to four complementary agents (Quadruple chemotherapy) has provided worthwhile responses. Massive chemotherapy of this nature must be handled with care since the distressing side-effects may be poor palliation in patients with terminal disease.
6. *Immunotherapy.*—Non-specific stimulation of the immune defence mechanisms by means of B.C.G. or *corynebacterium parvum* has been used in breast cancer. At this stage there is no firm evidence as to its efficacy.

THE 'FOLLOW-UP' OF CASES OF CARCINOMA OF THE BREAST

It is the duty of the surgeon to examine all his cases periodically for life, so that in event of recurrence he can inaugurate such treatment as is applicable without delay. The following indicates a routine suitable for this periodic examination :

History.—This includes an inquiry as to the physical energy, general health, and the presence of an unexplained cough. Symptoms that the patient usually ascribes to rheumatism, lumbago or sciatica (humerus, spine or femur) must be regarded with suspicion, for often skeletal metastases announce themselves in this way.

Examination.—The operation field is examined for nodules. The axillæ, supraclavicular lymph nodes, and opposite breast[1] are palpated. The hand and arm are

[1] A few surgeons recommend early simple mastectomy on the contralateral breast because 7·5 per cent. of patients with carcinoma of the breast develop carcinoma in the contralateral breast.

Andrew Patrick McEwen Forrest, Contemporary. Regius Professor of Surgery, Edinburgh.
John Langford Hayward, Contemporary. Surgeon, Breast Unit, Guy's Hospital, London.

FIG. 720.—A braces button being lost, the remaining button draws the brace inwards, and the buckle rubs against the nipple.

examined for œdema. The chest is percussed and auscultated and the abdomen examined for evidence of enlarged liver or ascites. If considered necessary, a rectal or vaginal examination is made in order to detect pelvic or ovarian metastases.

Radiography.—Regular annual mammography of the remaining breast and a routine radiographic examination of the chest is a valuable part of the follow-up, while in doubtful cases X-rays should be taken of any bones suspected of harbouring metastases because of pain.

THE MALE BREAST

The mammary tissue of the male is the leading, if not the only, example of an external secretory mechanism that persists without actual or potential function.

Mastitis of puberty is discussed on p. 638.

Mastitis from local irritation is by no means rare in men; in civil life it usually occurs in manual labourers with ill-fitting braces (fig. 720). It is not uncommon among soldiers carrying heavy equipment across their shoulders. The treatment is to remove the cause; substitution of a belt for braces is sound advice.

Gynæcomazia.—(*a*) *Idoipathic.*—Hypertrophy of the male breast may be unilateral or bilateral. The breasts enlarge at puberty, and sometimes present the characteristics of a well-developed female organ. The subjects of this deformity are often virile. Chengwayo, chief of the Zulus (fig. 721), a gynæcomast, at the age of fifty-five, had forty wives and over a hundred children. Tribal tales of a father nurturing his motherless infant with milk from his own breast belong to the realms of mythology, but pseudo-lactation has been observed in rare instances, and fluid akin to colostrum has been expressed.

FIG. 721.—Chengwayo, from a photograph by Schujelot.

(*b*) *Hormonal.*—Enlargement of the breasts often accompanies stilbœstrol therapy, e.g. for carcinoma of the prostate (Chap. 56); it may also occur as a result of a teratoma of the testis, in anorchism, and after castration. Rarely it may be a feature of ectopic hormonal production in a bronchial carcinoma and in adrenal or pituitary disease.

(*c*) *Associated with Leprosy.*—Gynæcomazia is very common in male persons suffering from leprosy. Possibly this is the result of bilateral testicular atrophy, which is a frequent accompaniment of leprosy (Bowesman).

FIG. 722.—Carcinoma of the male breast.
(*Dr. Y. V. Shah, Vamnagar, India*).

(*d*) *Associated with Liver Failure.*—Gynæcomazia sometimes occurs in patients with cirrhosis due to failure of the liver to metabolise œstrogens.

(*e*) May occur in patients with *Klinefelter's syndrome* (a sexual anomaly giving a chromatin positive male and infertility). Certain drugs such as digitalis, spironolactone and isoniazid may also cause gynæcomazia.

Treatment.—Provided the patient is healthy and comparatively young, the treatment of idiopathic gynæcomazia is mastectomy with preservation of the nipple and areola, for their absence is subject to ridicule.

Fibroadenosis and Fibroadenoma are not exceedingly rare and present the same clinical features as in the female.

Carcinoma of the male breast (fig. 722) accounts for about 0·6% of all cases of carcinoma of the breast, and generally develops in men with a pre-existing gynæcomazia. It has an evil reputation; more than one-third

Charles Bowesman, Contemporary. Formerly Surgical Specialist, Lately Colonial Medical Service, Kumasi, Ghana.
Edmund William Klinefelter, Contemporary. Radiologist, Massachusetts General Hospital, Boston, Mass., U.S.A.

of cases are totally inoperable when the patient first presents. In the first place this is due to the fact that so often he does not seek advice for months or years. Secondly, the breast is so small that the enlarging growth reaches the extramammary tissues much sooner than in the female; this favours earlier metastasis.

Treatment.—Stages I and II are treated as in the female. In inoperable cases bilateral orchiectomy has an even more advantageous effect than oöphorectomy in the female, favourable results having been reported in as high as 70% of cases. Œstrogen therapy sometimes produces amelioration after the good effects of orchiectomy have waned.

Other Tumours of the Breast

Lipoma.—A true lipoma is rare.

Pseudolipoma.—A swelling like a lipoma, if found, commonly indicates underlying breast cancer (Shucksmith and Dossett).

Sarcoma.

Sarcoma of the breast is usually of the spindle-celled variety, and accounts for 0·5 per cent. of malignant tumours of the breast. Some of these growths arise in an intracanalicular fibroadenoma. It may be impossible to distinguish clinically a sarcoma of the breast from a medullary carcinoma, but areas of cystic degeneration suggest the probability of sarcoma. On incising the neoplasm its pale, friable consistency is characteristic. Sarcoma of the breast is met with most often in women between the ages of thirty and forty. Treatment is by simple mastectomy followed by radiotherapy. Surprisingly enough the outlook in this disease is good.

Henry Samuel Shucksmith, Contemporary. Surgeon, General Infirmary, Leeds, England.
John Arthur Dossett, Contemporary. Pathologist, St. James's Hospital, Leeds, England.

CHAPTER 36

THE PHARYNX

TONSILS AND ADENOIDS

Surgical Anatomy.—The lymphadenoid tissue of the nasopharynx is Nature's barrier to bacterial invasion. The ætiology of certain cervical inflammations can be better understood if Waldeyer's inner and outer rings (fig. 723) are studied. *The faucial tonsils* are the largest and most important moieties of the inner ring. The tonsils contain tortuous crypts, which extend throughout the tonsillar substance to the external capsule. These crypts can harbour pus and micro-organisms. Clothing the lateral two-thirds of each tonsil is the capsule, a well-defined structure composed of fibrous and elastic tissue, and muscle fibres. The medial third of the tonsil lies between the pillars of the fauces and, being bereft of covering, is accessible to clinical examination. The tonsil has an exceptionally good blood supply (fig. 724). It is well to bear in mind that a tortuous *facial artery* may be closely related to the lower pole. A vein unaccompanied by an artery—the paratonsillar vein—is often a source of serious venous bleeding following tonsillectomy. When divided, the bleeding end retracts into the upper part of the tonsillar fossa, and must be found and ligated before the patient leaves the theatre.

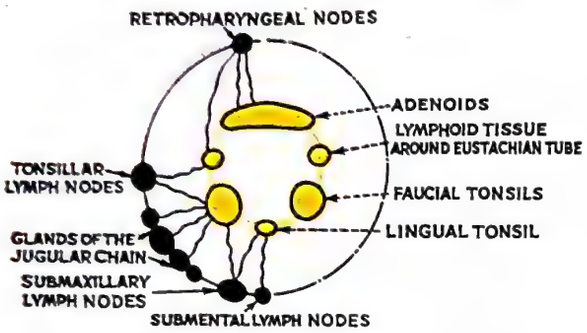

FIG. 723.—Waldeyer's rings. Inner ring—first barrier to infection; outer ring—second barrier.

ENLARGEMENT OF THE TONSILS AND ADENOIDS

Enlarged tonsils are not necessarily infected; a certain amount of hypertrophy is common in early childhood. As adult life approaches, the tonsils, together with other lymphoid tissues, tend to atrophy. Excessive hypertrophy is often bilateral. Occasionally, the tonsils are so large that they almost meet in the middle line.

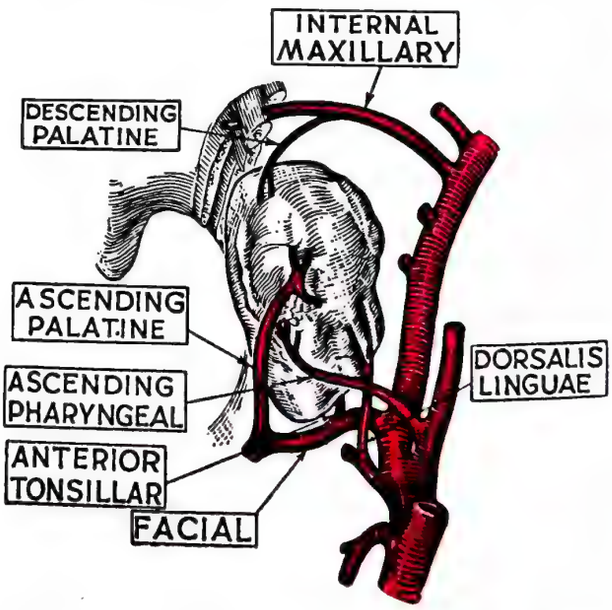

FIG. 724.—The arterial supply of the tonsil from branches of the external carotid. (*After R. H. Fowler.*)

Enlarged Adenoids[1].—The 'nasopharyngeal tonsil' is present at birth but undergoes atrophy at puberty, although remnants of it often persist into adult life. The most common period for hypertrophy is between the ages of

[1] To be exact—there is only one adenoid.

Heinrich Wilhelm Gottfried Waldeyer-Hartz, 1836–1921. Professor of Pathological Anatomy, Berlin.

four and fourteen, and a damp climate favours the development. Enlarged adenoids consist of masses of lymphoid tissue covered by ciliated epithelium and supported by a delicate framework of fibrous tissue.

Considerable adenoid hypertrophy causes the patient to snore loudly at night and to breathe through the open mouth, giving that well-known vacant expression (fig. 725). Added to this, hearing is impaired by the hypertrophied lymph-adenoid tissue obstructing the orifices of the Eustachian tubes, and infections of the middle ear and upper respiratory tract occur frequently.

FIG. 725.—The adenoidal facies. Tonsillar hypertrophy is a usual accompaniment.

Acute follicular tonsillitis is a common condition characterised by pyrexia associated with a sore throat. The cervical lymph nodes are enlarged and tender. Pain occasionally radiates up to the ears. The most usual cause is *streptococcus pyogenes*. On examination the tonsils are swollen, and yellow spots, due to pus exuding from the tonsillar crypts, can often be discerned. The condition can be distinguished from diphtheria by a rapid bacteriological examination of a smear.

Treatment.—Aspirin is administered to relieve pain and gargles of glycerol-thymol are soothing. If the symptoms persist after 24 hours, a throat swab should be taken for culture and penicillin is given until antibiotic sensitivities are known.

Chronic tonsillitis is sometimes associated with hypertrophy. During early childhood chronically inflamed tonsils are usually soft, but by the time puberty has been reached they have frequently become indurated and adherent, due to recurrent attacks of inflammation and subsequent fibrosis. The tonsillar lymph node of the jugular chain is usually palpable. Sometimes pus and debris can be expressed from infected tonsillar crypts to enable a bacteriological examination to be made.

TONSILLECTOMY[1]

Indications.—1. A history of recurrent attacks of acute tonsillitis.
2. One attack of peritonsillar abscess.
3. Chronic tonsillitis.
4. Biopsy for suspected malignancy.

Removal of the tonsils may also be considered in the treatment of tuberculous and non-tuberculous cervical adenitis.

Operation[2].—Tonsils are removed by dissection. Pre-operative treatment with penicillin, and for several days after operation, is a wise precaution, as 30 per cent. of patients develop bacteræmia and are in danger of developing infective lesions elsewhere in the body (e.g. bacterial endocarditis, pyelonephritis).

---

[1] Should a recently tonsillectomised patient contract poliomyelitis, he is liable to develop the more lethal bulbar type. Tonsillectomy is therefore contraindicated during an epidemic of this disease. The British Association of Otolaryngologists recommend inoculation against poliomyelitis before tonsillectomy is undertaken. The child should have had at least two inoculations before the operation.

[2] Suggested pre-op. drugs for children—Quinalbarbitone 6 mg./kg. (max. 200 mg.). Atropine 0·02 mg./kg. (max. 0·6 mg.).

Bartolommeo Eustachi, (Eustachius), ?1520–1574. Professor of Anatomy, Rome.

Either local or general anæsthesia can be employed. The mouth is kept open and the tongue depressed with a Davis's gag. The tonsil is seized with vulsellum forceps. An incision is made through the mucous membrane (fig. 726), and the capsule of the tonsil is exposed. The tonsil is removed by dissection, starting at the upper (palatal) pole. When the pedicle is defined, it is severed by a wire snare. Bleeding can be accurately stopped by ligating any bleeding vessels, arteries or veins, so that the patient does not leave the operating table until all bleeding has ceased. Until the patient has recovered consciousness he should be kept with his head low and well over to one side (fig. 727). On no account should he be permitted to lie on his back or be left unattended.

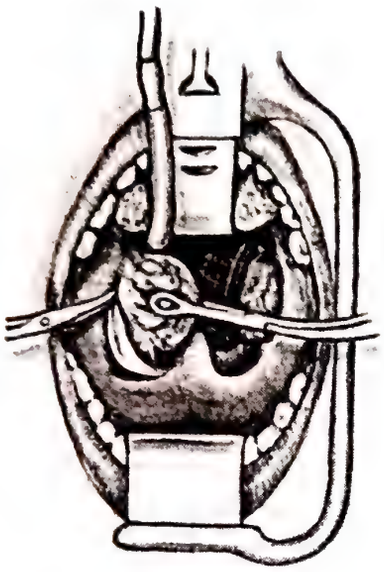

FIG. 726.—Removal of the tonsils by dissection. Davis's gag in place.

Complications after tonsillectomy

1. *Obstruction of the airway*, e.g. blood clot or the tongue falling back.
2. *Inhalation of foreign material*, e.g. blood, vomitus, broken teeth.
3. *Hæmorrhage.* Reactionary hæmorrhage occurs within the first few hours. It may be recognised by blood appearing from the corner of the mouth or nostrils, a rising pulse rate, generalised irritability. Immediate measures to be taken are: (1) Removal of clot from the tonsillar bed, (2) The application of pressure by means of a swab on a holder.

FIG. 727.—Position of patient after tonsillectomy.

If bleeding persists in spite of these measures, an intravenous infusion must be set up and blood taken for grouping and cross-matching (p. 73). The patient should be returned to the operating theatre, and under general anæsthesia the bleeding point sought and ligated. When the bleeding-point cannot be found, coaptation of the pillars of fauces with sutures will arrest the hæmorrhage.[1]

ADENOIDECTOMY

Indications.—Hypertrophic adenoids associated with: (*a*) Recurrent otitis media. (*b*) Post-nasal obstruction. (*c*) Post-nasal discharge. (*d*) Recurrent sinusitis.

Removal of Adenoids.—Removal is undertaken either before dissection of the tonsils, or at the conclusion of guillotine tonsillectomy. Adenoids are removed with a guarded curette (fig. 728) pressed against the roof of the nasopharynx (fig. 729) and then carried backward and downward with a firm sweeping movement. The after-treatment is similar to that described above. Reactionary hæmorrhage may be stopped by sitting the patient bolt upright. As a last resort, the nasopharynx may have to be packed (p. 532).

FIG. 728.—St. Clair Thomson's adenoid curette.

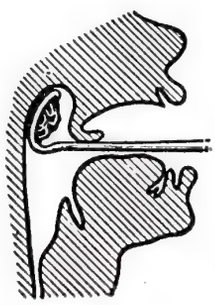

FIG. 729.—Curettage of adenoids.

[1] Morphine must not be given to children suffering from post-operative hæmorrhage. It is a factor in tonsillectomy deaths.

The original Davis's gag was invented by Dr. Davis, of Boston, Mass. Henry Edmund Gaskin Boyle, 1875–1941, anæsthetist, St. Bartholomew's Hospital, London, improved it. Sir St. Clair Thomson, 1859–1943. Surgeon, Ear, Nose and Throat Department, King's College Hospital, London.

MALIGNANT TUMOURS OF THE TONSIL

Both carcinoma and lymphosarcoma occur in the tonsil. The diagnosis in many instances is not easy. Any unilateral enlargement of the tonsil occurring in adult life should be regarded with suspicion. A biopsy is often required to confirm the diagnosis.

Carcinoma of the Tonsil (85 per cent.).—The patient is commonly an elderly man and pain is the leading symptom. The pain is severe and radiates to the ear, and, unlike that of tonsillitis, is unilateral. The breath is foul. Later, bleeding occurs, and as the ulcer deepens the loss of blood may be copious.

Treatment is by external irradiation of the primary growth and the side of the neck as far as the clavicle. Small residues can be treated with accessory local irradiation. The five years' survival rate after treatment is 25 per cent.

Lymphosarcoma of the tonsil (15 per cent.) has the reputation of being very malignant. While this is true if it is allowed to grow beyond the peritonsillar bed, the condition is by no means hopeless in its early stages. The patient is usually between fifty and sixty years of age, complains of a lump in the throat, which in the early stages is painless. Thick speech is a common symptom, and the tonsil appears large and pale. Later, the growth spreads, and often forms a swelling of the palate, which may be mistaken for a peritonsillar abscess, and incised. Once the barrier formed by the capsule of the tonsil has been breached, the growth extends rapidly into the neck, often forming a swelling behind the angle of the mandible. While the cervical lymph nodes soon become involved, a swelling in this position is likely to be an extension of the primary growth. Eventually bleeding, dysphagia, and dyspnœa foretell that the end is not far distant.

Treatment is by external irradiation of the growth and of the lymph nodes, and some apparently hopeless cases may respond dramatically.

QUINSY (PERITONSILLAR ABSCESS)

As a rule the abscess is unilateral, but it is not uncommon for the contralateral side to become involved a few days later. The condition is rare in children, the incidence being highest in adult males. Extreme pain is experienced in the tonsillar region, radiating to the ear and to the side of the neck. Swallowing is so painful that saliva dribbles from the mouth; speech is thick and muffled. As the patient can open the mouth only to a slight extent, examination is often difficult. With good illumination, a diffuse swelling of the soft palate, mainly near the superior border of the affected tonsil, will be seen. The swelling displaces the œdematous uvula to the contralateral side.

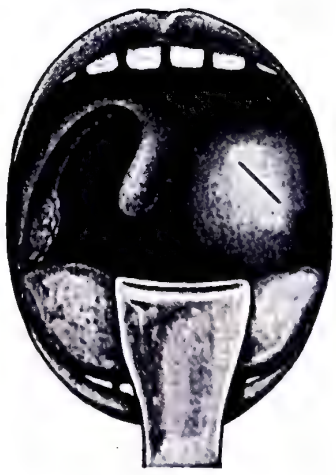

FIG. 730.—Peritonsillar abscess, showing site of incision.

Treatment, in the early stages, is the same as that for acute follicular tonsillitis (p. 665). If suppuration occurs, evacuation of pus in the following manner should not be delayed.

A small scalpel is modified by winding a strip of strapping around the blade so that only 1 cm. of the tip projects. Except in small children, no general anæsthetic is used.[1] The patient sits upright. An incision is made in the position shown in fig. 730, which is usually described as midway between the base of the uvula and the third upper molar tooth. Dressing forceps are now pushed firmly *directly backwards.* As soon as pus is encountered, the forceps are opened widely and withdrawn.

Parapharyngeal abscess is similar to the above, but the maximum swelling is behind the posterior faucial pillar, and there is little or no œdema of the palate. The abscess is opened with a really blunt instrument, such as a tongue depressor. Often the gloved finger will suffice.

[1] In adult patients surface anæsthesia (five per cent. cocaine on a pledget of wool), is the safest.

RETROPHARYNGEAL ABSCESSES

Acute retropharyngeal abscess is due to suppuration of the prevertebral lymph nodes. It is seen most commonly in children and 50% of cases occur under one year of age. The portal of entry is the tonsils, the nasopharynx, or the oropharynx. The condition may be accompanied by rigors, convulsions and vomiting. The neck is held rigidly, usually on one side, saliva dribbles from the child's mouth, and feeds are regurgitated. A croupy cough is common. The cry may resemble a 'squawk'. *Difficulty in breathing is the leading symptom* and this should always be the signal to examine a child's throat. The posterior wall of the pharynx is swollen. On digital examination a localised soft cushion-like projection can be felt on the posterior pharyngeal wall. The only condition with which acute retropharyngeal abscess may be confused is laryngeal diphtheria. A less acute form is seen in older children as a complication of otitis media.

FIG. 731. — Chronic retropharyngeal abscess secondary to tuberculous disease of the cervical vertebræ.

Treatment.—No anæsthetic is used for infants, who must be placed in the prone position, with the head low. A pair of dressing forceps guided by the finger is thrust into the abscess cavity, the contents of which are evacuated. Suction must be available. Suitable antibiotic therapy is prescribed.

Chronic retropharyngeal abscess is sometimes due to an extension of tuberculosis of a cervical vertebra (fig. 731). When the collection of pus is large, in addition to the retropharyngeal swelling, there is a fullness behind the sterno-mastoid on one side. A chronic retropharyngeal abscess must never be opened into the mouth, for such a procedure will lead to secondary infection. The pus should be evacuated by an incision in front of the sternomastoid, to lead into the plane between the carotid sheath and the thyroid gland. The dissection towards the retropharyngeal space is conducted carefully until the abscess is opened. The cavity is then mopped dry and the wound closed. Suitable treatment of the underlying tuberculous lesion must then be instituted (p. 32).

DIVERTICULUM OF THE PHARYNX

Pharyngeal Pouch.—Ætiology.—The inferior constrictor muscle is composed of two portions—the upper oblique fibres (thyropharyngeus) of each side that interdigitate posteriorly, and the lower fibres (cricopharyngeus) that are arranged transversely, and function as a sphincter. Between these two sets of fibres there is a weak area in the middle line posteriorly, known as Killian's dehiscence which is marked by a dimple in the overlying mucous membrane. The lower (sphincteric) portion of the cricopharyngeus constantly maintains enough tone to prevent the entry of air into the œsophagus during inspiration (Negus). If for some reason, the cricopharyngeus fails to relax during swallowing, the pressure exerted by the bolus falls on Killian's dehiscence; so commences a pharyngeal pouch (fig. 732). As time goes on, the sac becomes larger and fills with food at every meal. Unable to expand posteriorly because of the resistance of the vertebral column, the pouch turns outwards, usually to the left (fig. 733).

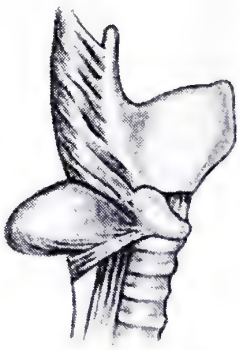

FIG. 732.—Pharyngeal pouch protruding between the thyropharyngeal and cricopharyngeal portions of the inferior constrictor of the pharynx. (*After Sir Victor Negus.*)

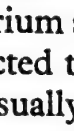
Gustav Killian, 1860–1921. Professor of Laryngo-rhinology, Berlin.
Sir Victor Ewings Negus, 1887–1974. Surgeon, Ear, Nose and Throat Department, King's College Hospital, London.

Clinical Features.—Patients suffering from this condition are usually elderly, and it is twice as common in men as in women.

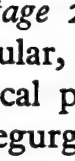
There are three stages in the development of symptoms. Rarely does the patient present during the first stage.

Stage 1.—As shown by a lateral radiograph after a barium swallow, there is a small diverticulum directed towards the vertebral column, viz.→



Usually a small pharyngeal diverticulum is symptomless, and the finding of it is incidental during the course of a barium meal. Occasionally it gives rise to symptoms identical with those of a foreign body in the throat. At this stage the diverticulum can be ignored.

Stage 2.—The diverticulum is larger and more globular, but its mouth still lies in the vertical plane, viz. ——————→



Regurgitation of undigested food at an unpredictable time after a meal, during the swallowing of the next meal, or after turning from one side to the other at night, is the chief complaint. Sometimes the patient is awakened from sleep by a feeling of suffocation, followed by a violent fit of coughing. Infrequently an abscess of the lung results from food inspired from the pouch. Removal of the pouch is indicated.

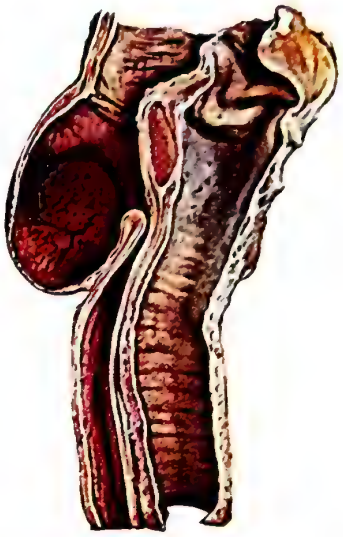


FIG. 733.—A pharyngeal pouch, showing compression of the adjacent œsophagus.

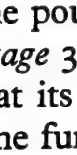
Stage 3.—The pouch has become larger, and what is so important is that its mouth looks horizontally upwards, viz. ——————→



The fundus of the pouch has become dependent, and consequently when the pouch is full it compresses the œsophagus. The symptoms of the second stage persist; in addition, there are gurgling noises in the neck, especially when the patient swallows. In about one-third of cases, the pouch is large enough to form a visible swelling in the neck : sometimes such a pouch can be seen to enlarge when the patient drinks. Nevertheless, when this stage has been reached the symptom that transcends all others is increasing dysphagia, and in a large number of instances it is this symptom alone that compels the patient to seek relief. However, even at this stage a few intelligent patients acquire a knack of overcoming their disability. It is recorded that Lord Jeffrey, a Scottish nobleman, was in the habit of emptying his pouch with a large silver spoon after every meal. Other sufferers have found that they can swallow their food better if the pouch is full, and accordingly take porridge as a first course. Notwithstanding these ingenious devices, eventually there is progressive loss of weight due to semi-starvation, and cachexia is sometimes extreme.

Radiography.—If a pharyngeal pouch is suspected, a very thin emulsion of barium should be used for the barium swallow; a thick mixture often requires much washing through a tube to remove the barium from the pouch. Quite often the fundus of the sac will be seen invading the

superior mediastinum. Radiologically, the antero-posterior appearance of a barium-filled pouch can be simulated closely by a partial septum obstructing the commencement of the œsophagus. Therefore, if this mistake is to be avoided a semi-lateral view (fig. 734) also must be taken. In this view the overflow of barium emulsion into the œsophagus often can be seen to come from the top of the pouch—not from the bottom, as is the case with an œsophageal web.

FIG. 734.—Semi-lateral radiograph of a pouch after barium has been swallowed.

Œsophagoscopy or bouginage is unnecessary for diagnosis, and may be dangerous. On many occasions the tip of the instrument has entered the pouch and has perforated its fundus, which is thin and fragile, and mediastinitis has resulted.

Treatment.—When the pouch is of a considerable size, operation is strongly advised, because progressive symptoms are inevitable. When emaciation is extreme a preliminary temporary 'feeding' gastrostomy or jejunostomy may be required.

The operation is performed in one stage. To prevent mediastinitis, antibiotics should be given before and after operation.

Operation.—The pouch is approached through either a transverse incision at the level of the cricoid cartilage, or, as many prefer, an oblique incision following the anterior border of the left sternomastoid. The first step is to mobilise the lateral lobe of the thyroid gland, therefore it is necessary to ligate and divide the middle thyroid veins, and sometimes the inferior thyroid artery. When this has been completed, the lateral lobe is retracted forwards, and the carotid sheath is retracted backwards. At this stage a large stomach tube is passed by the anæsthetist and it enters the pouch; the tube is guided by the surgeon from the pouch into the œsophagus, and there it remains during the operation as a *helpful guide in determining the limits of the neck of the sac during the later stages of the dissection.*

The walls of the sac vary in thickness; in some cases they are so thin that great care must be taken not to tear them. Having freed the pouch completely, a cuff of the outer layer of the pouch is dissected from the mucous membrane. This permits the closure of the neck of the sac, which must be performed very accurately in two layers. It is very important not to narrow the upper end of the œsophagus at the point where the pouch is removed. In some cases it is useful to divide any hypertrophied circular muscle (crico-pharyngeus) (cf. Heller's operation, p. 773). The wound is closed with drainage.

After-treatment.—The patient is fed through an in-dwelling transnasal gastric tube for three days. Fluids only are permitted for the next three days. After this, semi-solids are given, and the diet is then increased gradually.

Complications.—1. *Infection.*—Severe infection of the wound and the mediastinum is now infrequent. 2. *Pharyngeal Fistula.*—Usually the fistula closes spontaneously if the upper end of the œsophagus has not been narrowed.

Congenital lateral diverticulum is really a blind internal branchial fistula (p. 571) opening into the fossa of Rosenmüller (the pharyngeal recess). Occasionally such a fistula becomes distended and food lodges within it.

Johann Christian Rosenmüller, 1771–1820. Professor of Anatomy and Surgery, Leipzig, Germany.

NEOPLASMS OF THE PHARYNX

Surgical Anatomy.—Concerning neoplasms of the pharynx, the clinico-anatomical division into three component parts (fig. 735) is of practical importance.

The nasopharynx (*syn.* post-nasal space, epipharynx) is that portion of the pharynx lying above the level of the soft palate which forms its incomplete floor. With the exception of this floor, the nasopharynx has rigid, immovable walls.

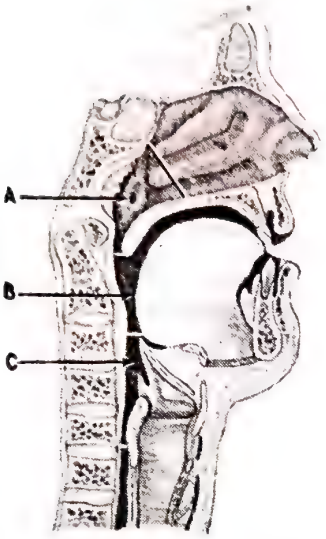


FIG. 735.—The component parts of the pharynx. A. Nasopharynx. B. Oropharynx. C. Laryngopharynx, the antero-superior portion of which contains the inlet of the larynx, and is known as the epilarynx.

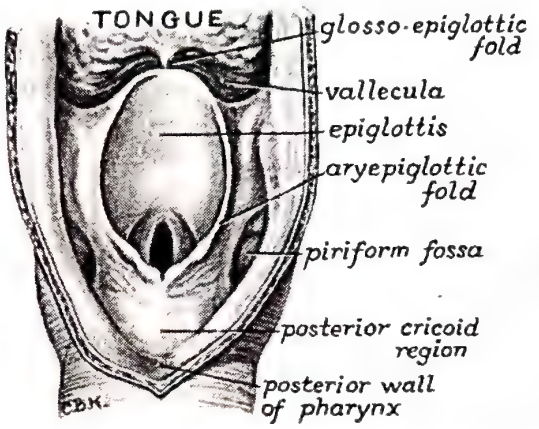

FIG. 736.—The epilarynx: the valleculæ are shown also. In, or on, all the structures labelled a carcinoma can arise.

Each Eustachian tube opens into the antero-lateral wall of the nasopharynx just behind the posterior end of the inferior turbinate. Above and behind this orifice is the supratonsillar fossa of Rosenmüller.

The oropharynx (*syn.* the mesopharynx) extends from the inferior border of the soft palate to the lingual surface of the epiglottis. In the sulcus between the back of the tongue and the anterior (lingual) surface of the epiglottis lie a median glosso-epiglottic and a right and left pharyngo-epiglottic fold. The corresponding depression on either side of the glosso-epiglottic fold is known as the vallecula (fig. 736).

The laryngopharynx is the longest of the three divisions of the pharynx and it diminishes in width from above downwards. It extends from the tip of the epiglottis to end opposite the body of the sixth cervical vertebra, where it is continuous with the œsophagus. It is convenient to subdivide the laryngopharynx into the *epilarynx* above (fig. 736) and the *hypopharynx* below, the dividing line being at the level of the upper border of the cricoid cartilage (Stanford Cade). The inlet of the larynx faces almost backwards, and is bounded above by the epiglottis, laterally by the aryepiglottic folds, and below by the short interarytenoid fold. On the lateral side of each aryepiglottic fold is a recess—the pyriform fossa.

TUMOURS OF THE NASOPHARYNX

Benign:

Angio-fibroma[1].—Although its local behaviour is the antithesis of benignity, this tumour is not malignant, for it never metastasises, neither does it infiltrate tissues. However, on account of its ability to send tentacles into first one and then the other nasal fossa, and thence into the accessory nasal sinuses, and above all because of its power to cause pressure necrosis of bone, it is a *highly destructive* tumour. As a result of these intrusions the tumour expands the nose, may fill the antra and in turn expand the cheek, and cause the palate to bulge, and at times invades the ethmoid and produces a 'frog face' appearance.

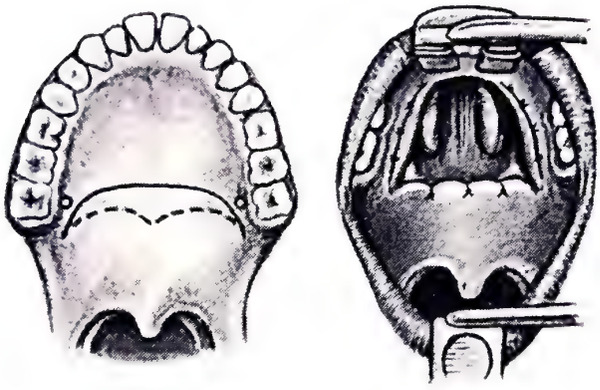
Nasopharyngeal angio-fibroma is a reddish, firm tumour covered with normal mucous membrane. Ulceration seldom occurs unless the tumour is traumatised.

[1] Formerly called 'nasopharyngeal tumour', which is ambiguous.

Sir Stanford Cade, 1895–1973. Formerly Surgeon, Westminster Hospital, London.

Histologically it is composed of immature fibroblasts and blood-vessels; in the early stages cavernous blood-vessels predominate. In long-standing cases fibrous tissue is more plentiful.

Clinical Features.—This tumour is almost confined to juvenile male patients. Appearing at the age of puberty, the tumour usually regresses in the early twenties, provided that no secondary complications occur. Although nasopharyngeal angiofibroma is rare, when a boy presents with progressive nasal obstruction, recurrent epistaxis, a purulent nasal discharge and a firm mass in the nasopharynx, this clinical entity should spring to mind.



A B

FIG. 737.—Transpalatine approach to the nasopharynx. A. Incision. B. Permanent fenestration of the hard palate. (*After the late C. P. Wilson, F.R.C.S.*)

Biopsy should be avoided unless there are compelling reasons for undertaking it, when matched blood must be in readiness and the surgeon must be prepared to deal with hæmorrhage.

Treatment.—Pre-operative external irradiation will shrink the tumour and render it less vascular. Removal of the tumour should follow some six weeks later.

Operation.—The transpalatal route (fig. 737A) is used. The tumour is excised with diathermy and the soft palate is replaced and sutured to the mucoperiosteum of the hard palate. Hypotensive anæsthesia and cryosurgical techniques have facilitated the procedure. Alternatively, in order that early recurrences may be seen, and destroyed by diathermy, a permanent palatal fenestra can be made (fig. 737B). The fenestra is closed by an obturator attached to a denture. The patient can then talk and eat quite normally.

A choanal polypus may give rise to difficulty in differential diagnosis. Ætiologically it belongs to nasal polypi, originating either in the ethmoid region or in the maxillary antrum. If large, it may descend through the posterior nares into the nasopharynx and present behind the soft palate. A choanal polypus may be distinguished from angiofibroma by its mobility due to the long pedicle by which it is attached, avascularity and an elastic rather than firm consistency. It can be easily removed with a snare.

Malignant:

In China, Japan, and Malaya malignant tumours are more common in the nasopharynx than in any other part of the body save the cervix uteri, a possible cause being the use of smoky kerosene lamps in these countries.

Other tumours, including mixed salivary tumour	7 „ „

(James Ewing)

Fifty per cent. of these growths arise in the lateral wall of the nasopharynx, mostly in the supratonsillar fossa of Rosenmüller (fig. 738 and p. 671); the remainder are divided equally between the roof and the posterior wall.

[1] A tumour containing many lymphoid elements in addition to carcinomatous elements.

James Ewing, 1866–1943. Professor of Pathology, Cornell University, New York, U.S.A.

Clinical Features.—These depend mainly on whether the growth is obstructive (reticulosis), or infiltrating (carcinoma). Usually the *first* symptoms for which advice is sought fall into four groups:

1. *The Nasal Group.*—Slight, intermittent epistaxis and nasal speech are early nasal symptoms; other nasal symptoms, viz. a feeling of obstruction to the airway and a post-nasal discharge, usually are delayed.

FIG. 738.—Papillary carcinoma of the fossa of Rosenmüller, as seen in a laryngeal mirror. (*After W. L. Mattick.*)

2. *Aural Group.*—Unilateral deafness, with pain in the ear, is the usual complaint. Obstruction of the pharyngeal orifice of the Eustachian tube by a growth leads to a collection of sero-sanguinous fluid within the middle ear. The deafness that results is relieved by paracentesis of the tympanic membrane and suction, but a fresh accumulation soon occurs. Bleeding on Eustachian catheterisation is a sign of the utmost importance.

3. *Enlarged Cervical Lymph Nodes.*—By the time the diagnosis is established, 70 per cent. of patients with a malignant tumour of the nasopharynx have enlarged cervical lymph nodes, and 40 per cent. present on account of the cervical swelling. The swelling is in the upper jugular chain and the nodes are firm, rather than hard, and may be mistaken for tuberculous adenitis.

Unlike carcinoma of the tongue, metastases more distant than the neck occur eventually in about a quarter of cases.

4. *Cranial Nerve Involvement.*—In Far Eastern patients this is the most common presenting symptom; in British patients 30 per cent. have some cranial nerve involvement when first seen. All suffer implication by the growth either at their exit through their respective foramina at the base of the skull or, less frequently, by intracranial extension of the growth. Pain of trigeminal distribution is an important feature in this group. X-ray of the base of the skull may show destruction of bone by the tumour, but it is not unusual for patients to develop root pains without X-ray changes.

Trotter's Triad.—The three cardinal symptoms of a locally invasive tumour can be summarised as follows: (i) Conductive deafness. (ii) Elevation and immobility of the homolateral soft palate—due to direct infiltration. (iii) Pain in the side of the head—due to involvement of the fifth cranial nerve from infiltration via the foramen lacerum.

Biopsy is necessary to ascertain the histological characteristics of the tumour. Inspection of the nasopharynx is facilitated if a soft rubber catheter is passed through the nose, and withdrawn through the mouth. Gentle traction displaces and immobilises the soft palate, and thereby an uninterrupted view is obtained. If more detailed inspection is desirable, Wilson's approach (fig. 737) through the junction of the hard and soft palate should be used.

Treatment.—Present practice favours supervoltage external irradiation, given to the primary tumour and to the lymph node fields on both sides of the neck at least as far down as the clavicles. Reticulosarcoma, undifferentiated carcinoma, and lympho-epithelioma are very radio-sensitive. If the

Wilfred Batten Lewis Trotter, 1872–1939. Professor of Surgery, University College Hospital, London.
Charles Paul Wilson, 1900–1970. Surgeon, Ear, Nose and Throat Department, Middlesex Hospital, London.

primary responds satisfactorily, it is feasible to perform a cervical block dissection of the enlarged lymph nodes.

Prognosis.—Owing to their secluded position and consequent late diagnosis, and the inaccessibility of the nasopharynx, the prognosis is poor. The five-year survival rate is about 40 per cent. for the reticulosis group and under 20 per cent. in the case of carcinoma.

NEOPLASMS OF THE OROPHARYNX

Benign:

Diffuse cavernous angioma involving the pharynx, fauces, and often extending into the neck (where it forms a swelling) has been treated successfully by injecting into the bluish mass in the pharynx 0·5 ml. of 1:4 solution of ferrous chloride in sterile water. The injected area immediately turns bright red, remains swollen for a few days, and then cicatrizes. Further injections may be required. Later, if necessary, abnormal tissue is removed by diathermy, with practically no bleeding. Recently cryosurgery (p. 678) has been shown to be most effective in dealing with these lesions.

Malignant:

Usually carcinoma of the oropharynx is of the ulcerative type. The commonest site of origin is the tonsillo-lingual sulcus. There is discomfort at the back of the throat, fœtor, and blood-stained sputum. Pain is absent until the growth is far advanced.

Treatment.—The management is identical to tumours of the nasopharynx of similar histological picture.

Operation.—Although the long-term results are far from good, when possible, extirpation of the growth and the regional lymph nodes holds out a better prospect of success than irradiation.

Lateral pharyngotomy with partial pharyngectomy is performed as follows. A tracheostomy is usually performed as the first step. Then a block dissection of the cervical and retropharyngeal lymph nodes is carried out. The lateral lobe of the thyroid is then mobilised and displaced forwards. The inferior constrictor muscle is detached from the thyroid and cricoid cartilages. The great cornu of the hyoid bone and the posterior two-thirds of the ala of the thyroid cartilage are removed without opening the mucous lining.

Should the growth be situated on the lateral wall and have invaded the tonsillar region, the cervical operation is halted at this stage, and through the widely open mouth an incision is made at least 2·5 cm. distant from the accessible margins of the neoplasm with a diathermy knife, the internal carotid artery being held aside in the neck (Raven). Returning to the neck, the pharynx is opened longitudinally and that portion of the pharyngeal wall containing the growth and a wide margin of healthy tissue is removed in continuity with its lymphatics.

When the loss of the pharyngeal wall is not great the pharynx is closed. A portion of the upper part of the posterior skin flap is anchored by stitches to the prevertebral fascia, thus providing free exit to infected matter should leakage occur. The remainder of the cervical wound is closed with drainage at its lower end.

After-treatment includes transnasal intragastric feeding and antibiotic therapy.

When it is known beforehand that the defect in the pharyngeal wall is likely to be a large one, the operation is performed through a rectangular skin flap, and after partial pharyngectomy has been performed, the first stage of the plastic procedure is carried out as shown in fig. 739. In the early post-operative period, the patient is fed by a tube passed into the stomach through the fistula.

In both the procedures just described the resulting cervical fistula will require closure; this is undertaken after a short convalescence.

Ronald William Raven, Contemporary. Consulting Surgeon, The Royal Marsden Hospital, London.

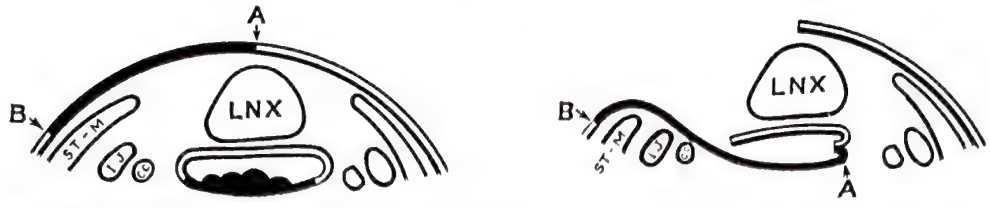

FIG. 739.—Trotter's method of reconstructing the pharynx from a flap of the skin (A–B) of the neck after excision of an extensive pharyngeal carcinoma.

Growths situated in the vallecula, unless very advanced, must be treated by pharyngolaryngectomy with, if necessary, excision of a portion of the back of the tongue.

NEOPLASMS OF THE LARYNGOPHARYNX

In accordance with their site of origin, it is customary to subdivide malignant tumours of this part of the pharynx into four groups :

1. Epilaryngeal (20 per cent.).—Nearly always the patient is a man between fifty and sixty years of age. The lesion is situated on an aryepiglottic fold, extending to the epiglottis or the corresponding arytenoid cartilage, and is either of the ulcerative or the papillary type. It may be symptomless in the early stages. The earliest symptom is a slightly sore throat. A muffled voice and increasing dysphagia occur later. Real hoarseness indicates involvement of the interior of the larynx, i.e. the vocal cord. Later there are attacks of dyspnœa associated with blood-stained sputum. The diagnosis is made by indirect laryngoscopy.

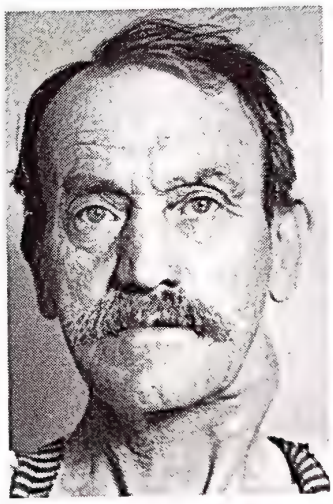

FIG. 740.—Malignant lymph nodes of the neck secondary to laryngo-pharyngeal carcinoma in the 'silent' area. The patient presented himself on account of the lump in the neck.

2. Sinus Piriformis[1] (40 per cent.).—Again, this group occurs chiefly in men about fifty years of age, and the lesion is notoriously silent. Often its first intimation is an enlarged lymph node behind the angle of the jaw. Frequently this is not heeded in its early stages (fig. 740). Exceptionally, the patient presents himself at an earlier stage, because of slight difficulty in swallowing saliva, as opposed to food. Pain is absent until the growth has involved the superior laryngeal nerve. The pain is referred to the ear. Carcinoma of the piriform fossa is nearly always of the ulcerative type. The growth may be seen with a laryngeal mirror, but sometimes its extent cannot be determined without direct laryngoscopy.

3. Lateral Wall (12 per cent.).—Once again men are attacked much more often than women. Contrary to the sinus piriformis, the growth is often papillary.

A lateral radiograph of the neck, with air inflation of the pharynx, is often more informative than a barium swallow in the demonstration of a neoplasm in this and nearby situations.

4. Post-cricoid (28 per cent.) occurs on the anterior wall of the hypo-

[1] Piriformis—Latin, *pirum* = a pear.

pharynx at the level of the cricoid cartilage. The patient is nearly always a woman of over forty years of age, who gives a history of increasing dysphagia.

The higher incidence in women is possibly due to their ability to swallow hotter fluids and food than men can tolerate. Many of these neoplasms are secondary to the Plummer-Vinson syndrome (p. 772).[1] Indirect laryngoscopy seldom reveals the growth, which lies hidden beneath a pool of mucus. Radiographic examination after a barium swallow is often helpful in determining the site of the lesion. Direct pharyngoscopy is the most informative, and allows a portion of the growth to be removed for biopsy.

Treatment of Carcinoma of the Laryngopharynx.—The condition is notoriously difficult to treat successfully. Surgery is often the treatment of choice : it involves the major operation of laryngo-pharyngectomy, combined with block dissection of the neck, the establishment of a permanent tracheostomy, and the plastic reconstruction of the pharynx. About 20 per cent. of patients survive five years.

External irradiation is the alternative method of treatment and is advised for those patients who are considered unsuitable for such a major procedure, either because of their poor general condition, or because it is thought that they will not be able to adjust themselves to a life without a larynx.

Types of Operation.—Operations which combine excision and reconstruction of the gullet in one stage are preferable to staged procedures. The following is an example of a one-stage operation, in which the colon is used to replace the pharynx :

Two teams are used. The first team performs the pharyngo-laryngectomy, the block dissection of the lymph nodes of the neck on the side of the tumour, and establishes the tracheostomy. The larynx and pharynx are excised from above the level of the hyoid bone down to the level of the third or fourth tracheal ring, and including the whole of the cervical œsophagus. The stump of the œsophagus is closed by inverting sutures and allowed to slide into the thorax. The thyroid gland is included in the excision. A block dissection of lymph nodes on the less involved side may be undertaken, but the sternomastoid muscle and the internal jugular vein are usually spared.

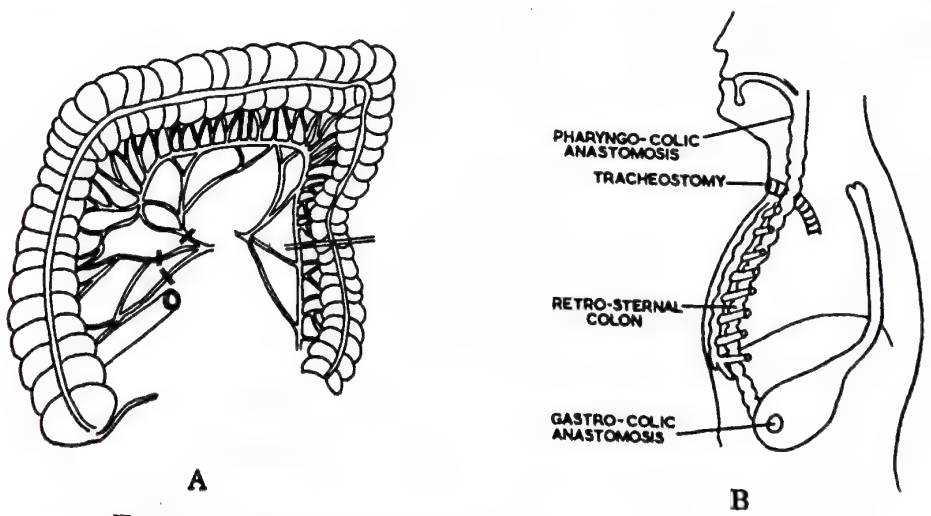

FIG. 741.—Reconstruction of the pharynx, using colon.

(*A*) Mobilisation of the colon. The middle and right colic vessels are divided. The blood supply of the colon now depends upon the left colic artery and the marginal arterial anastomoses. (*B*) The completed operation. The right and transverse colon have been passed retrosternally up into the neck. (*J. T. John, F.R.C.S., Bath.*)

[1] Also widely known as the Paterson-Brown Kelly syndrome.

The second team, working in the abdomen, mobilises the colon so that it is attached only by the mesocolon and its blood supply. The pattern of the blood supply of the colon is such that a long enough length of bowel can be obtained to join the oro-pharynx to the stomach based on a single feeding artery, usually the upper left colic artery (fig. 741A). A tunnel is made in the anterior mediastinum by stripping the pericardium, pleura, and great vessels from their sternal attachments. The colon is drawn up through the tunnel and the upper end anastomosed to the divided oro-pharynx and the lower end to the front of the stomach (fig. 741B). Restoration of continuity of the abdominal colon is achieved by end-to-end anastomosis.

The patient is allowed to swallow fluids the following day and to eat normal foods within two weeks. Should recurrence of the neoplasm occur, radiotherapy can be given with little risk of damage to the artificial gullet and hence little interference with the patient's swallowing.

Alternatives. (i)—The colon may be drawn up through a presternal, subcutaneous route (fig. 742). (ii) Another method of reconstruction is to transect the œsophagus at the cardia closing its distal end, and mobilising the stomach to elevate it through the posterior mediastinum: then it is sutured to the pharyngeal remnant high in the neck.

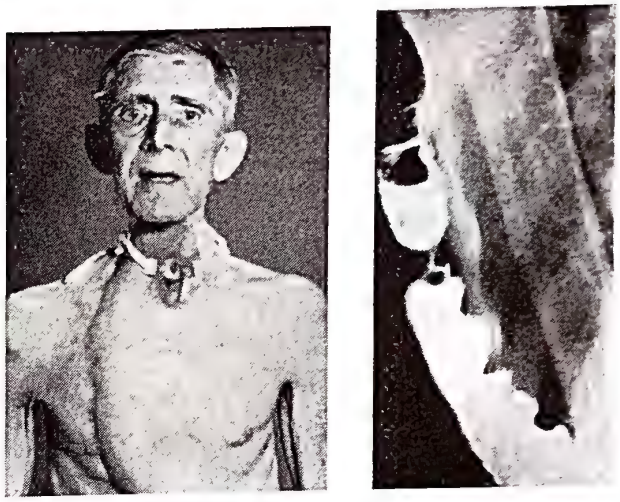

FIG. 742.—Reconstruction of the pharynx with pre-sternal colon, showing patient (*left*) and his barium swallow (*right*). (*P. V. Reading, F.R.C.S., London.*)

CHEMOTHERAPY IN HEAD AND NECK CANCERS

Cytotoxic drugs in the treatment of head and neck cancers cannot at present compete with surgery or radiotherapy, but they do have a limited value as an adjunct to these forms of therapy in patients who have not responded, or who have recurrent growths. Various methods of administration are possible. Growths in this region are particularly suitable for treatment by *intra-arterial infusion.* The reasons are that the neoplasms are mainly within the supply of the external carotid artery and that they rarely metastasise systemically until very late. Tumours of the ear, nasopharynx, oropharynx, and tonsils, maxillary sinuses and laryngopharynx can be treated in this way.

The cytotoxic agents are of several types: *Biological alkylating agents,* such as nitrogen mustards and epoxides (Ethoglucid). These are given by single injections directly into the exposed appropriate artery. Their activity only lasts a few minutes and further injections, say every other day, may be given. *Anti-metabolites,* such as methotrexate; these are administered as a continuous intra-arterial infusion lasting two or three weeks. *Antimitotic* drugs such as vinka-alkaloids.[1] Others, such as Bleomycin may interfere directly with D.N.A.

Technique.—The external carotid artery is exposed through an oblique neck incision. Its branches are identified so that the arterial supply to the tumour area can be isolated. A catheter is threaded through an incision in the superior thyroid branch, passed in a

[1] Derived from Periwinkle extracts.

retrograde manner to the external carotid and thence to the artery of supply. It is firmly tied in place. For tumours in the lower part of the neck such as hypopharynx, the superficial temporal artery is catheterised instead.

Other branches of the external carotid are either clipped off or ligated. A tracer dye (methylene blue or disulphine blue) injected into the cannula will discolour the area of infusion and ensure that it is limited only to the region of the tumour (fig. 743). The artery must also be isolated if the single injection method is being used. The neck incision is closed and the infusion fluid is injected using a small pump, calibrated to give the appropriate rate of flow.

FIG. 743.—Perfusion with cytotoxic drugs. The tracer dye (see text) shows that the intra-arterial catheter is correctly placed for perfusion of carcinoma of the ethmoid. *(Professor D. F. N. Harrison, F.R.C.S., London.)*

The infusion can be followed up with intravenous or oral cytotoxic drugs. To be effective, the white cell count should not rise above 2000 per mm^3.

The toxic side-effects of cytotoxic drugs include: bone marrow depression, alopecia, cutaneous vesiculation, and œdema. They may be lessened by giving a systemic antidote at the same time as the infusion (e.g. protective doses of folinic acid may be given intramuscularly with methotrexate). The technique itself enables the smallest effective dose to be infused into the tumour area with minimal spill-over into the systemic circulation. A later development by Harrison is to use hypothermia, cooling the patient during the infusion. This gives added protection to the bone marrow and brain.

Before deciding to give chemotherapy, one must balance the prognosis of the disease against the expected relief and possible toxic side-effects. Intravenous therapy or oral administration with combinations of different drugs are now being increasingly used. But its future use may well be in combination with surgery and radiotherapy rather than as a sequel to them.

CRYOSURGERY

Cryosurgery[1] is a technique in which tissues are exposed to extreme cold in order to produce irreversible cell damage. Alternate rapid freezing and thawing to a temperature of at least −20° C. causes multiple intra-cellular ice crystals to form which will be lethal to the cell. Its main use in surgery at present would seem to be, 1. destruction of benign vascular lesions of the head and neck (e.g. hæmangioma, angiofibroma), 2. palliation and relief of pain in uncontrolled or recurrent accessible cancers (e.g. carcinoma of nasopharynx), 3. a large number of ophthalmological procedures, including fixation of detached retina. It has also been used in pituitary gland ablation and prostatectomy.

Technique.—Modern equipment consists of a hollow probe refrigerated by liquid nitrogen or pressurised nitrous oxide. Incorporated in the probe is a rewarming device, thus tissue can be rapidly frozen and thawed as required. The probe is applied to the tissue and freezing started, and when a ' tissue ice-ball ' has formed in the area to be treated, it is then immediately allowed to thaw. The process must be repeated 2 or 3 times to achieve maximum destruction.

[1] The idea of ' freezing surgery ' is not new; a Dr. James Arnott in 1851 at the Middlesex Hospital described the beneficial effects of a salt-ice mixture at −20°C. in the treatment of various superficial cancers.

James Moncrieff Arnott, 1794–1885. Surgeon, Middlesex Hospital, London.

CHAPTER 37

THE LARYNX

FOREIGN BODY IN THE LARYNX

IMPACTION of foreign bodies is more likely to occur in children, e.g. plastic bags, than in adults. The first symptoms are those of acute laryngeal obstruction, succeeded by those of irritation. There is pain, persistent cough, and often expectoration of blood-stained mucus. From time to time there are paroxysms of dyspnœa. Cardiac arrest and death may occur.

Treatment.—If the foreign body cannot be dislodged by hooking it out with a finger, or by inverting a child and slapping its back, immediate tracheostomy is necessary in urgent cases with obstructive symptoms. In less urgent cases radiography is useful when the foreign body is radio-opaque. By the aid of direct laryngoscopy the object can be seized and removed.

ACUTE ŒDEMA OF THE GLOTTIS

Pathology.—There is œdema of the entrance of the larynx, especially of the aryepiglottic folds and the epiglottis. Strictly speaking, the œdema is not of the glottis (the chink between the vocal cords) but of the tissues at a higher level, but this ancient and inaccurate term is difficult to displace.

Ætiology.—1. Extension of acute inflammation, especially acute streptococcal laryngitis or tonsillitis, diphtheria, acute parenchymatous glossitis (p. 546), and Ludwig's angina (p. 578).

2. Angioneurotic œdema.

3. Irradiation either with or without perichondritis.

4. Trauma (e.g. car accidents).

5. Indirect irritants such as ingested corrosives, scalds or inhaled noxious gases.

6. Extension of an adjacent carcinoma.

7. Local dropsy (renal or heart failure).

The patient's voice is reduced to a hoarse whisper and some dysphagia may be present. Increasing dyspnœa occurs and frequently the œdema is sufficient to cause urgent stridor. If laryngoscopic examination is possible, the entrance to the larynx can be seen resembling the appearance of the cervix uteri.

Treatment.—Inhalation of steam and spraying with a dilute solution of adrenaline afford relief in early and mild cases. Systemic antihistamines (e.g. Phenergan) or cortisone are valuable.[1] When dyspnœa is urgent, intubation (p. 682) or tracheostomy must be performed forthwith.

---

[1] In cases of laryngeal obstruction, never give morphine. A patient under the influence of morphine stops fighting for breath, seems peaceful, and not infrequently the nurse returns to find him dead (Chevalier Jackson.)

Chevalier L. Jackson, 1900–1961. Professor of Laryngology and Broncho-Œsophagoscopy, Temple University, Philadelphia, Pennsylvania, U.S.A.

TRACHEOSTOMY

The indications are as follows:

(*a*) **To relieve obstruction of the upper air passages.**

1. Impaction of a foreign body.
2. Acute infections such as: acute laryngo-tracheo-bronchitis of children, acute epiglossitis of influenzal or virus origin. Laryngeal diphtheria.
3. Œdema of the glottis.
4. Bilateral abductor paralysis of the vocal cords following injury to the recurrent laryngeal nerves during thyroidectomy.
5. Tumours, particularly carcinoma of the larynx.
6. Chronic stenosis following tuberculosis or scalding.
7. Congenital webs or atresias.
8. Cut throat.

(*b*) **To improve respiratory function,** by reducing the anatomical dead space, and also enabling effective aspiration of bronchial secretions to be done.

1. Fulminating bronchopneumonia.
2. Chronic bronchitis with severe emphysema.
3. Chest injuries, particularly 'flail' chest.

(*c*) **Respiratory Paralysis.**—It allows assisted or positive pressure respiration to be performed. Also secretions or inhaled foreign material (e.g. vomitus) can be aspirated.

1. Unconsciousness associated with head or facio-maxillary injuries.
2. Coma from other causes persisting for more than a few hours where there is difficulty in maintaining a free airway, e.g. barbiturate poisoning.
3. Bulbar type of poliomyelitis.
4. Tetanus. Many of these patients are, of necessity, heavily sedated, have trismus, and are in mortal danger because of inability to expectorate.

(*d*) **As a preliminary to certain operations, particularly extirpation of the larynx.**

In cases of dire emergency the operation has been performed successfully with nothing available except a penknife. If at all possible, intubation even with a small intratracheal tube, should be attempted. If successful, a general anæsthetic can be administered and a hurried procedure transformed into a deliberate, calm operation. Intubation brings the abnormally low intrapleural tension to normal and prevents the occurrence of surgical emphysema and possibly pneumothorax, especially in children (see Mediastinal emphysema, p. 682). Insertion of an intratracheal tube also permits aspiration of secretions which have accumulated below the laryngeal obstruction. Intubation will also prevent spasm of the glottis.

FIG. 744.—The position for tracheostomy.

Operation.—If a skilled anæsthetist is unavailable, local anæsthesia is employed, but in desperate cases none is required. The patient may be pinned in a blanket so that a sudden movement of the arms may not embarrass the surgeon. When preparations are complete, a rolled towel or a small sandbag is inserted beneath the shoulders, and an assistant keeps the head extended strictly in the midline (fig. 744).

The surgeon, standing at the right side of the patient, places his left index finger on the upper border of the cricoid cartilage, with the thumb and the second finger on either side of the trachea, and makes an incision vertically downwards for 2·5 to 3·75 cm., dividing skin, fascia, platysma, pretracheal fascia, and passing between the infrahyoid muscles. (When circumstances permit, a horizontal skin incision midway between the cricoid and the suprasternal notch should be used, as subsequent healing is far more satisfactory.) If seen, the isthmus of the thyroid gland is divided between hæmostats. In an emergency, hæmorrhage is ignored. A cricoid hook (fig. 745) is then inserted under the cricoid cartilage and grasped in the left hand. The hook steadies the trachea and brings it to the surface of the wound. The trachea is incised with a scalpel, the second, third, and often the fourth rings being divided: the lower the tracheostomy, the less will be the liability to laryngeal stenosis. A tracheal dilator is inserted through the tracheostoma, the cricoid hook removed, and the edges of the tracheal wound are separated gently. In the case of diphtheria the surgeon places a swab over the wound so that the violent expiratory efforts which follow do not spray membrane, infected mucus, and blood over himself and his assistants. When respiratory efforts have become less violent, a tracheostomy tube on a pilot (fig. 745) is inserted into the trachea, the dilator is removed, and the surgeon keeps his finger on the tube while the assistant ties the attached tapes around the patient's neck. The inner tube[1] is then fixed in position, and one or two nylon or silk stitches are introduced if necessary.

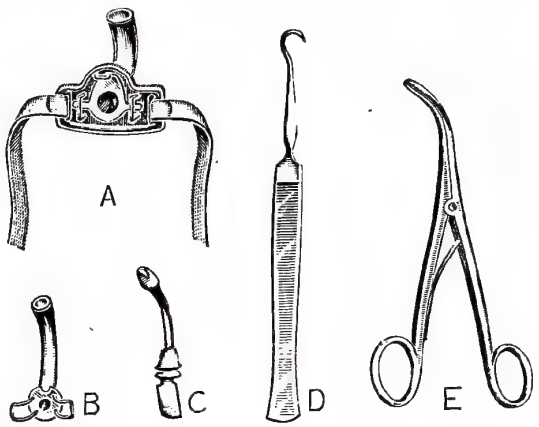

FIG. 745.—Instruments for tracheostomy (excluding scalpel and hæmostats).

A. Outer tube with tapes attached. B. Inner tube[1]. C. Pilot. D. Cricoid hook. E. Tracheal dilator.

In the case of a less urgent tracheostomy all bleeding is stopped before the trachea is opened. The injection of a few drops of 2 per cent. Xylocaine before the trachea is incised prevents the bout of coughing that follows the insertion of the tube. When the operation is performed on an adolescent or an adult, the isthmus of the thyroid gland is divided. The tracheostomy opening should be circular in shape (not just a vertical slit), by excising the edges of the incision with a scalpel strong enough to cut cartilage. A circular stoma facilitates the introduction and later changing of the tracheostomy tube, and heals well after eventual removal of the tube.

If a patient is unable to breath unaided, an *inflatable rubber or polyethylene cuff-tube* is introduced through the tracheostomy opening in order to seal off the air passage. The airway must be kept clear by frequent aspiration, assisted by postural drainage.

After-treatment.—Beside the bed is placed a trolley containing a tracheal dilator, duplicate cannulæ and introducer, retractors, and dressings. Oxygen is at hand. For the first few days a special nurse must be in constant attendance. A mechanical humidifier is essential in order to render the secretion less viscid. A sucker with a catheter attached should be at hand to keep the tracheo-bronchial tree free from secretions. The catheter must be kept sterile on a special tray covered by a sterile towel. The introduction of the catheter must be carried out under aseptic precautions by all concerned (nurses and physiotherapists). Unless these precautions are observed, secondary broncho-pneumonial infection is inevitable. When mucus is very

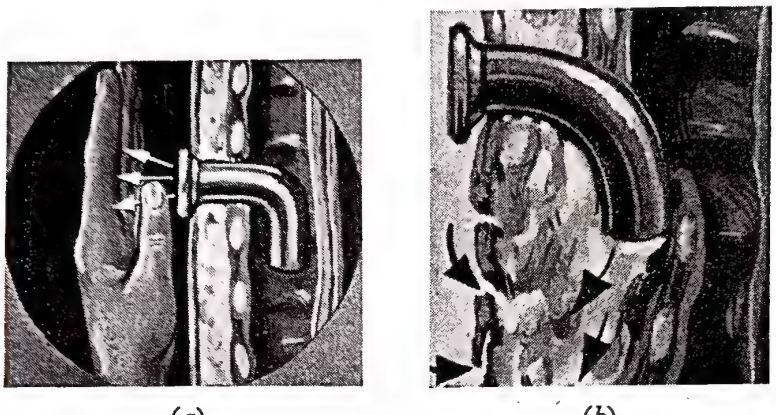
[1] The inner tube is longer than the outer tube, so that the latter cannot remain obstructed when the inner tube is removed for cleaning. To carry out suction effectively, the inner tube must be of such a diameter that it will not be occluded by the passage of a No. 3 or 4 rubber catheter.

tenacious, and consequently difficult to aspirate, normal saline or a detergent such as Alevaire (Bayer Products Ltd.) is administered through the tracheostomy by a fine nebuliser.

The inner tube is removed and washed in sodium bicarbonate solution every four hours, or more often if necessary. Before removal the patient should be able to sleep with the tube occluded.

Complications:

1. *Crusting in the trachea* or main bronchi can seriously embarrass the airway, it can be cleaned by the aid of a bronchoscope passed through the tracheostome.
2. *Surgical emphysema* in the neck is a complication and may occur if the skin is too tightly sutured around the tube, or if the tube slips into the tissues of the neck (fig. 746).



(*a*) (*b*)

FIG. 746.—(*a*) Tracheostomy tube in the correct position. Testing for a free airway. (*b*) The tube has slipped, or has been incorrectly positioned, so causing surgical emphysema.

3. *Mediastinal Emphysema.*—The cause is an abnormally low intrapleural tension—air is sucked into the tissue planes during the operation before the trachea is opened, causing subsequent dyspnœa and cyanosis. In severe examples the air in the mediastinum causes the mediastinal pleura to rupture, and a pneumothorax results. The diagnosis can be confirmed by radiography. Apart from oxygen therapy in high concentration, there is no specific treatment. The extravasated air is slowly absorbed.
4. *Tracheal Stenosis* is described on page 703.

Endotracheal catheterisation is a substitute for tracheostomy (mainly cases in group (c), p. 680), but it is usually less desirable, for two reasons:

(*a*) Repeated bronchial tree toilet is performed more easily by a nurse through a tracheostomy. (*b*) Intubation granuloma of the vocal cords (p. 684) and subsequent stricture may occur.

LARYNGEAL PARALYSIS

The muscles of the larynx are innervated by the recurrent laryngeal nerves, with the exception of the crico-thyroid muscle which is supplied by the superior laryngeal nerve. Lesions of the recurrent laryngeal nerve cause the vocal cord on the affected side to lie in the paramedian position; this is due to the unopposed tensing and adducting action of the crico-thyroid. Lesions of the vagus nerve above the origin of the superior laryngeal nerve will cause complete vocal cord paralysis on the affected side. The cord will be flaccid and lie midway between abduction and adduction, which is the state and position of the vocal cords soon after death.

Ætiology.—The lesion may be central, cervical, or mediastinal. Of over-riding importance is the relation of a goitre, and especially of thyroidec-

tomy, to recurrent laryngeal paralysis. Routine laryngoscopic examination must be made before thyroidectomy, as 3 to 5 per cent. of patients are found to have paresis or paralysis of one vocal cord, possibly due to neuritis following exanthemata during childhood, although no symptoms point to such a lesion. Pre-operative laryngoscopy is especially necessary when operating on a case of recurrent goitre. If pre-operative paralysis of a vocal cord is found, this fact *must* be recorded in the patient's notes in order to protect the surgeon from possible litigation. Pre-operative paralysis of a vocal cord with symptoms, e.g. a recent husky voice, is highly suggestive that the goitre is carcinomatous. Other causes of recurrent laryngeal paralysis are a central lesion (e.g. tabes), carcinoma of the upper œsophagus, carcinoma of the bronchus, malignant disease of the mediastinal lymph nodes, aneurysm of the arch of the aorta (always left-sided), and peripheral neuritis. Thirty per cent. of cases are idiopathic.

Clinical Features.—Unilateral recurrent laryngeal palsy of sudden onset produces a whispering voice and occasionally some slight difficulty in

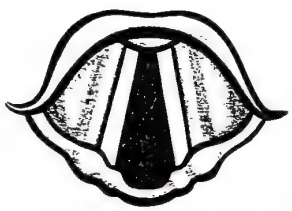


FIG. 747.—Normal larynx on inspiration. Indirect laryngoscopy.

FIG. 748.—Left recurrent nerve laryngeal palsy.

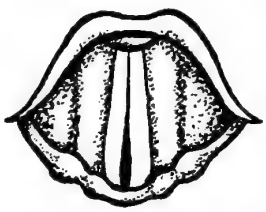

FIG. 749.—Bilateral recurrent nerve laryngeal palsy.

swallowing fluids, due to paralysis of the crico-pharyngeus on the affected side. These symptoms are short-lived and the voice may return to normal within a few weeks as the muscles in the opposite cord compensate and move it across the midline to meet the paralysed cord. Owing to this efficient compensation, in slowly progressive lesions, the patient may only experience slight weakness of the voice towards the end of the day.

Bilateral recurrent laryngeal palsy is an occasional and very serious complication of thyroidectomy. Acute dyspnœa occurs due to the paramedian position of the cords which tend to get sucked together on inspiration. Unless tracheostomy or intubation is carried out forthwith, death from asphyxia is probable.

Unilateral complete laryngeal paralysis causes a hoarse voice in which compensation does not readily occur owing to the flaccid state of the vocal cord and its lateral position. The healthy vocal cord has difficulty in meeting it.

Bilateral complete laryngeal palsy is an uncommon condition which occurs in lesions of the brain stem. It is usually associated with other cranial nerve lesions.

FIG. 750.—Bilateral flaccid paralysis of the vocal cords. The cadaveric position.

Treatment.—Tracheostomy should be performed in all cases of bilateral lesions, even when the paralysis is flaccid, for it is far better to provide the patient with a free airway than to permit him to suffer from chronic dyspnœa and its attendant evils, chief of which is the risk of asphyxia. The use of a tracheostomy tube with a recessed valve allows the patient to speak: the delicate valve opens on inspiration and closes on expiration. The expired air passes through the vocal cords so that the patient has an audible voice. With an ordinary tracheostomy tube the inspired and expired air by-passes the larynx and the patient's voice amounts only to a whisper. In cases following thyroidectomy where the patient is otherwise in good health, the next step is to wait up to a year in the hope that one or both of the nerves will recover, otherwise extralaryngeal arytenoidectomy may be considered. It gives permanent relief of stridor at the expense of a good voice.

SIMPLE SWELLINGS OF THE LARYNX

1. **Vocal Cord Polypus.**—This is the most common of the simple swellings in the larynx and must be distinguished from true benign neoplasms. It originates in the sub-epithelial space within the vocal cord. Initial congestion is followed by localised areas of œdema and hyalinisation ; a soft, pearly grey often pedunculated mass is formed. It is easily removed endoscopically with cupped forceps.

2. **Intubation granuloma** may arise as a rare complication following the use of endotracheal anæsthetic tubes.

3. **Laryngocele.**[1]—A laryngocele is a unilateral (occasionally bilateral) narrow-necked, air-containing diverticulum resulting from a herniation of laryngeal mucosa. It originates in the laryngeal sacculus, situated in the anterior third of the laryngeal ventricle, and ascending between the false cords and the ala of the thyroid cartilage, and it herniates through the thyrohyoid membrane, and when distended forms a visible, often resonant, swelling in the neck.

The symptoms, due to a recrudescence of infection, come in attacks when the swelling, which often appears when the patient blows his nose, does not abate completely for hours or days; the explanation being that the neck of the sac becomes obstructed by mucopus. The attack often terminates with a gurgling noise and discharge of mucus into the pharynx. The sac should be excised and the neck, which is crushed, ligated, and divided, is invaginated like the stump of a vermiform appendix.

NEOPLASMS OF THE LARYNX

Benign.—Papilloma is the commonest benign tumour of the larynx.

In an adult a papilloma is usually single, and its pedicle is attached to one of the true or false vocal cords. The symptoms to which it gives rise are similar to those of carcinoma of the larynx, from which it must be distinguished. The diagnosis is made by laryngoscopic examination. Rarely, a papilloma becomes malignant; therefore the papilloma should be removed and submitted to microscopical examination.

In a child the growth is relatively common: it is usually more vascular and softer than a papilloma appearing during adult life. Moreover, implantation growths soon appear in the vicinity and may obstruct the glottis. There is a

[1] Cervical air-pouches are present in many mammals, and can be inflated voluntarily; they are exceptionally well developed in South American monkeys that utilise them for howling (howling pouches). The condition, therefore, can be looked upon as partly atavistic but mainly acquired, for it occurs in professional trumpet-players, glass-blowers, and in persons with chronic cough.

marked tendency to recurrence after removal, and the papillomas may spread to almost any site in the larynx, pharynx, or trachea.

Treatment.—Chevalier Jackson's warning was not to be too radical in the treatment of multiple papillomas for fear of damaging the vocal cords. 'Laryngeal papilloma,' he said, 'is a self-limiting disease and disappears spontaneously in early adult life provided the patient can be carried through until that time.'

Endoscopic removal with cupped forceps is the usual method of treatment.

Micro-surgery of the Larynx.—This is a technique whereby the vocal cords can be inspected under magnification and benign lesions more carefully and accurately removed (Kleinsasser). The operating microscope is used with a special laryngoscope which is inserted and fixed to a clamp for stability. Healing of the cords and the post-operative voice are generally much better than after ordinary laryngoscopy.

Angiofibroma is always single, and is distinguished from a papilloma by its smooth contour (fig. 751). Except that occasionally it gives rise to hæmoptysis, it resembles a papilloma in symptomatology. In appropriate cases the condition must be distinguished from *singer's nodules*, which are nearly always bilateral. The latter condition, which produces a pearly-white nodule on the free edge of the vocal cord, is not a neoplasm, but an epithelial hypertrophy, and should, if possible, always be treated by prolonged rest (which is sometimes successful) before resorting to operation. On the other hand, an angiofibroma should be removed endoscopically with cupped forceps. Great precision is necessary, because if normal tissue is removed the speaking voice will be impaired and the singing voice ruined.

FIG. 751.—Angiofibroma of the left vocal cord. It seldom becomes much larger than depicted here.

Malignant.—Carcinoma is more common than an innocent tumour of the larynx. It usually occurs between forty and sixty years of age, and men are ten times more often attacked than women.

There are three varieties of laryngeal carcinoma:

1. *Glottic* (70 per cent. of growths), arising from the true vocal cord, which is relatively common and the most favourable type.
2. *Subglottic* (10 per cent.), below the vocal cords, with a worse prognosis.
3. *Supraglottic* (20 per cent.), originating from the ventricular bands (false vocal cords), laryngeal ventricles or the root of the epiglottis. This group has the worst prognosis.

FIG. 752.—Carcinoma of a true vocal cord.

1. Carcinoma of a vocal cord (glottic) usually arises from the anterior half of one of the true vocal cords. Most frequently it is of the papillary variety (fig. 752), occasionally it is flattened, rarely it is ulcerative. Due to the paucity or absence of lymphatic vessels of the vocal cords, this type of carcinoma of the larynx remains locally malignant for a long period.

The first symptom is huskiness of the voice. The huskiness is progressive, and the patient can speak only in a low whisper, which finally gives place to

Oskar Kleinsasser, Contemporary. Associate Professor, Ear, Nose and Throat Clinic, Cologne, Germany.

aphonia. About this time the growth breaks through its confines, and metastases occur in the cervical lymph nodes and elsewhere.

The diagnosis is made by laryngoscopic examination and biopsy, and every patient with hoarseness persisting for more than three weeks should be submitted to this form of examination. According to the length of time the growth has been present, *four stages* of the disease are recognised:

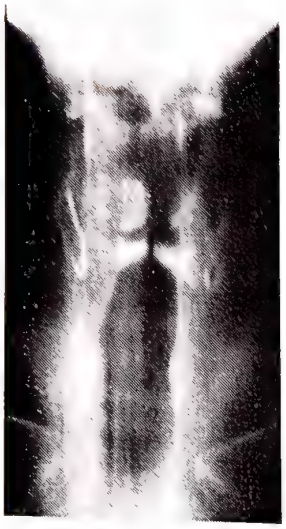

FIG. 753.—Tomogram of the larynx showing tumour of the right false vocal cord encroaching on the laryngeal ventricle. The vocal cords are not affected.

i. The growth is confined to a *still mobile* vocal cord.

ii. Infiltration impairing mobility of the cord. Extension to other cord.

iii. Fixation of the cord. The growth has entered adjoining part of larynx. Isolated involved lymph nodes.

iv. Extension to the pharynx or skin. Lymph node metastases with fixation.

2. **Subglottic carcinoma** is a less common variety that occurs beneath the vocal cords. In this site the neoplasm grows steadily and silently, until dyspnœa develops. The paratracheal and lower deep cervical nodes, and even the thyroid gland may be involved.

3. **Supraglottic Carcinoma.**—The inital symptom is often a sense of discomfort in the larynx. Pain and hoarseness come relatively late. In 60 per cent. of cases there is cervical lymph node involvement at the time of presentation.

Tomograms are very helpful to determine the extent of the growth (fig. 753).

Treatment.—Supraglottic tumours metastasise early into the cervical lymph nodes, whereas tumours of the true vocal cords remain locally malignant for many months. For early (stage 1 and 2) carcinoma of the true vocal cord, the results of irradiation are as good as those of surgery and the voice is better. Therefore, where adequate facilities exist, irradiation (super voltage X-ray therapy, or telecobalt) is preferable to surgery. Although in the stage 1 growths there is an 80 per cent. five years' survival rate, every effort should be made to have a careful follow-up. If recurrences occur, or where the cervical lymph nodes are involved by metastatic deposits of squamous-celled carcinoma, laryngectomy, with block dissection of the lymph nodes in continuity, gives results superior to irradiation.

Total laryngectomy is performed for carcinoma of the vocal cord which is already *fixed* by infiltration, when radiotherapy fails to destroy the growth or where the growth recurs after radiotherapy.

Anæsthesia.—General anæsthesia is given through an endotracheal tube inserted via the nose. This is changed by the surgeon during the later stages of the operation after delivery of the larynx (fig. 755B).

Incision.—A variety of incisions are used. A satisfactory exposure is shown in fig. 754. This may be modified if a block dissection is necessary.

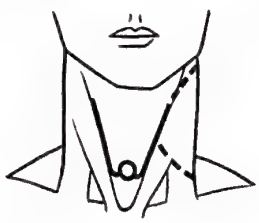

FIG. 754.

Dissection.—The laryngeal cartilages and trachea are exposed by division of the thyroid isthmus. The strap muscles are divided and the inferior constrictor is carefully dissected off the thyroid cartilage. The hyoid is freed. The pharynx is opened by incisions above the hyoid

bone (fig. 755A). After changing the anæsthetic tube, the hyoid is drawn forward and the mucous membrane incised down each pyriform fossa, to meet along the back of the arytenoids (fig. 755B). A nasal feeding tube is passed into the œsophagus and the defect in the pharynx is closed by interrupted sutures, and reinforced by suturing the inferior constrictors together anteriorly (fig. 755C).

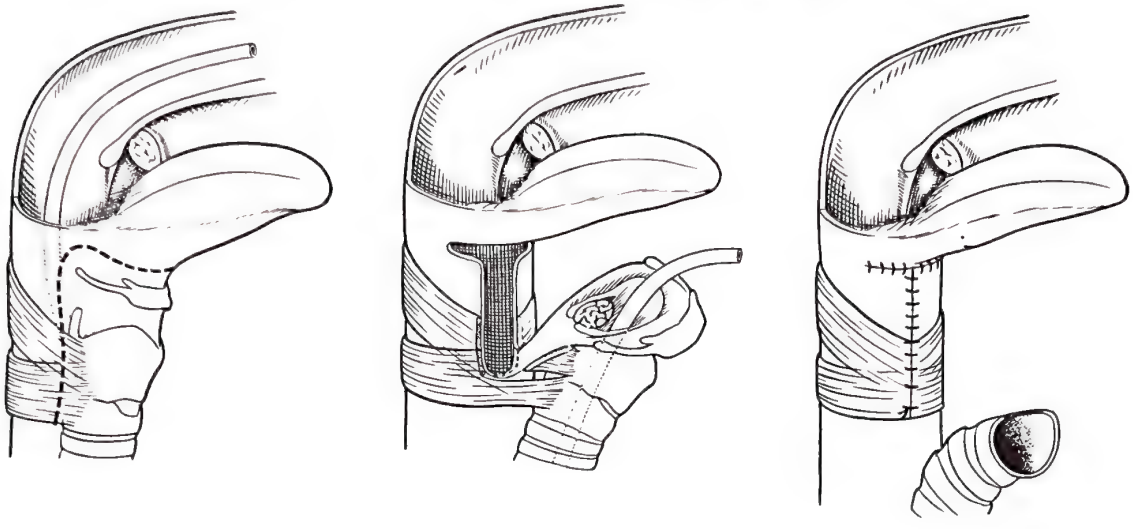

FIG. 755.—Total laryngectomy (see text).

The trachea is divided between the second and third rings. The tracheostomy is fashioned by suturing the trachea to the cut edges of the wound in the suprasternal notch.

For supraglottic carcinoma, subglottic tumours, and in cases where cervical lymph nodes are obviously the sites of secondary deposits, block dissection of the lymph nodes must be combined with the laryngectomy. If the carcinoma extends into a lobe of the thyroid gland, this lobe is also removed.

Speech after Laryngectomy.—Many younger patients learn œsophageal speech, belching swallowed air for this purpose. Others require a mechanical larynx which can be fitted to the tracheostomy tube. Another type of electrically operated *oral vibrator* attached to the patient's upper denture or an artificial palate has been invented recently.

FIG. 756.—Patient after complete laryngectomy. A transverse skin incision was used in this case. (*Jackson and Babcock.*)

Laryngo-fissure and Excision of the Growth.—The vocal cord must be still mobile. After preliminary tracheostomy, the thyroid cartilage is bisected and the whole vocal cord is removed. The tracheostomy tube is removed after a few days. As the vocal cord becomes replaced by fibrous tissue, the patient tends to have a gruff voice.

CHAPTER 38

THE THORAX

ANATOMY OF THE BRONCHIAL TREE

A THOROUGH knowledge of the anatomy of the bronchial tree is essential, not only for the diagnosis of many chest conditions, but for the planning and execution of the majority of pulmonary operations.

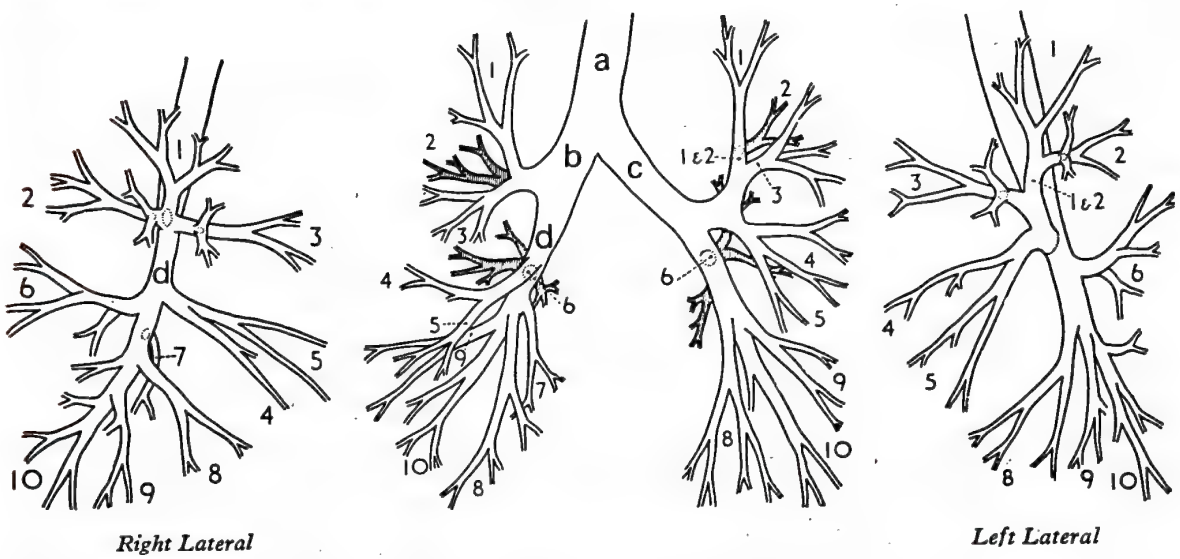

FIG. 757.—The bronchial tree with internationally adopted nomenclature.

10. Posterior basal			

(a) Trachea, (b) R. main bronchus, (c) L. main bronchus, (d) Intermediate bronchus.

Fig. 757 illustrates the common pattern of the bronchial tree. Each bronchus is accompanied by a branch of the pulmonary artery and together they form a broncho-vascular pedicle supplying conical segments of lung tissue. The pulmonary veins lie between the segments with tributaries issuing from adjacent segments. Each segment is largely an independent unit which can be removed (segmental resection) without interfering with adjacent segments. The veins indicate the true position of the intersegmental plane, which must be followed accurately during the operation. Two or more bronchial arteries on each side enter the lung in the areolar tissue surrounding the bronchi. They arise from the descending thoracic aorta and supply the broncho-pulmonary tissues with arterialised blood. They develop links with the smaller pulmonary vessels which, in certain diseases, may enlarge considerably.

The trachea and main bronchi with their lobar and first segmental divisions can all be examined visually by bronchoscopy. This investigation will demonstrate abnormalities in size (stenosis, obstruction or dilatation), movement (immobility or spasm), shape or position. The examination may also reveal the presence of a tumour or an intrabronchial foreign body (fig. 758). Material for biopsy and secretions for cytological or bacteriological examination can be obtained. Only the proximal part of the bronchial tree can be examined with the rigid bronchoscope even with the aid of a telescope. The flexible or fibre-optic bronchoscope can be introduced much farther into the bronchial tree and permits examination and biopsy of peripheral lesions. Introduced under fluoroscopic control its accuracy is further enhanced.

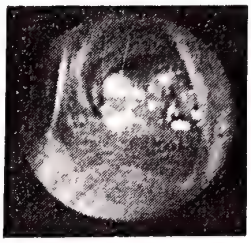

FIG. 758.—Chondroma: Right main bronchus. Bronchoscopic photograph. *(Dr. P. Stradling, London.)*

A more detailed anatomical study can be made by bronchography, which consists of the introduction of radio-opaque material (iodised oil) into the bronchial tree. An attempt is made to fill all the branches of the bronchial tree on one side, and radiographs are taken in two or more planes. Bronchography provides information about the size and distribution of the bronchi, and will also demonstrate bronchial occlusion or narrowing.

Developmental Anomalies

The trachea develops as a bud from the primitive fore-gut which soon divides into two main branches—the right and left main bronchus. Each bronchus continues to develop by branching so that all generations are present by the sixteenth week of intrauterine life. The fully developed segment has approximately 20 to 25 generations of branches. Failure of a main bronchus to develop results in *unilateral agenesis*, whilst failure of a lobar bronchus to develop produces *lobar agenesis*. Subsequent aberrations of development result in variations of the segmental pattern. Each developing bronchial bud becomes closely associated with the future pulmonary artery which covers its surface. Failure to link up with the pulmonary artery system occurs occasionally. In this case, ectopic bronchial buds develop anomalously, producing a mass of bronchial elements which often lose their connection with the parent bronchi. Vascular supply is derived direct from the descending aorta. In adult life the condition presents as a bizarre cystic mass, usually lying in the posterior aspect of the lower lobe with large systemic arteries the size of the radial artery or even larger entering the mass through the pulmonary ligament—*intralobar sequestration*. Infection of the cystic spaces is common and is the usual cause of symptoms. Removal of the lower lobe with the offending mass is recommended.

INJURIES TO THE CHEST

Apart from road accidents and stab-wounds chest injuries are not common in civil practice ; in war, however, they constitute nearly 10 per cent. of all wounds, whilst of those killed in battle, 25 per cent. have chest injuries. They are often associated with injuries elsewhere, particularly the head and abdomen. Two main varieties are encountered—crush injuries and wounds —although in any particular patient both may be present.

Crush Injuries

These are common both in war and in civilian practice. The injury may be produced by a localised blow or a more extensive crushing force. Road accidents frequently result in severe crush injuries. Similar injuries can also be produced by concussion waves from explosions conveyed either through air or water (blast injuries).

The injuries may produce contusion of the chest wall, rib fractures, a stove-in chest, a flail chest, lung contusion or laceration, aortic rupture or myocardial damage.

The effects of a crush injury depend on its severity and the extent of involvement of chest wall, pleura and lung. The more severe forms interfere seriously with ventilation and coughing either from pain or from instability or deformity of the chest wall. The presence of blood or secretions in the bronchial tree makes ventilation still less effective. Respiration may, in addition, be depressed further by an associated head injury.

The serious interference with ventilation results in rapid and shallow respiration with cyanosis, tachycardia and hypotension. Respiration may be noisy from tracheo-bronchial secretions. Milder degrees of hypoxia produce cerebral confusion and restlessness, and this is followed by unconsciousness in severe cases.

Management in the early stages depends on a careful assessment of the damage. The chest wall is examined for paradoxical movement (multiple fractured ribs), depressions (stove-in chest) or sucking wounds. The posterior aspect of the chest should be examined as the patient is gently rolled on one side. The position of the mediastinum (trachea and apex beat) provides useful information concerning the presence of a pneumothorax, a hæmothorax or massive collapse of the lung. An early chest X-ray is imperative for accurate diagnosis of the intrathoracic damage.

Early Treatment is directed at improving ventilation by the following means where indicated :

(1) Relief of pain with repeated small doses of morphine or other analgesics, or intercostal nerve block.

(2) Stabilisation of the chest wall : (*a*) strapping can be used in mild cases and temporarily in emergencies ; (*b*) internal fixation of fractured ribs by wire or nails for more severe cases ; (*c*) tracheostomy is often effective by reducing the effort of respiration.

(3) Removal of pleural blood or air should they be large enough to compress the lung. Simple aspiration may be sufficient, but rapid reaccumulation may demand an indwelling tube or thoracotomy.

(4) Removal of tracheo-bronchial secretions may be effected by natural means after relief of pain. Bronchoscopic aspiration may be used in an emergency but if secretions persist a tracheostomy is advisable.

(5) *Tracheostomy* is the most important measure in all serious cases (see also p. 680). It permits effective and repeated aspiration of the tracheo-bronchial tree. By eliminating the dead space of the oropharynx it reduces the

ventilatory demands and the work of respiration. It reduces or eliminates paradoxical chest wall movements.

Tracheostomy alone will often transform the condition of a seriously ill patient. If ventilation is seriously depressed, artificial respiration can be applied through the tracheostomy tube by mechanical ventilators. Repeated blood gas estimations are desirable to control artificial ventilation.

Tracheostomy and artificial respiration are of particular value in serious multiple injuries, especially those involving the head, in addition to the chest.

(6) Oxygen is usually necessary and is best administered by a mask.

(7) Blood transfusion, fluid replacement and hypertensive agents may be required to maintain the circulation.

Fractured Ribs.—Isolated rib fractures due to direct violence are a common complication of many varieties of chest trauma. The condition is painful but rarely disturbing. Localised tenderness and crepitus are often elicited, but the fractures may be difficult to demonstrate radiologically. Local support and analgesics are often all that is required for treatment. Intercostal nerve block may be required for persistent pain.

Multiple rib fractures (indirect or burst) are produced by crushing. The ribs fracture at the site of maximum curvature and stress, at the anterior and posterior angles. The stability of the chest wall is often greatly disturbed and in addition to pain, paradoxical movement occurs with difficulty in breathing and coughing. Ventilation is considerably hampered with the development of hypoxia and carbon dioxide retention; these changes are further aggravated by retained secretions.

Tracheostomy is advised in severe injuries; this will often correct paradoxical respiration and provide a ready route for tracheo-bronchial suction.

Artificial ventilation should be used with caution due to the risk of lung laceration by rib fragments.

Stove-in Chest.—This severe injury is produced by an extensive but localised crushing force which produces multiple rib fractures and a permanent indentation of the chest wall. The affected hemithorax may be considerably reduced in size and the function of the underlying lung markedly reduced. Some paradoxical movement is usually present. The compression of the underlying lung and its relative immobility results in the accumulation of broncho-pulmonary secretions.

The minor degrees of stove-in chest may require little specific treatment additional to that already outlined for rib fracture, but the more severe forms require surgical correction. Under anæsthesia it is possible to elevate the depressed chest wall with towel clips placed around the ribs. Reduction of the deformity is sometimes achieved by positive pressure ventilation, but where this proves impossible surgical elevation of the depressed ribs is required. This can sometimes be achieved by traction using percutaneous towel clips. Occasionally the depressed ribs will have to be exposed for elevation and fixation.

Crushed chests associated with a fractured clavicle are particularly serious as the deformity will increase unless the clavicle is controlled with a plate or pin.

Flail Chest.—This type of injury is seen particularly after automobile accidents of the more severe type, and is often accompanied by other serious injuries.

Multiple rib fractures result in a flaccid unstable chest wall exhibiting paradoxical movement in which the flail area is sucked inwards during inspiration and pushed out in expiration. With quiet respiration paradoxical movement may not be apparent, but if the respirations are difficult or if the patient should cough the paradox becomes more obvious. The paradoxical movement produces imperfect ventilation with hypoxia whilst defective coughing results in the retention of secretions. Any attempt on the part of the patient to overcome these defects by over-breathing or coughing only aggravates the condition.

Tracheostomy is urgently required and will often result in dramatic improvement. The dead space of the mouth and pharynx is eliminated with a consequent reduction in the ventilatory requirements. The presence of a tracheostomy will permit ready and repeated removal of broncho-pulmonary secretions by a catheter, and a clear airway will similarly result in quieter respiration. Paradoxical movement is often 'cured' by tracheostomy, but if it persists the affected ribs should be exposed and the ends joined by stainless-steel wire or nails.

With the acute ventilatory crisis adequately controlled by the tracheostomy, attention must be given to the prevention and control of the broncho-pulmonary infection by breathing exercises and antibiotics.

Traumatic Pneumothorax.—Air in the pleural cavity appears commonly after many forms of trauma. In the majority it is associated with blood as well (*hæmo-pneumothorax*). Air may reach the pleural cavity through a wound in the chest wall (*sucking wound*). More commonly air leaks from damaged lung; if the leak is valvular a considerable quantity of air will accumulate producing total collapse of the lung and displacement of the mediastinum towards the opposite side (*tension pneumothorax*).

Sucking wounds should be sealed with an occlusive pad until definitive surgical repair can be arranged. A tension pneumothorax can be relieved in an emergency by plunging an unmounted aspirating needle into the chest which allows the air under tension to escape. Subsequently, a small soft catheter should be introduced through a cannula and connected to a water seal or suction motor.

Traumatic Hæmothorax (see also p. 698).—Blood collects in the pleural cavity in the vast majority of chest injuries. The chest wall, lung or heart and great vessels (p. 757) may be the source of the bleeding. Bleeding is usually limited and should be dealt with by repeated daily aspirations after an initial interval of twenty-four hours to allow the bleeding vessel to seal. If the accumulation is large, earlier aspiration is necessary but, if progressive, a thoracotomy will be required to control the bleeding.

Pulmonary Contusion and Laceration.—The lung is injured in the majority of cases of moderate and severe trauma. Contusion results in areas of consolidation which will usually resolve spontaneously. Laceration

permits the leakage of blood and air into the pleural cavity. Minor lacerations heal spontaneously, but more severe degrees produce persistent collapse of the lung and leakage of air and should be explored by thoracotomy. Secondary infection of the damaged lung is an important complication which can often be prevented by chemotherapy, bronchial aspirations and physiotherapy.

Fracture of Bronchus.—Severe crushing injuries occasionally result in a transverse fracture of a bronchus. The commonest site is at the junction of the relatively fixed mediastinal bronchus and the more mobile hilar bronchus. Total atelectasis and mediastinal surgical emphysema result. The condition can be confirmed at bronchoscopy. Early repair should result in a functioning lung, but delay will lead to irreversible infection and fibrosis.

Wounds of the Chest

These may be simple, or complicated by serious underlying visceral damage. In either case the wound may be penetrating or perforating (through and through wound). In all cases, however simple, it is necessary to exclude serious damage to either thoracic or abdominal viscera.

Simple wounds from stabs or bullets may give rise to little trouble—the external wound is small and usually clean. A hæmothorax is usual and will require aspirations until the pleural cavity is dry.

Complicated wounds are common in injuries with large missiles such as shell and bomb fragments. The chest wall damage may be considerable and fragments of clothing, etc., may be carried into the chest. Lung contusion and laceration is common and the mediastinal structures, the diaphragm and abdominal viscera may be involved.

Operative treatment will be required in the majority of cases, and should be carried out as soon as practicable after resuscitation. The only indication for emergency thoracotomy is uncontrollable internal or external bleeding.

Endotracheal anæsthesia is essential in order to ensure adequate ventilation and permit the removal of bronchial secretions during the operation. The chest wound is excised, rib fragments removed, and intercostal vessels ligated, if necessary. If the wound is conveniently situated, the pleural cavity can be explored through it, but if not, a separate thoracotomy is required. All blood, clot, and debris should be removed from the pleural cavity in addition to any retained foreign bodies. Lung lacerations should be sutured if small, or a formal resection carried out if more extensive. The pleural cavity should be drained through a separate stab incision. After operation it is essential that the lung should expand rapidly and completely; this is encouraged by suction drainage, breathing exercises and early ambulation.

Thoraco-abdominal Wounds.—These are always potentially serious owing to the involvement of both the abdomen and the chest; their importance depends on whether or not one of the hollow abdominal viscera is damaged. The predicted course of the missile should be considered in order to anticipate the visceral damage. Apart from serious involvement of the chest, as outlined above, the main indications for exploration are signs of persistent bleeding or evidence of involvement of a hollow viscus. The thoracic approach has the advantage of permitting correction of the thoracic injuries, whilst giving adequate exposure of the upper abdomen through the diaphragm.

Shock Lung

Post-traumatic respiratory failure or shock lung may develop in 50% of patients after major trauma (Blaisdell). There is severe depression of gas exchange in the lungs due to pulmonary consolidation. Lung compliance is markedly decreased (stiff lung). Urgent treatment is required if a fatal outcome is to be avoided. Endotracheal intubation and positive pressure ventilation is instituted and large doses of steroids administered. Additionally, antibiotics and intravenous infusion are administered where indicated.

The condition is caused by micro-thrombo-embolism of small lung vessels following extensive intravascular coagulation produced by trauma. Similar changes are seen in septicæmia, after massive transfusions and following heart-lung bypass (pump lung).

DISEASES OF THE CHEST WALL

Kypho-scoliosis.—Deformities secondary to pleural and pulmonary disease are frequent unless preventive measures are taken; they can cause a considerable loss of pulmonary function, and may lead to repeated respiratory infections and cardiovascular disturbances. Vigorous breathing exercises can do much to prevent serious deformity provided they are initiated sufficiently early, but even in established cases some improvement can be expected. Primary kypho-scoliosis is considered on p. 271.

FIG. 759.—Funnel chest deformity.

Tietze's disease is a not uncommon painful and non-suppurative swelling of the second or third costal cartilages. X-ray is negative. Reassurance and not exploration is required. Local heat will often relieve pain but injections of hydrocortisone into the perichondrium may be required to encourage resolution.

Funnel Chest (Pectus Excavatum).—This deformity consists of a depression of the body of the sternum and the xiphoid process, combined with an inward curving of the costal cartilages and adjacent ribs. The deformity is usually minimal at birth, but becomes progressively more obvious during childhood. It predisposes to repeated respiratory infections and to cardiovascular disturbances, whilst the cosmetic appearances are frequently embarrassing (fig. 759).

Correction of the deformity is carried out through a midline or transverse incision: the sternum and costal cartilages are exposed and the deformed costal cartilages are resected subperichondrially. The attachments of the diaphragm to the xiphoid process are detached and the sternum separated from the mediastinal tissues. A wedge osteotomy of the anterior table of the sternum is performed at the upper limit of the deformity, and the mobilised sternal body can then be easily elevated. The sternum should be maintained in an elevated position by a stainless steel strut which is placed beneath the sternum with the ends resting on the ribs laterally. The strut is not removed for at least a year. The use of internal splinting has greatly improved the long-term cosmetic results.

Cold Abscess

The majority of cold abscesses of the chest wall are secondary to tuberculous intercostal lymphadenitis. A minority are associated with Pott's disease of the spine and tuberculosis of the ribs or sternum. The intercostal lymph nodes are situated posteriorly near the neck of the rib, or an-

F. William Blaisdell, Contemporary. Surgeon, San Francisco General Hospital.
Alexander Tietze, 1864–1927. Surgeon, Breslau, Germany (now Wroclaw, Poland).
Percivall Pott, 1714–1788. Surgeon, St. Bartholomew's Hospital, London.

teriorly in association with the internal mammary vessels. Tuberculous pus, forming in these sites, may track a considerable distance in the intercostal space before becoming subcutaneous. It usually reaches the superficial tissues by following the lateral or anterior branches of the intercostal vessels, and thus most commonly presents in the anterior axillary line or the parasternal region. The abscess has all the characteristics of a tuberculous cold abscess. Involvement of the skin and rupture is common in neglected cases, resulting in a presistent discharging sinus surrounded by typical tuberculous granulation tissue. A cold abscess must be distinguished from a lipoma or an empyema necessitatis; in the latter, the swelling is often tender and may exhibit an impulse on coughing, and is associated with the physical and radiological signs of an empyema.

The abscess should be treated by repeated aspirations through healthy skin with the instillation of streptomycin. If the abscess fails to respond to repeated aspirations, surgery will be required. The extent of the ramifications of the abscess should first be determined by the injection of iodised oil into the abscess. Ideally, the abscess and its ramifications should be completely excised, together with any secondary involved bone; but if this is not practicable, the abscess should be evacuated, granulation tissue removed and the wound closed. Chronically discharging sinuses can sometimes be cured by regular instillations of streptomycin; alternatively, excision of the track is advisable. All patients should have a long course of chemotherapy.

Empyema Necessitatis

This is caused by an empyema perforating the chest wall and presenting with a subcutaneous collection of pus communicating, often by a tortuous channel, with the main pleural collection. The condition is seen either with a neglected or an undiagnosed empyema, or following aspirations of thin, highly infective pus from an empyema. In the latter case, the superficial tissues are infected by the seepage of pus through a needle track. The site of the subcutaneous abscess does not always correspond to the site of pleural perforation, as the abscess may track along the intercostal spaces before becoming superficial. The signs are those of a diffuse, fluctuant, tender swelling which may exhibit an impulse on coughing, and is associated with the clinical and radiological signs of an empyema. Treatment is primarily aimed at the empyema, which should be aspirated and drained. The superficial abscess may disappear as a result of aspirating the empyema, or may itself require separate aspirations or drainage.

Tumours of the Ribs

Rib tumours may be benign or malignant, and the latter either primary or secondary.

Benign tumours are frequently discovered by routine radiography. Many are symptomless and produce no external evidence of their presence. A few produce pain or an external swelling. The commonest is the chondroma (figs. 760 and 761), whilst osteochondroma, multiple exostoses, fibrous dysplasia, lipoid granulomas and multiple myelomas are less common. Benign tumours usually produce expansion of the rib and are less dense radiologically than normal rib, whilst pathological fracture is rare. Malignant change can occur, especially in chondromas, and removal is advisable.

Primary malignant tumours are rare, the commonest being chondrosarcoma ; they should be widely excised. *Secondary deposits* in rib are particularly common in carcinoma of the lung and with breast cancer. The deposits are almost always painful and tender. They result in destruction of bone, and pathological fracture is common. X-ray therapy will usually relieve the pain.

FIG. 760.—Chondroma of rib.

FIG. 761.—Chondroma of rib (same case as fig. 760).

Neurogenic Tumours (see also p. 734).

These are of two main types—neurofibroma (figs. 762 and 763) arising from the intercostal nerves and ganglioneuroma from the sympathetic chain. The former appear close to the neck of the rib, whilst the latter lie slightly more medially applied to the vertebral bodies. The majority are found on routine radiography. They are usually symptomless and single. Their growth is slow and the adjacent ribs and vertebral bodies are often distorted and eroded. A small percentage extend through the intervertebral foramen into the vertebral canal, where compression of the spinal cord may result in paraplegia (dumb-bell tumour). Removal of the tumour is safe and simple and is recommended owing to the risks of malignant changes. Dumb-bell tumours, and particularly those with spinal-cord involvement, require urgent treatment. A small intraspinal extension can easily be removed from the chest, but extensive intraspinal tumours will require laminectomy for their removal; the latter can usually be carried out at the same time as the chest operation, but if very extensive, separate operations are advisable.

FIG. 762.—A large neurofibroma of the chest wall. The tumour is lying posteriorly.

FIG. 763.—Tumour removed from case illustrated in fig. 762.

DISEASES OF THE PLEURA

Pneumothorax —A pneumothorax is produced by the presence of air between the layers of the pleura. The air may be present alone or associated with serous fluid (*hydro-pneumothorax*), pus (*pyo-pneumothorax*), or blood (*hæmo-pneumothorax*). Air may be deliberately introduced into the pleura, in the treatment of pulmonary tuberculosis (*artificial pneumothorax*), or be associated with trauma (*traumatic pneumothorax*), or may appear without any obvious exciting cause (*spontaneous pneumothorax*). The physical signs of a pneumothorax are a hyper-resonant percussion note with absent breath-sounds. Radiographs reveal translucency on the affected side with absence of lung markings; the edge of the collapsed lung is usually visible.

Spontaneous Pneumothorax.—Causes :

(*a*) Tuberculous. (*b*) Non-tuberculous:— (1) *Emphysematous bullæ.* (2) *Solitary lung cysts.* (3) *Honeycomb or cystic lung.* (4) *Idiopathic.*

Tuberculous spontaneous pneumothorax is usually associated with obvious clinical or radiological signs of tuberculosis. The condition is produced by the rupture of a small subpleural tubercle or cavity, and is usually associated with infection or irritation of the pleura resulting in the appearance of fluid in the pleural cavity and a febrile reaction. Treatment depends on the underlying pulmonary lesion.

A non-tuberculous spontaneous pneumothorax by contrast is rarely associated with fluid formation or fever. In a minority an obvious underlying pulmonary lesion, such as an emphysematous bulla, a lung cyst, or a honeycomb lung, can be demonstrated. Absorption may occur spontaneously and rapidly, or may be considerably delayed (*chronic spontaneous pneumothorax*). Attacks may be single or repeated (*recurrent spontaneous pneumothorax*). With a first attack, in the absence of an underlying cause, air can be allowed to absorb spontaneously, or expansion can be encouraged by occasional aspirations. Should tension occur, however, air should be aspirated, but if reaccumulation is rapid, a fine catheter should be introduced into the pleural cavity and attached to an under-water seal or suction motor. A soft catheter is preferable to a rigid needle or cannula as it will not lacerate the lung as it expands.

Failure of absorption (*chronic spontaneous pneumothorax*), or repeated attacks (*recurrent spontaneous pneumothorax*), demand full investigations to determine the cause. The most useful investigations are tomography and thoracoscopy (inspection of the lung.) These investigations may reveal:

(*a*) A localised lesion, such as a cyst.
(*b*) Generalised lesions, such as emphysema or honeycomb lung.
(*c*) Nothing abnormal.

A localised condition is best treated by thoracotomy and excision, but the latter two groups should be treated by artificial obliteration of the space (pleurodesis). This is achieved by the use of chemical or other irritants (5 per cent. silver nitrate, iodised talc, 0·5 per cent. camphor in oil) introduced either through a needle or applied to the lung surface at thoracoscopy. These irritants set up a diffuse pleuritis which will result in the fusion of the visceral to the parietal pleura if the two surfaces can be maintained in apposition. It is thus important to ensure that the lung expands rapidly and completely after pleurodesis by using catheter drainage with suction. Thoracotomy is preferred by some for all cases. The lung leak is oversewn, cysts if present are

excised and the parietal pleura at the apex is removed or abraded in order to ensure fusion of the lung to the chest wall and prevent recurrence.

Hæmothorax.—Blood in the pleural cavity may occur in a variety of conditions and is often associated with air as well. The respiratory and cardiac movements defibrinate the blood as it reaches the pleural cavity so that the collection remains fluid. Massive clotting only occasionally occurs. Blood is a pleural irritant and its presence produces pain and shock in the early stages and later excites the formation of a considerable effusion. It is also an excellent culture medium and infection is relatively common.

Causes.—(1) Trauma (fig. 764).

(2) Post-operatively, following pulmonary, cardiac or œsophageal operations, thoracoscopy for division of adhesions, cervical sympathectomy and after refills of an artificial pneumothorax.

(3) Associated with new-growths of lung, mediastinum or pleura.

(4) Leaking aneurysms.

(5) Spontaneous.

FIG. 764.—A small left hæmothorax with two retained metallic foreign bodies.

The signs are those of a collection of fluid in the pleura, and the diagnosis is confirmed by exploring with a needle.

Treatment.—The initial treatment should be aimed at relieving pain, shock and blood loss. Aspirations of blood for therapeutic purposes is only indicated in the early stages if respiration is embarrassed. If signs of persistent bleeding are present, thoracotomy is advised. In all other cases the aim should be to remove the blood by aspiration as early and as completely as possible. Aspirations can be safely started twenty-four hours after the onset and should be repeated daily until no more fluid is obtained and the X-rays appear clear. Air replacement should be avoided. Early and vigorous breathing exercises are advised.

A clotted hæmothorax is diagnosed when the aspirating needle fails to remove a collection of blood. Liquefaction of the clot is often possible with streptokinase or Trypsin ferments (Trypur). An initial dose of 200,000 units of streptokinase or 1 ml. of Trypur is injected into the clot and aspirations performed after twenty-four hours. Further doses can be given if the initial injection is not effective. In many instances however, the result is unsatisfactory, and thoracotomy with evacuation of clot and decortication of the lung is required.

An infected hæmothorax should be treated initially with repeated aspirations and the instillation of suitable antibiotics. Early drainage or decortication will probably be required, owing to the difficulty of sterilising and aspirating the hæmothorax if clotting has occurred.

Pleural Effusion.—The pleural cavity is constantly bathed in fluid which exudes from the visceral pleura and is absorbed by the parietal pleura. Any disturbance of the finely adjusted balance may result in the accumulation of

fluid in the pleural cavity. Disturbances in osmotic or hydrostatic pressures produce a transudate (protein less than 3 g/100 ml.); inflammatory lesions produce an exudate (protein more than 3 g/100 ml.) and neoplasms produce variable changes and the fluid is often blood stained.

Pleural fluid when first formed gravitates to the most dependent part of the chest (usually posterior costo-phrenic angle), but later adhesions may lead to loculation.

Pleural fluid produces stony dullness with absent breath sounds and vocal fremitus with displacement of the mediastinum to the opposite side. Diagnosis can only be confirmed with the aspirating needle.

In all cases the ætiology must be determined by (*a*) bacteriological, biochemical and cytological analysis of fluid, (*b*) needle biopsy of pleura (Abrams), (fig. 765), (*c*) thoracoscopic examination and biopsy of pleura, or (*d*) open thoracotomy.

In addition to these local measures a careful assessment of the lung and the

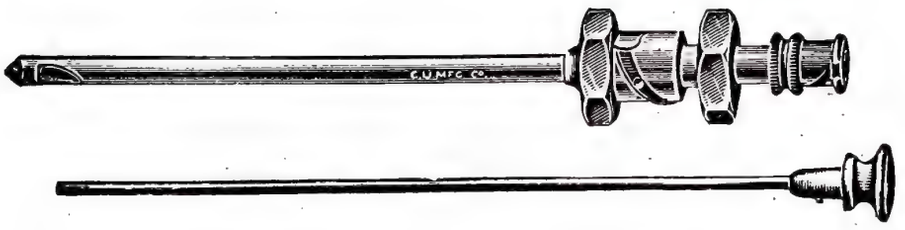

FIG. 765.—Abrams' Pleural Biopsy Punch.

heart is required and a search should be made for distant neoplasms (ovarian carcinoma, ovarian fibroma—Meigs' syndrome).

Chylothorax.—Chyle may leak into the pleural cavity from the thoracic duct or its tributaries as a result of trauma (stab wounds, crush injuries, surgical injury) or obstruction by tumour. It is commonly mistaken for pus.

Chyle contains fat and the diagnosis depends on its demonstration by naked eye or microscope. Confirmation is obtained by giving 100 g of butter mixed with 1 g of confectioner's green dye (D and C green No. 6) by mouth. The effusion is aspirated twelve to twenty-four hours later when a chylous effusion will be uniformly green.

Pseudochylous effusions have a milky appearance not due to fat (cholesterol and calcium phosphate crystals, filarial parasites).

Chyliform effusions contain fat, but this has been derived from the breakdown of cells in encysted effusions. The dye test will be negative.

Management will depend on the cause. The majority of surgically produced chylous effusions and some traumatic ones resolve with conservative measures (low fat diet and chest aspiration). If accumulation continues after a trial period of two weeks, thoracotomy is indicated to locate and suture or ligate the severed duct.

Empyema.—An empyema is a pleural abscess and consists of a collection of pus in the pleural cavity. The term is often wrongly used in a much wider sense to include all phases of pleural infection from an infected turbid effusion to a mature abscess containing thick pus. In the management of an empy-

Leon David Abrams, Contemporary. Thoracic Surgeon, United Birmingham Hospitals, England.
Joe Vincent Meigs, 1892–1963. Emeritus Professor of Clinical Gynæcology, Harvard University, Boston, U.S.A.

ema, it is just as important to consider the degree of localisation and pus formation as it is in other forms of septic cellulitis.

Ætiology.—An empyema is never primary. The majority are secondary to pulmonary infection, particularly pneumococcal pneumonia and bronchopneumonia, but any infective process, such as tuberculosis, lung abscess and bronchiectasis may be complicated by an empyema. Any inflammatory condition in the vicinity of the pleura may give rise to an empyema, namely:

(*a*) Chest wall (wounds, osteomyelitis of rib).
(*b*) Lung (pneumonia, abscess, bronchiectasis, tuberculosis, newgrowth).
(*c*) Post-operatively (thoracotomy).
(*d*) From the œsophagus (perforations, carcinoma).
(*e*) From below the diaphragm (subphrenic abscess).

Pathology.—In the common post-pneumonic empyema actual pleural infection is preceded by the development of a serous effusion. The pleura is subsequently invaded by organisms from the lung with associated inflammatory changes and further exudation of fluid. Fibrin is deposited on the surfaces of the pleura, whilst intrapleural clotting is common in certain types which form a protein-rich exudate (pneumococcal empyema). The natural defences of the body are aimed at encircling the septic area by a barrier of fibrous tissue: this is initially achieved by the fusion of the lung to the chest wall at the periphery of the collection of fluid. Subsequently the fibrin deposits on the pleura are invaded by blood-vessels from the adjacent lung or chest wall with the formation of granulation tissue, and later of fibrous tissue. This process is progressive with an ever-increasing thickness of the wall of the empyema. Left to her own devices, nature will try to obliterate the empyema by converting it into a plaque of fibrous tissue. As the empyema becomes walled off by adhesions, the fluid thickens so that the presence of thick pus is a good indication that the empyema is localised and is unlikely to spread further. A mature empyema consists of visceral and parietal layers of fibrous tissue on the lung- and chest-wall surfaces respectively, with pus and debris between them. There is usually a good plane of cleavage between the wall of the empyema and the visceral pleura which is important in the operation of decortication. Secondary changes in the surrounding structures appear as the fibrous tissue contracts. The ribs are drawn together and lose their mobility. The diaphragm is elevated and fixed, and the mediastinum drawn towards the affected side. The lung is encased in a rigid covering of fibrous tissue and is immobile and functionless. The final picture of a neglected chronic empyema is a rigid contracted chest with relatively functionless lung underneath (frozen chest).

Clinical Features.—Empyemas, for convenience, can be divided into three groups: (1) Acute. (2) Subacute. (3) Chronic.

There are many potential causative organisms but many empyemas are sterile on the first aspiration owing to previous chemotherapy. The most frequently isolated organisms are therefore those resistant to the commoner antibiotics (*E. Coli, Ps. pyocyaneus*, resistant staphylococci).

Acute Empyema.—The acute fulminating toxic empyema is now rare except when it follows perforation of the œsophagus or rupture of a lung abscess. There is profound toxæmia and shock with pleural pain and rapid, shallow respiration. The signs are those of pleural fluid, which should be confirmed by needle exploration. Early thoracotomy is required if the condition follows rupture or perforation of the œsophagus. Other cases should be treated by repeated aspirations with systemic and intrapleural antibiotics in an attempt to control the infection. If these measures fail to control the toxæmia, drainage should be carried out with an intercostal catheter inserted through a cannula and connected to an under-water seal, even though the pus is thin and the empyema not walled off. Subsequent management will be that of the subacute empyema.

Subacute Empyema.—The majority of empyemas present in a less severe form largely owing to the general use and efficiency of the antibiotics administered for the primary condition. As a result, an empyema may develop insidiously and its presence be completely overlooked. It should always be considered in cases of delayed resolution, slow convalescence or persistent fever following a pneumonic illness. Likewise, it should be suspected where the physical or radiological signs of resolution are inconclusive. Clinical signs are those of fluid with stony dullness, absent breath-sounds, diminished chest movements, and displacement of viscera.

Chronic Empyema.—Many chronic empyemas are the result of mismanagement of the acute or subacute stages, some are due to failure to diagnose the original condition, and the remainder to some underlying pathology in the lung (bronchiectasis, lung abscess, tumour), pleura (foreign bodies, actinomycosis), or chest wall (rib sequestrum). Toxic absorption from the empyema is slight but symptoms of vague ill-health, febrile bouts, anæmia etc., may occur. A chronic empyema may present in one of several ways, namely :

(1) A closed collection of pus completely walled off from its surroundings (localised empyema).

(2) An empyema which is discharging either continuously or intermittently into a bronchus (bronchopleural fistula).

(3) An empyema which is discharging either continuously or intermittently through a sinus in the chest wall.

Diagnosis.—An empyema is diagnosed by finding pus with an exploring needle. Failure to find pus may be due to :

(1) Use of too narrow a needle or the employment of an inefficient syringe

(2) Selection of the wrong site for aspiration.

(3) The presence of clot or fibrin tags which block the aspirating needle.

The commonest cause of failure is selection of the wrong site, but this should be avoided by a careful clinical and radiological examination beforehand. If pus is found, it is an advantage to keep two specimens—one for bacteriological studies, and the other for comparison with subsequent specimens.

Iodised oil can be injected into the empyema so that in subsequent radiographs the lowest limits of the space will be outlined (fig. 766).

Having confirmed the diagnosis, it is important to determine the underlying cause; if the empyema is secondary to a carcinoma, lung abscess or a subphrenic abscess, etc., the primary lesion requires appropriate treatment.

Management.—The principles of management of an empyema are basically the same for all varieties though the emphasis tends to vary in the different types. Following diagnosis and the determination of the cause, management resolves itself into controlling infection and eliminating the dead space. Every case requires vigorous breathing exercises if residual deformity and limitation of movement are to be minimised or possibly avoided.

Control of Infection.—Initially all empyemas should be treated by aspirations repeated on alternate days, with the removal of as much pus as possible

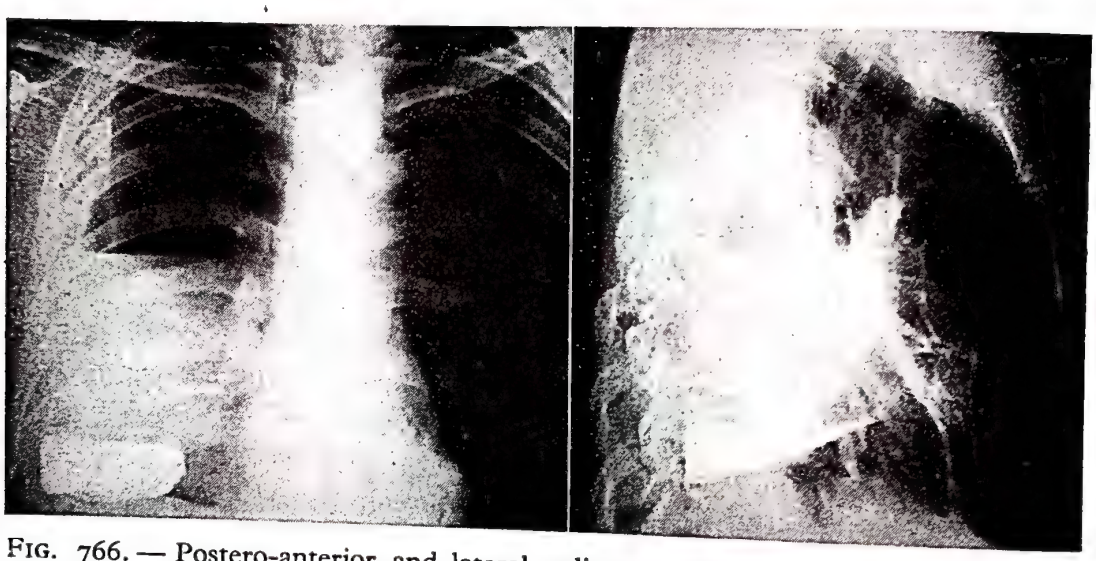

FIG. 766. — Postero-anterior and lateral radiograph of an empyema after injection of iodised oil to delineate the lower limits of the space prior to drainage.

and the introduction of antibiotics. Sterilisation is usual within seven to ten days. Only occasionally do aspirations fail to control infection, in which case drainage should be carried out.

Elimination of Dead Space.—(*a*) *Aspirations.*—Repeated aspirations without replacement of air will often result in full expansion of the lung and cure of the empyema. This is often the case with children and is more likely after the use of streptokinase. Aspirations should be continued until fluid is no longer obtained and the X-rays show no residual opacity.

(*b*) *Drainage.*—Simple tube drainage after rib resection is indicated when aspirations fail to produce expansion of the lung.

The operation is carried out under local anæsthesia. The site selected for drainage lies immediately above the lowest limit of the empyema posteriorly. The lower posterior site is preferred because this is the most dependent part of the empyema with the patient sitting up in bed. A vertical incision is made over the selected rib and the muscles divided in the line of incision. The periosteum of a 7·5cm. segment of rib is elevated and the segment removed. The intercostal bundle should be securely ligated. The empyema is entered through the posterior periosteal bed and the hole enlarged to permit complete evacuation of the empyema and a thorough

inspection and biopsy of the pleura. Drainage should at first be closed, using an under-water seal, but when the discharge is reduced to 60 ml. daily open drainage should be instituted. Drainage must be maintained until the empyema cavity is completely obliterated, which may take as long as six to eight weeks. Premature removal of the tube is a frequent cause of chronicity. Control is effected by carrying out serial pleurograms with radio-opaque oil injected into the empyema cavity at intervals of three weeks. The tube should project 2·5 to 5 cm. into the empyema cavity and will require little alteration until the final stages, when it should be adjusted to keep it 4 cm. shorter than the empyema track.

(*c*) *Decortication* (Excision of Empyema).—This operation, as an alternative to drainage, has become popular since the last war, when experience showed that satisfactory results could be obtained. The operation aims at a complete removal of the empyema with its fibrous-tissue walls, leaving the lung and chest wall free to expand. It gives excellent functional results with minimal pleural thickening. Convalescence is rapid without the necessity for repeated dressings, and return to work is possible within a few weeks. The operation is, however, a major one requiring skilled anæsthesia and blood transfusion. It is indicated particularly for large and chronic empyemas, and for those secondary to bronchiectasis, lung abscess, or carcinoma where the underlying lung condition can be dealt with at the same time. It is contraindicated in the frail and elderly, or where complete resolution of a pneumonic process has not yet occurred.

(*d*) *Operations on the chest wall*, such as a thoracoplasty, the deroofing procedure of Schede, Roberts' flap operation, and the use of muscle grafts have been almost entirely replaced by the operation of decortication.

Tuberculous Empyema.—May be either a simple tuberculous infection or one complicated by secondary infection or a bronchopleural fistula. The majority are complications of an artificial pneumothorax or surgical treatment. They are much less common than they were, partly due to the widespread use of antituberculous drugs, but also to the decreased popularity of artificial pneumothorax. *Treatment* is basically the same as for any empyema, namely control of infection and obliteration of the pleural space, but is complicated by the presence or not of active tuberculosis of the lung or a bronchopleural fistula. Control of infection is often possible with regular aspirations and the use of systemic and intrapleural streptomycin, P.A.S., or I.N.A.H. The method adopted to obliterate the empyema depends on the condition of the underlying lung. If active pulmonary disease is present, either a thoracoplasty or a pleuropneumonectomy will be required. If the lung disease is controlled and inactive, obliteration may be possible by repeated aspirations over a prolonged period, or alternatively, by excision of the empyema. The operations of decortication and pleuropneumonectomy have dramatically altered the outlook in these cases.

Interlobar Empyema.—An interlobar empyema is a rarity, but one which is wrongly diagnosed with remarkable frequency. It can only occur when the interlobar space is completely shut off from the general pleural cavity. Occasionally a collection of pus remains localised in the fissure in cases of generalised pleural infection when the main collection has been adequately dealt with by aspiration. The diagnosis is largely a radiological one. The collection of fluid is oval or fusiform in shape with the long axis lying in the plane of one of the fissures. The appearances are easily confused with those of segmental atelectasis; if suspected, pus should be sought with an aspirating needle. Treatment consists of repeated aspirations with chemotherapy, or drainage if aspirations fail.

THE TRACHEA

Tracheal Stenosis.—Tracheal narrowing can be caused by extraluminal compression (carcinoma of thyroid, aortic aneurysms, aberrant aortic arch,

Max Schede, 1844–1902. Professor of Surgery, Bonn, Germany.
James Ernest Helme Roberts, 1881–1948. Surgeon, St. Bartholomew's Hospital, London.

enlarged lymph nodes, etc.) or by fibrous strictures of the tracheal wall (tuberculous, post-tracheostomy) or by intratracheal tumours or foreign bodies.

The commonest type, at the present time, is stenosis following tracheostomy (p. 680). The stenosis most commonly occurs at the site of the inflatable cuff of a tracheostomy tube. It results from an ischæmic necrosis from an over-inflated cuff. It can be prevented by meticulous attention to tracheostomy drill and frequent deflation of the tracheostomy cuff. Less frequently, obstruction can occur at the level of the stoma and is usually the result of an ill-executed tracheostomy.

Resection of Trachea.—Two to three centimetres of the trachea or 5 cartilagenous rings can be resected and an end to end anastomosis carried out. The trachea is fully mobilised from the larynx to the carina to obtain relaxation. Lesions in the upper half of the trachea can be approached by a cervical collar incision but lower strictures may require a sternal splitting incision. The stricture or neoplasm is excised and an end to end anastomosis carried out with interrupted everting mattress sutures. The patient should be nursed during the first week with the head fully flexed to avoid tension on the anastomosis. Replacement of a whole segment of the trachea by artificial prosthesis has not been entirely satisfactory. Best results have followed the use of pericardium reinforced with tantalum gauze or marlex mesh.

DISEASES OF THE BRONCHI

Intrabronchial Foreign Bodies

Inhalation of foreign bodies is not a rare occurrence, particularly in children. In many instances the individual assumes that the foreign body has been expelled as the initial choking may soon pass. The commonest foreign bodies are teeth, mutton and rabbit bones, peanuts, pins, screws and nuts. The changes produced depend upon the size and nature of the foreign body. Small, smooth metallic foreign bodies produce little reaction, whilst larger foreign bodies may lead to partial or complete obstruction of one of the bronchi. Organic foreign bodies, particularly peanuts, produce marked inflammatory changes in the bronchial wall.

The clinical features may be :

(1) Wheezing, irritating cough and signs of unilateral obstructive emphysema (figs. 767 and 768).

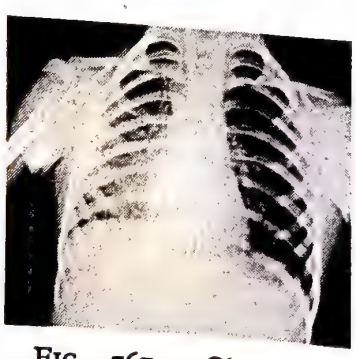

FIG. 767. — Obstructive emphysema of the left lung due to an inhaled peanut.

FIG. 768.—Peanut removed bronchoscopically from case illustrated in fig. 767.

(2) Symptoms due to atelectasis or pulmonary suppuration; cough, sputum, fever, etc.

(3) The patient may be symptomless.

Radiography is an essential investigation in every suspected case. If the foreign body is radio-opaque, it should be visible either in the postero-anterior or lateral film. In many instances the foreign body is either not opaque or is obscured by the heart shadow or secondary inflammatory changes.

Treatment.—Bronchoscopy must be performed in all suspected cases. Removal is easier before secondary swelling and inflammation of the bronchial wall have occurred. Many can be removed without special equipment. Prolonged attempts at removal should not be made owing to the risks of œdema of the glottis or of damaging the bronchial tree further. Operative removal is preferable in such cases. Antibiotics should be given beforehand to minimise the inflammatory reaction. Removal is often possible by bronchotomy, but if suppurative changes have already occurred in the lung resection will be necessary.

Bronchiectasis

The term bronchiectasis strictly describes any abnormally dilated bronchus. Bronchial dilatation may follow many inflammatory conditions of the lung, especially those associated with obstruction of the bronchus. These changes, which are often patchy and affect only small peripheral bronchi may follow pulmonary tuberculosis, a lung abscess or pulmonary suppuration. Only rarely do they give rise to symptoms. Clinical 'bronchiectasis', however, is usually applied to the variety where involvement of the bronchi is more extensive and usually follows an anatomical pattern, e.g. a segment, a lobe or a lung. It is infection in these abnormally dilated bronchi which produces cough, sputum and hæmoptyses; these together form the pattern of the clinical condition of bronchiectasis.

Ætiology.—Many cases are considered to be congenital in origin, though there is no good evidence to support such a thesis. The majority are the result of compression of the small soft bronchi in children by enlargement of the hilar lymph nodes associated with whooping-cough, measles or primary tuberculosis; the obstruction is often made complete by viscid intrabronchial secretions. Bronchial obstruction produces atelectasis. (The majority of cases of pneumonia complicating whooping-cough are really atelectases.) The subsequent course depends on whether or not secondary suppurative changes occur in the atelectatic lobe. If no infection occurs and the obstruction is relieved, the lobe may expand and return to normal. If suppuration occurs, the bronchial walls are severely damaged and distended by purulent secretions. They lose their elasticity and mobility, and when obstruction is eventually relieved they remain as inert, dilated tubes.

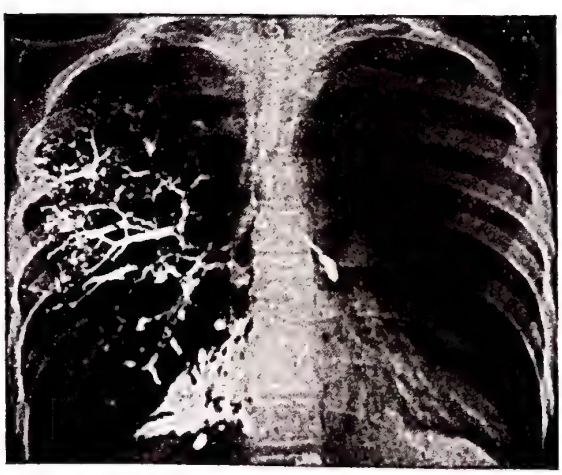

FIG. 769.—Bronchogram showing bronchiectasis and atelectasis of right middle and lower lobes.

Pathology.—The bronchi appear thickened and irregular, whilst histologically there is marked destruction of all the normal elements and extensive infiltration of the remnants with inflammatory cells. The columnar epithelium is replaced by granulation tissue or by squamous or cuboidal epithelium. The lung supplied by the affected bronchi may be fibrotic and airless with loss of the alveolar pattern and infiltrated with inflammatory cells (bronchiectasis with an atelectatic lobe) (fig. 769). In other cases the abnormal bronchi are surrounded by aerated lung tissue but the latter is usually emphysematous and relatively functionless.

Clinical Features.—The majority of cases date their symptoms from an attack of whooping-cough, measles or pneumonia in childhood. The symptoms may persist from that time or the attack may be followed by a latent period of some duration. They may subsequently be intermittent and are often regarded as attacks of bronchitis. Frequently, especially in severe cases, they are persistent throughout the year, but with exacerbations from time to time. Characteristically, the patients have a loose cough productive of purulent sputum; the latter may be offensive and is often blood-stained, whilst frank hæmoptyses are not infrequent. Acute exacerbations with fever and increase of cough and sputum are frequent during the winter months. In children, both physical and mental retardation may occur. Finger clubbing is frequent and persistent râles and rhonchi are audible over the affected areas. Dullness and bronchial breathing with mediastinal shift occurs with an atelectatic lobe.

Diagnosis.—The diagnosis is usually possible on clinical grounds from a prolonged history of cough and sputum associated with finger clubbing and physical signs over a localised area of the lung. Bronchography is essential, not only to demonstrate the presence of bronchiectasis but also to determine its extent (fig. 769). Bronchoscopy is advisable in order to exclude the presence of a foreign body or tumour.

Treatment.—(*a*) *Prophylactic Treatment.*—Much can be done to prevent the development of bronchiectasis by treating the respiratory complication of measles and whooping cough with antibiotics and breathing exercises, and carrying out bronchoscopy at an early date should atelectasis occur.

(*b*) *Conservative Treatment.*—Considerable reduction of infection can be achieved by postural drainage, physiotherapy and chemotherapy. Such medical treatment, however, cannot cure the condition as the essential abnormality still remains. Relapse is frequent even though treatment is maintained for long periods. Postural drainage is carried out in a position designed to place the affected lobe above the draining bronchi so that pus will gravitate from the lobe into the bronchus from whence it can be expectorated. Periods of half to one hour two or three times daily are advisable. Chemotherapy is reserved for acute attacks or as a preparation for surgery.

(*c*) *Surgical Treatment.*—Extirpation of the diseased area is the only available method of curing the condition, but is not applicable to every case. It is essential in all cases to carry out complete bronchograms on both sides. Resection is only practicable if less than half of the total lung tissue is in-

volved. Ideally, all abnormal areas should be removed (radical treatment) but in certain circumstances it is justifiable to remove a grossly diseased lobe and leave behind less severely damaged tissue (palliative resection). Children will tolerate the removal of more lung tissue than adults, and bilateral resections are rarely advisable after the age of thirty-five years. Removal should be as conservative as possible, particularly in the more extensive cases. Prior to operation, the patient should have intensive treatment with postural drainage and chemotherapy in order to reduce sputum to a minimum, whilst after operation, rapid and complete expansion of the remaining lung is encouraged by breathing exercises, posture and suction drainage to reduce the risks of empyema and bronchopleural fistulæ. The results of surgical treatment are best in cases with limited bronchiectasis in an atelectatic lobe. Disappointing results are encountered in patients with generalised bronchitis or asthma in addition to bronchiectasis.

Lobectomy.—The operation is carried out through a postero-lateral thoracotomy The passage of pus from the bronchiectatic lobe into normal lung is prevented by intrabronchial balloons or by posture (face down position). The hilum is approached either from its posterior or interlobar aspect. The relevant bronchus, artery and vein are isolated by blunt dissection using long curved artery forceps. The bronchus is divided between clamps and the vessels are securely ligated. The bronchus is closed by interrupted sutures of silk, thread, nylon or steel wire. The lobe is then freed from its attachments to the parieties and mediastinum. Apical and basal pleural drainage tubes are inserted for the removal of air and blood respectively and to ensure the rapid and full expansion of the remaining lung.

TUMOURS OF THE LUNG AND BRONCHI

With one or two rare exceptions, all pulmonary tumours arise from some part of the bronchial tree.[1]

Classification

Benign.—Adrenoma.
Hamartoma (fibroma, chondroma, lipoma, angioma)

Malignant

Primary.—Carcinoma (common).[2]
Alveolar-cell carcinoma (rare).
Sarcoma (rare).

Secondary.—Sarcoma.
Teratoma of testis.
Carcinoma (bowel, breast, thyroid, kidney).

Symptomatology.—The symptoms produced by a tumour may be due to:

(1) The presence of an irritating lesion in the bronchial tree producing cough, sputum, wheezing and hæmoptysis.

(2) The occurrence of partial or complete bronchial obstruction giving rise to obstructive emphysema or atelectasis respectively.

(3) Secondary inflammatory changes in the lung producing consolidation, suppuration or abscess formation.

(4) Symptoms due specifically to the presence of a primary tumour or of its secondary deposits—malaise, anorexia and loss of weight.

---

[1] Mesothelioma is another type of tumour but it originates from the pleural membrane. It is believed to occur more commonly in those who work with blue asbestos fibre.

[2] Kenneth Robinson, former Minister of Health, stated that over the period 1950–1965 deaths from lung cancer had increased by 73 per cent.

(5) Pressure on the œsophagus (dysphagia), trachea (stridor), recurrent laryngeal nerve (hoarseness) or superior vena cava.

(6) Systemic disturbances due possibly to active secretion by the tumour cells—(carcinoid syndrome,[1] Cushing's syndrome, osteo-arthropathy, neuropathy).

Benign Tumours

Representing about 2 per cent. of all pulmonary tumours, they are slightly commoner in women and more frequent in the younger individual.

Pathology.—The tumours fall into two main anatomical groups, those arising from the larger bronchi and those situated in the periphery of the lung. The former are usually visible through the bronchoscope. The intra-bronchial portion of the tumour, however, may only represent a portion of the whole as there is often a large extra-bronchial portion (iceberg tumour). Peripheral tumours are not visible through a bronchoscope. Three main varieties are found; carcinoid adenoma, the commonest and most frequently found in the lobar or segmental bronchi; the cylindromatous adenoma (adenoid cystic carcinoma) is the least common and is largely confined to the trachea and main bronchi where it is slowly invasive. The hamartoma most frequently occurs in the lung but is occasionally found in a large bronchus. Histologically the cells of the carcinoid tumour are regular, well formed and consistent in appearance anp tend to be arranged in solid acini. Mitoses are infrequent. In the cylindroma the cells are similar but arranged in columns or cylinders. The hamartoma is a composite tumour composed of two or more tissue elements. They represent an abnormal mixing or development of the normal components of the organ in which they occur. Thus, in the lung, cartilage, fat, glandular or vascular tissue and respiratory epithelium may be found. The hamartomas are usually described according to the preponderant tissue, e.g. chondromatous, hæmangiomatous hamartoma, etc. (p. 53).

Clinical Features.—(1) Many are symptomless and found on routine radiography; this particularly applies to the peripheral types.

(2) Recurrent hæmoptysis. The adenoma is one of the causes of repeated large hæmoptyses occurring over a period of years. There is frequently complete freedom from symptoms between attacks, though occasionally wheeziness and an irritating cough are present.

FIG. 770.—Adenoma of bronchus (arrow) producing secondary bronchiectasis of the left lower lobe.

(3) Symptoms due to bronchial obstruction and lung infection. Simple uninfected atelectasis or pulmonary suppuration with abscess formation and bronchiectasis both occur commonly (fig. 770). In some cases of a lung abscess or an empyema, the underlying adenoma is completely unsuspected until bronchoscopy is performed.

Diagnosis.—The diagnosis is often suggested by the history, but can only be confirmed by bronchoscopy. The adenoma appears as a round, smooth or slightly lobulated raspberry-like tumour which is neither ulcerated nor necrotic. Tumours containing cartilage appear pale and hard and biopsy may be difficult. Bronchography is necessary to determine the presence and extent of any secondary lung changes which will influence subsequent treatment.

Treatment.—Surgical resection is the treatment of choice. This can be planned

[1] Carcinoid tumours of bronchus are second in frequency only to those of the appendix; only a small minority produce systemic disturbances.

Harvey Cushing, 1869–1939. Professor of Surgery, Harvard University, Boston, U.S.A. (1912–1932) (See footnote p. 71.)

conservatively as the risk of recurrence is negligible. Treatment by radon implantation, curettage or irradiation is ineffective and cannot be recommended. One or other of the following methods may be applicable to the individual case:

(1) *Bronchoscopic Removal.*—This is only practicable for the rare, strictly intra-bronchial and pedunculated tumours. Bronchoscopy is advisable at regular intervals after removal in order to detect a recurrence.

(2) *Bronchotomy.*—Local removal of the tumour with part of the bronchial wall is practicable for tumours of localised extent without extra-bronchial extension and without secondary lung damage.

(3) *Lung Resection.*—A conservative resection, either segmental, lobar, or total, is required in those cases associated with permanent lung damage. The extent of the resection is determined by the bronchographic findings.

Carcinoma of the Bronchus

Ætiology.—Carcinoma of the bronchus has shown a fifteen-fold increase during the last thirty years. It is ten times more common in men than women, and most frequently occurs during the fifth and sixth decades, but is not unknown in children and young adults. Statistical surveys show that heavy cigarette smoking over many years predisposes to the development of lung cancer. The exposure to other irritants, such as arsenic and radio-active substances (Schneeberg[1] cancer), exhaust fumes, sulphurous smoke and fog, and tarry particles from the roads may possibly be implicated. Workers in the chromate industry have a high incidence of lung cancer.

Pathology.—Three main macroscopic types are described:

(1) *Main Bronchus Tumours.*—These arise in the main bronchus or one of its primary or secondary divisions. They produce bronchial irritation and ulceration at an early stage and frequently give rise to bronchial obstruction. They are usually visible through the bronchoscope (fig. 771).

FIG. 771.—Carcinoma of the left upper lobe bronchus. The upper lobe is atelectatic and its bronchi are dilated and filled with mucopus. The lower lobe is normal.

(2) *Peripheral Tumours.*—These arise from the smaller bronchi and may only be visible with the fibreoptic bronchoscope. They rarely produce secondary lung changes. Some are discovered at routine radiography (figs. 772 and 773).

(3) *Pancoast 'Tumours'.*—These are essentially peripheral lung carcinomas arising at the apex of the lung. The tumour extends early along pre-existing apical adhesions to invade the brachial plexus, sympathetic chain, upper ribs and adjacent vertebræ producing the Pancoast syndrome (lower brachial plexus lesion, Horner's syndrome, an apical shadow, and rib erosion). The lesion is particularly distressing owing to the early production of intractable pain which is difficult to relieve, combined with a relatively slow growth.

Histology.—Three main histological types are recognised. (1) Squamous-cell carcinoma = 50 per cent. (2) Anaplastic, oat-cell or round-cell carcinoma = 25 per cent. (3) Adenocarcinoma or columnar-cell carcinoma = 20 per cent. The anaplastic carcinomas are poorly differentiated tumours exhibiting rapid growth with early metastases. They are more common in young individuals.

---

[1] The name of a district in Germany where these substances are mined.

Henry Khumrath Pancoast, 1875–1939. Professor of Rontgenology, University of Pennsylvania, Philadelphia, U.S.A. Johann Horner, 1831–1883. Professor of Ophthalmology, Zürich, described his syndrome in 1869.

Metastases.—(1) Direct extension into the mediastinum, the pleura, the chest wall or the pericardium

(2) The lymphatic system to the hilar lymph nodes and thence to the subcarinal nodes or the paratracheal chain. The upper nodes of the chain are continuous with the inferior deep cervical group and may be detected by digital palpation deep to the insertion of the sternomastoid muscle, or by scalene node biopsy.

(3) The blood-stream to the liver, brain, and bone (ribs, vertebræ, pelvis particularly). Other tissues and organs may be involved.

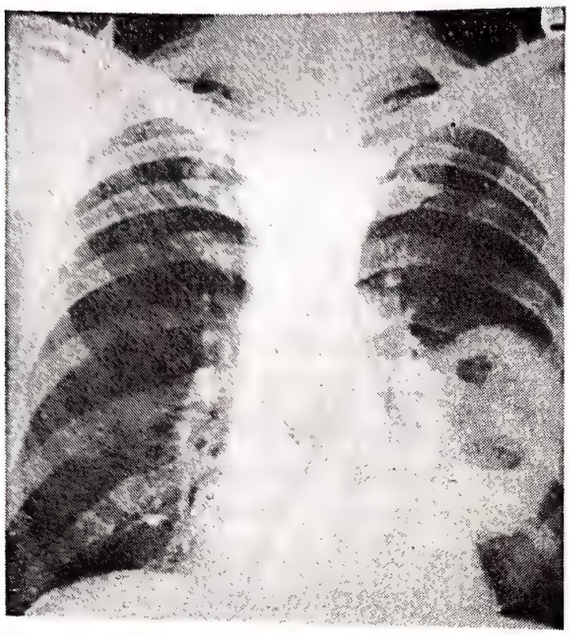

FIG. 772.—Peripheral carcinoma of the lung showing thick-walled irregular cavity.

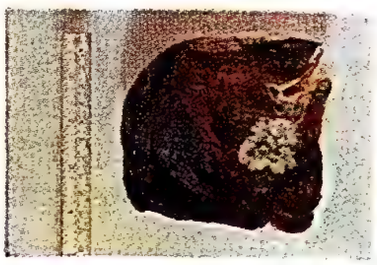

FIG. 773.—Peripheral type of lung carcinoma, showing typical lobulated outline and absence of secondary changes in the lung.

Clinical Features.—Symptoms produced by a carcinoma of the bronchus are many, but the most important are cough, sputum, hæmoptysis, dyspnœa, pain and wheezing. It is important to recognise the early manifestations as it is at this stage that treatment is likely to be most effective. Any of the above symptoms appearing for the first time in a middle-aged individual and tending to become more severe with time, demand early investigation. Only some 10 per cent. of cases present initially with an hæmoptysis; more frequently, the first symptoms may occur suddenly with an influenzal-like illness which fails to resolve satisfactorily. A number start insidiously with cough and dyspnœa, whilst in the case of the chronic bronchitic there may be an alteration in the typical pattern of his symptoms. Occasionally, first symptoms are due to the presence of secondary deposits (especially in the brain) or invasion of the mediastinum. A diagnosis of unresolved or virus pneumonia should always be made with reservations, and if recovery is not complete, carcinoma should be suspected. Finger clubbing is a frequent and important sign. A small group present with neurological (carcinomatous neuropathy) or arthritic (osteo-arthropathy) symptoms without chest symptoms. The true nature of the condition is revealed by chest X-ray.

Investigations.—The suspicion of a lung cancer demands a thorough investigation. *A chest X-ray* is the most important single investigation and it is usual for some abnormality to be revealed. The appearances vary from that of a hilar or peripheral shadow due to the presence of the tumour to

those of obstructive emphysema, atelectasis or consolidation due to secondary lung changes.

Bronchoscopy.—This is not only an essential diagnostic procedure but produces important information regarding operability. The examination will reveal the presence of the tumour in those lesions which are centrally placed and enable a biopsy to be made and the histology determined. Paralysis of a vocal cord, compression of the trachea, widening of the main carina, and involvement of the main bronchus within 1·5 cm. of the carina are regarded as evidence of inoperability. It should be emphasised that bronchoscopy may not reveal the presence of some tumours, particularly those arising in the segmental divisions of the upper lobes, or the peripherally placed tumours.

Cytological examination of sputum will reveal malignant cells in about 40 per cent. of cases.

Barium Swallow.—This may provide evidence of extension of the growth into the mediastinum or the enlargement of mediastinal lymph nodes. If œsophageal distortion is considerable, adequate removal is improbable.

Tomography is useful in demonstrating enlarged mediastinal nodes.

Liver, brain and bone scanning is indicated if involvement of these organs is suspected.

Bronchography.—This may provide valuable information in cases of doubtful diagnosis but has little place in the investigations of the proven case.

Scalene Node Biopsy and Mediastinoscopy.—This is a routine practice in some clinics. Nodes from the paratracheal and inferior deep cervical groups may be obtained by these means. If invaded radical surgery is contra-indicated.

Diagnosis.—A positive histological diagnosis is available in about 60 per cent. of cases, whilst malignant cells in the sputum or pleural fluid provide positive evidence in some of the remainder. In about one-third of cases, however, only a presumptive diagnosis can be made.

In the unproven case, a carcinoma is most likely to be confused with chronic suppurative pneumonia, a lung abscess or solid tuberculous lesions, and occasionally with a benign tumour. Careful consideration of the history and response to antibiotics will often provide strong circumstantial evidence against a carcinoma, whilst bronchography and tomography may be helpful in doubtful cases.

Treatment.—Surgical removal of the tumour offers the best prospects for cure, although in selected cases the results of radical radiotherapy are equally good.

The aim of operative treatment must be the adequate removal of the primary tumour and the regional lymph nodes, but with the preservation of as much normal lung tissue as possible.

The extent of the lung resection will thus depend on the site of the tumour. For lesions confined to one lobe *lobectomy* will suffice, but those involving the main bronchus *pneumonectomy* will be required (fig. 774). An intermediate group can be adequately treated by removing the involved lobe and a cylinder of the main bronchus—*sleeve resection*—thus preserving some

normal lung tissue. In all cases the paratracheal, subcarinal and para-aortic lymph nodes are removed. Limited resection of the chest wall, pericardium or diaphragm can be carried out should these structures be invaded.

Radical Pneumonectomy

'One lung anæsthesia' is advisable. The feasibility of lung resection should be determined with as little lung disturbance as possible. At an early

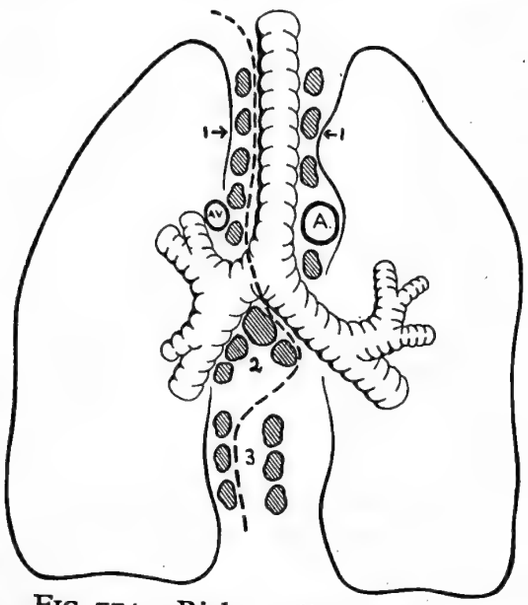

FIG. 774.—Right radical pneumonectomy. The dotted lines indicate the plane of dissection. A.V. = azygos vein. A. = aorta. 1 = paratracheal nodes. 2 = subcarinal nodes. 3 = para-aortic nodes.

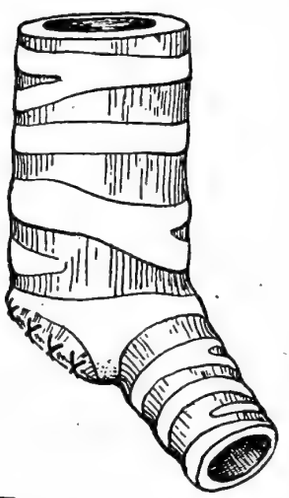

FIG. 775. — Sutured bronchus after right pneumonectomy. Note oblique division, absence of stump, and figure-eight stitches.

stage the pulmonary veins from the affected lobe should be tied to reduce the risks of tumour embolism. The remaining vessels are then isolated and divided after securing with double ligatures or a transfixed ligature. The bronchus is divided close to its origin after applying special bronchus clamps. The bronchus is closed with sutures of wire, nylon, or thread, using interrupted figure of eight stitches and occluding a rim of bronchus 3 to 4 mm. wide (figs. 774 and 775).

The paratracheal and subcarinal and para-aortic lymph nodes should be removed with surrounding tissues.

Only 20 per cent. of lung cancers are considered suitable for exploration and of these one in five is found to be too advanced for resection on exploration. The mortality of radical resection is 10 per cent. Of those surviving resection, 25 per cent. are alive in five years' time.

The following are contraindications to radical resection :

(1) A growth which involves the trachea or the first 1·5 cm. of the main bronchus.
(2) Evidence of spread into the mediastinum with involvement of the œsophagus, recurrent laryngeal or phrenic nerves, vena cava or pericardium.
(3) Extensive invasion of the chest wall (fixed chest pain).
(4) Evidence of distant metastases.
(5) Patients over the age of sixty-five unless remarkably fit.

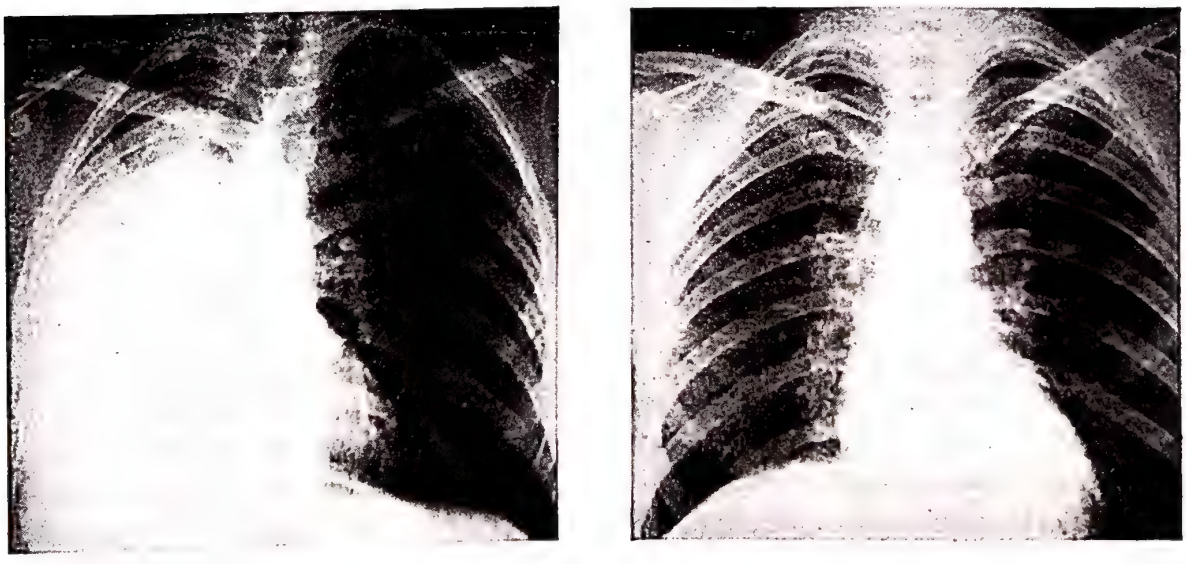
(6) Patients with poor respiratory reserve. (This can usually be assessed on clinical grounds with simple exercise tests).
(7) Patients with serious ischæmic heart disease or generalised arterial disease.
(8) Patients with chronic bronchitis with persistent signs in the normal lung who are likely to be severely crippled by dyspnœa and bronchitis after operation (respiratory cripple).

Palliative Resection.—At thoracotomy it is advisable to remove the lung with the primary tumour whenever possible even though the growth cannot be completely removed. Patients are better off without the primary tumour and die more peacefully from secondary deposits. Occasionally a deliberate palliative resection is justified in cases with repeated hæmoptyses or with much pulmonary suppuration.

Interstitial Irradiation.—This is carried out by the insertion of radioactive grains of gold ^{198}Au. It is a useful method of palliation in those tumours found to be irremoveable at thoracotomy and after palliative or incomplete resections. Gold grains can also be inserted into intrabronchial tumours through the bronchoscope.

X-ray Therapy.—Radical X-ray therapy, particularly with super-voltage machines, is employed in cases which are considered operable from the point of view of the tumour, but inoperable on other grounds. Survival rates of some years have been recorded but no extensive series is available (figs. 776 and 777). Palliative X-ray therapy is designed to relieve superior vena caval obstruction, bronchial obstruction and the pain of bone involvement. Considerable relief is obtained by such treatment, but survival is not appreciably lengthened.

Pre-operative X-ray therapy has given disappointing results largely due to an increased incidence of broncho-pleural fistulæ following resection.



FIGS. 776 and 777.—Main bronchus carcinoma, showing total atelectasis of right lung before irradiation, and aeration of the lung after treatment.

Post-operative treatment is used occasionally where small areas of growth have not been removed (e.g. on the chest wall). Only fit patients should be treated if serious debilitating reactions are to be avoided.

Chemotherapy.—The use of cytotoxic drugs alone has been disappointing. Some benefit may follow their administration combined with surgery.

Secondary Lung Tumours.—Secondary deposits in the lungs from carcinomas and sarcomas occur frequently. The deposits are usually multiple but occasionally occur singly. In the absence of other evidence of malignant disease solitary lesions should be excised. A 3 year survival of 30 per cent. is obtained overall but the results with testicular teratoma are excellent with many patients surviving for 10 or 15 years.

DISEASES OF THE LUNG

Lung Abscess

A lung abscess is a collection of pus in the lung substance. All cases are secondary to some pre-existing condition, such as foreign bodies, tumours, or bronchostenosis, or to the inhalation of infective material. There is no such condition as primary or idiopathic lung abscess, and in all cases the cause should be elucidated.

Classification.—*A. Due to specific pneumonias.*—(1) Staphylococcal, (2) Actinomycotic, (3) Friedländer's pneumonia, (4) Amœbic.

B. Due to bronchial occlusion.—(1) Carcinoma, (2) Benign tumours, (3) Intrabronchial foreign bodies, (4) Sputum plugs (post-operative atelectasis).

C. Due to vascular embolism.—(1) Infarct, (2) Pyæmic.

D. Traumatic.—(1) Infected hæmatoma of lung, (2) Foreign body in lung.

E. Aspiration (inhalation) pneumonia.—Non-specific suppurative pneumonia.

The commonest group is that due to an aspiration pneumonia. In these cases infected material, usually from the upper respiratory passages, is inhaled into the lung, where various grades of infection ensue from a relatively benign bronchopneumonia to more severe states with necrosis, suppuration and abscess formation.

The most important factors in the production of a lung abscess are:

(1) A source of infected material (dental sepsis, sinus infection, vomit, operations on the upper respiratory tract).

(2) A disturbance of the natural defence mechanisms of the body by depression of the cough reflex (with drugs, in coma, or after anæsthesia or alcohol).

(3) A disturbance of the normal mucous production and ciliary action of the bronchial mucosa (Negus).

Pathology.—Infected material is inhaled into the bronchial tree and obstructs one of the smaller bronchi. The resulting atelectatic segment is invaded by pathogenic organisms producing pneumonic consolidation. The commonest organisms are *Hæmophilus influenzæ* and Pneumococci but invasion by mouth organisms (anaerobic streptococci and spirochætes), coliform organisms and cross infection with drug-resistant staphylococci sometimes occur and may be detected by microscopy and culture of the sputum. Suppuration and necrosis develop in varying degrees within the involved segment, first with the production of a suppurative pneumonitis which later matures into an abscess. As pus accumulates, tension rises and eventually the abscess ruptures into the bronchus. This may be followed by complete expectoration of all sloughs and pus, and the inflammation may then subside. More commonly, however, a state of chronic infection with

Carl Friedländer, 1847–1887. Pathologist, Friedrichshain Hospital, Berlin. Described this bacillus, in 1882.
Sir Victor Ewings Negus, 1887–1974. Surgeon, Ear, Nose and Throat Department, King's College Hospital, London.

persistence of the abscess occurs (fig. 778). Progressive involvement of adjacent lung tissue or spread to other parts of the lung is possible.

Clinical Features.—The onset is often acute with influenza-like symptoms and variable toxæmia, but usually without any localising symptoms. After some days of ill-defined illness, pleural pain and a dry irritating cough may appear; the latter becomes worse and the patient may notice an offensive odour in his breath. About the tenth day, rupture of the abscess results in the sudden expectoration of considerable quantities of offensive blood-stained pus. With successful treatment, resolution occurs slowly with reduction of toxicity and diminution of cough and sputum, but healing takes several weeks and can only be regarded as complete when cough and sputum have disappeared and radiographs are clear. Chronicity is suggested by the persistence of cough with the expectoration of purulent sputum and the presence of a cavity on X-ray (fig. 779).

Complications.—(1) Spread of the disease to other parts of the lung by direct extension or by bronchial embolism : this is suggested by an exacerbation of symptoms and fresh radiographic changes.

(2) *Empyema.*—This may occur spontaneously or following surgical drainage but is less common following the introduction of antibiotics. Persistent fever, pleural pain, and signs of a pleural effusion call for exploration of the pleura with a needle.

FIG. 778.—Chronic lung abscess showing irregular cavity filled with inspissated pus and sloughs and surrounded by an area of chronic pneumonia.

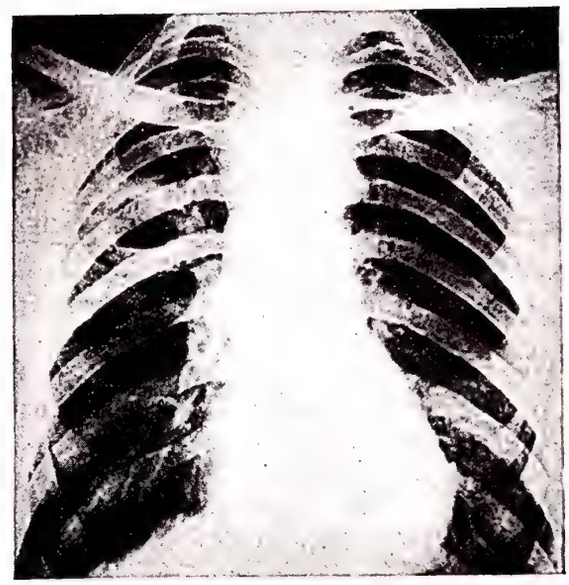


FIG. 779.—Lung abscess in the right upper lobe. There is an ill-defined area of consolidation surrounding the cavity which shows a fluid level.

(3) *Cerebral Abscess.*—Pyæmic emboli reach the brain through the paravertebra system of veins (Collis). The resulting abscesses are usually multiple but occasionally single. The onset is usually accompanied by headaches and fever. A fit is occasionally the first symptom. The incidence of cerebral abscess has fallen markedly since the introduction of antibiotics.

(4) *Secondary Hæmorrhage.*—Hæmorrhage may occur from a drained or an undrained abscess. It is often no more than blood-staining of sputum or discharge, but occasionally severe or fatal hæmorrhage occurs.

John Leigh Collis, Contemporary. Professor of Thoracic Surgery, United Birmingham Hospitals, England.

Diagnosis.—The diagnosis is suggested by a history of a sudden, acute influenza-like illness, followed later by coughing with purulent sputum and the demonstration of an area of lung consolidation, with or without cavitation. All cases must be investigated to determine the cause by:

(1) Bronchoscopy to exclude foreign bodies or neoplasm.

(2) Complete bacteriological examination of the sputum.

(3) Examination of the teeth and upper respiratory tract.

Treatment.—Eighty-five per cent. of lung abscesses resolve with conservative measures, and surgery is only required for the minority which do not respond. Medical treatment consists of:

(1) *Chemotherapy.*—Penicillin is the antibiotic of choice as it can be given in very large doses (2 to 8 million units daily) for long periods (four to six weeks) with little risk of side-effects. Other antibiotics should be used if the organisms are resistant to penicillin. The response to antibiotics is often slow and treatment must be continued for some weeks until there is no further clinical or radiological improvement.

(2) *Postural Drainage.*—This should be carried out for periods of up to one hour three or four times a day with the patient placed in such a position that the abscess lies above the appropriate draining bronchus.

(3) At the same time, percussion over the site of the abscess should be carried out to encourage drainage.

Conservative treatment is continued whilst there is clinical and radiological evidence of improvement, or until symptoms have disappeared and the X-ray is clear.

Surgical treatment is indicated in those cases where resolution does not occur with the above regime. In the majority of cases a formal resection (lobectomy) is possible. External drainage of the abscess—once the standard operation—is now only occasionally required in patients who show no response to chemotherapy and who remain too ill for resection.

Lung Cysts

These may be divided into four groups :

(1) *Epithelial Cysts.*—These are developmental in origin and may be solitary and large or multiple and small. They are lined by respiratory epithelium and may have traces of cartilage, muscle or glands in their wall.

(2) *Emphysematous Cysts.*—These include a wide variety of conditions where the normal alveolar framework is destroyed or disrupted, resulting in large air spaces which may become further distended with air.

(3) *Parasitic cysts,* of which the commonest is the hydatid.

(4) *Pseudo-cysts.*—Certain inflammatory conditions of the lung result in cavity formation, and in many instances the cavities may closely resemble epithelial cysts. The cavities, when chronic, are often lined by squamous epithelium. These pseudo-cysts may occur in association with staphylococcal pneumonia, pulmonary tuberculosis, or following a lung abscess. Their true nature is often suggested by their history, course, and radiological features, but the distinction is often difficult.

Epithelial Cysts.—These are often associated with other congenital abnormalities (cervical rib, pulmonary stenosis, patent ductus) (fig. 780). They appear as spherical shadows in the X-ray with a thin, sharply defined wall. They may contain air, fluid, or both air and fluid. Symptoms may be produced by:

(1) The size of the cyst which compresses the lung and produces dyspnœa, tightness in the chest, etc. This is particularly so in infants and children where the thorax is small and the cyst often relatively large.

(2) Infection is common with the production of fever, cough and sputum. Radiography will demonstrate a fluid level in the cyst. Infection is usually readily controlled with antibiotics, but recurrence is frequent and removal indicated.

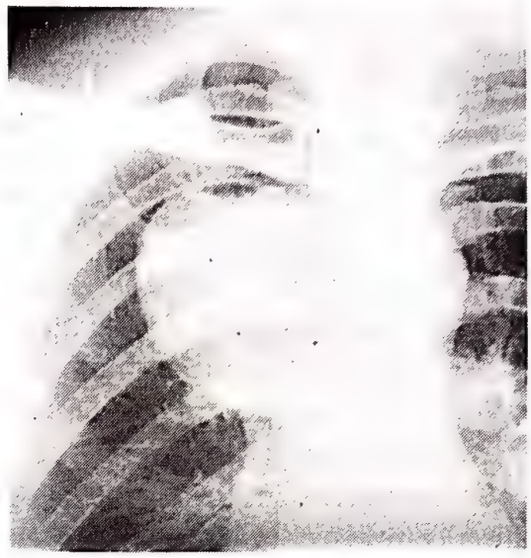

FIG. 780.—Simple congenital epithelial lung cyst containing fluid and air.

(3) Hæmorrhage from cysts is usually associated with infection.

Spontaneous pneumothorax is uncommon with epithelial cysts (cf. emphysematous cysts.)

Treatment.—Solitary cysts producing symptoms should be excised. Symptomless cysts can be kept under observation. Infection of multiple cysts should be controlled by antibiotics if excision is not practicable.

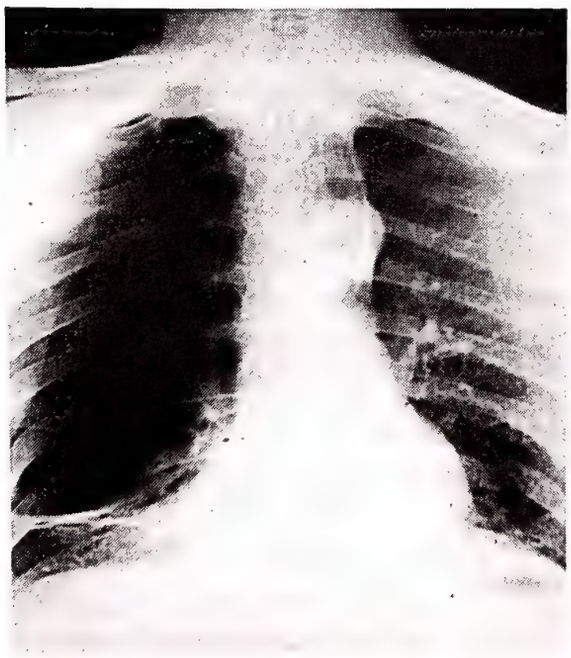

FIG. 781.—Giant emphysematous cyst of right lung.

Emphysematous Cysts. — Although many cases are acquired and due to degenerative changes in the lung, others cannot be explained on this basis. The latter may be due to a congenital deficiency of the elastic tissue of the lung, or to absence of cartilage in the walls of the bronchus. Either of these conditions may lead to abnormal distension of the lung with rupture of the alveolar walls. Progressive coalescence of alveolar spaces combined with distension with air may result in the development of an enormous cyst (figs. 781 and 782). These cysts have no epithelial lining, and when large the remnants of the more resistant bronchi and blood vessels are seen stretching across the space. The changes may be limited to a small area of the lung, such as a seg-

FIG. 782.—A giant emphysematous cyst which presented through the wound on opening the chest.

ment or a lobe, or the condition may be generalised and bilateral.

Clinical Features.—The most important symptom is dyspnœa, which is due to a combination of compression of normal lung tissue by the cyst, increase in the dead space, and a poor gaseous exchange. Emphysematous cysts are frequently associated with chronic bronchitis. In such cases persistent coughing tends to distend the cysts still further, whilst the presence of bronchial secretions impairs respiratory function still more. The presence of bronchitis is a serious complication which renders radical treatment more hazardous.

Spontaenous pneumothorax is a common and serious complication and may be the first presenting feature. Infection and hæmorrhage are unusual, (cf. epithelial cysts).

Treatment.—Emphysematous cysts which are not associated with generalised emphysematous changes should be excised, but if changes are widespread, excision is impracticable. Obliteration by plication with multiple sutures has given good results; it is applicable to multiple cysts and does not remove potentially functioning lung tissue. Removal of the pulmonary autonomic nerves can be combined with the above procedures; its chief value lies in the reduction of bronchial spasm. In cases complicated by a spontaneous pneumothorax, pleurodesis should be carried out to prevent further attacks of this serious complication.

Hydatid disease of the lung (Chap. 43) has been largely eliminated from such countries as Australia and Iceland by control of dogs and the proper slaughtering of sheep. The disease remains endemic in Asia and parts of the Middle East but is now rare elsewhere.

Pulmonary hydatid cysts occur in about 15 per cent. of all cases; the cysts are usually solitary, but multiple or bilateral cysts are not uncommon. The disease is more common in children and young adults.

The cases may present in any of the following ways:

(1) On routine clinical or radiological examination and without symptoms.

(2) Dyspnœa, pain or tightness in chest due to the presence of a large cyst.

(3) Hæmoptysis due to ulceration into the bronchus.

(4) Expectoration of watery fluid and ' grape skins ' due to rupture into the bronchial tree. This event may produce severe distress with suffocating symptoms or even death if the leak is a large one. Anaphylactic shock and urticaria may occur.

(5) Symptoms due to secondary infection of the cyst, viz, cough, purulent sputum and fever.

Radiology is the most helpful investigation:

(1) An uncomplicated cyst appears as an almost spherical, sharply defined dense homogeneous opacity.

(2) Communication with the bronchial tree may result in a crescentic cap of air overlying the cyst (perivesicular pneumo-cyst).

(3) Rupture of the cyst permits air to enter the cyst and the laminated membrane collapses. This floats on any fluid which may be present, producing an irregular projection above the fluid level (' water-lily ' appearance) (fig. 783).

(4) Infection results in disintegration of the laminated membrane with appearances simulating a lung abscess.

(5) Varying degrees of pneumonitis, atelectasis, or pleural effusion may accompany any of the above and modify the radiological appearance.

Diagnosis.—The most important point is to remember the condition. A history of residence in an endemic area may support the diagnosis. The intradermal test of Casoni will give a positive result in 75 per cent. of uncomplicated cysts provided fresh hydatid fluid is used. An eosinophilia of over 4 per cent. is suggestive of the condition.

FIG. 783.—Hydatid cyst. 'Water-lily' appearance.

Treatment.—Removal of the cyst is indicated in all cases owing to the considerable risk of serious or even fatal complications. The earlier operation of marsupialisation has been almost completely replaced by thoracotomy with enucleation of the cyst or lobectomy. Enucleation is employed for uncomplicated cysts without significant associated lung damage. Extreme care and utmost gentleness is required to remove the laminated membrane intact without spilling the contents with the risk of infecting the pleura or wound. The adventitia is carefully incised and the laminated membrane will usually slowly extrude itself. It should never be grasped with forceps as it is friable and is sure to tear. Extrusion can be expedited by gentle positive pressure by the anæsthetist. After removal, any bleeding-points or open bronchi are secured and the residual space can be obliterated by mattress sutures if desired. The pleura is drained as some leakage of air is inevitable.

Complicated cysts are best treated by a more formal resection (lobectomy), particularly if there is any surrounding lung damage.

Secondary Pleural Hydatid Disease.—This is an occasional but serious complication of rupture of a cyst into the pleura or of ill-executed surgery. Multiple cysts grow widely throughout the pleura and may invade the chest wall, diaphragm, or mediastinum. Radical pleuropneumonectomy offers the only hope of eradicating the disease.

Hepato-Bronchial Fistula (fig. 915) is caused by the rupture of an infected hepatic cyst into the lung. The infected material traverses the subphrenic and pleural spaces (both being obliterated by adhesions) before discharging into the lung. It results in the production of bile stained sputum. Treatment demands a thoracotomy with resection of the affected lobe; the track through the diaphragm must be enlarged to expose the underlying residual cyst which is drained through an independent opening.

Pulmonary Œdema

Blood in the lung capillaries is separated from air in the alveolar spaces merely by the thin capillary wall and the alveolar membrane. Gaseous diffusion occurs readily across this membrane and any disturbance of the physico-chemical balance in the blood may permit the transudation of fluid from the capillaries into the alveolar spaces.

Initially, transudation occurs into the interstitial tissues of the lung, producing dyspnœa and cyanosis; later, when fluid reaches the alveoli, thin frothy blood-stained fluid is expectorated, often in considerable quantities. Coarse râles are audible throughout both lungs and radiographs show consolidated areas spreading from each hilum towards the periphery ('bat's wing' appearance).

Causes.—(1) Obstruction to the flow of blood through the left side of the heart as in left ventricular failure and mitral stenosis.

Tomaso Casoni, 1880–1933. Physician, Ospedale Coloniale Vittorio Emanuele III, Tripoli, Libya.

(2) Increased volume of blood reaching the lungs as may occur after excessive transfusion of blood or saline.

(3) Disturbances of osmotic pressure in the blood.

(4) Traumatic, such as follows the inhalation of certain noxious gases (phosgene, mustard gas), hot air, smoke or steam.

(5) Inflammatory, as in influenzal pneumonia.

(6) Associated with certain brain injuries and lesions of the brain stem.

Treatment is urgently required along the following lines:

(1) Correction of the precipitating cause.

(2) Support of the heart and circulation with aminophylline (250 mg. intravenously), digitalis (0·5 mg. digoxin intravenously) pressor agents and oxygen.

(3) Morphine, which should be given intravenously, is particularly effective in left ventricular failure.

(4) Diuretics such as Frusemide (Lasix) 40 mg. intravenously, repeated in 4 hours if necessary.

(5) Positive Pressure Ventilation is the most effective method of controlling pulmonary œdema and should not be delayed when the above measures are not immediately effective. Initially it can be employed with a cuffed plastic endotracheal tube, but tracheostomy will be necessary if ventilation required for more than two or three days.

SURGICAL TREATMENT OF PULMONARY TUBERCULOSIS

In a book of this nature it is not possible to give more than an outline of the principles involved in the surgical treatment of pulmonary tuberculosis. Such treatment is usually an incident in the long-term management of the case, and as such can only be satisfactorily determined by consultation and discussion between physician and surgeon.

Principles of Treatment.—(1) *Rest.*—This can be either local or general, and is an essential part of all forms of treatment. General rest is obtained in bed, whilst local rest is achieved by the various methods of collapse therapy, phrenic paralysis, and pneumoperitoneum.

(2) *Chemotherapy.*—The introduction of various anti-tuberculous drugs since 1950 has revolutionised the treatment of all forms of tuberculosis and has resulted in a world-wide reduction in the prevalence and importance of this disease (p. 32).

Currently, best results are obtained with the following regime: streptomycin 0·75 g, isoniazid 300 mg, and rifampacin 450 mg in daily doses. Ethambutol is substituted for streptomycin in doses of 25 mg per kg for patients over 40 to avoid the risks of VIIIth nerve damage in older patients from streptomycin. Streptomycin (or ethambutol) are discontinued after two months whilst isoniazid and rifampacin are continued for a total of nine months. Subsequent relapses are very rare.

Pyrazinamide, para-amino salicylic acid and thiocetazone are sometimes used in place of rifampacin which is currently more expensive but has the advantage of requiring only a single daily dose.

(3) *Relaxation.*—Tuberculosis heals by the production of fibrous tissue resulting in the contraction of the diseased area and the collapse and obliteration of the destroyed areas and cavities. Complete contraction and healing is often prevented by anatomical structures (bony chest wall), so that artificial methods of relaxing the diseased lung are required in many instances. These are divided into the minor and major methods. The former include artificial pneumothorax, phrenic paralysis, and pneumoperitoneum, whilst the latter include thoracoplasty, extrapleural pneumothorax, and plombage.

(4) *Excision of Diseased Lung.*—Prior to the introduction of streptomycin, excision of tuberculous lungs usually met with disaster. Antibiotics used before, and as a cover for operation, have transformed the situation and resection has become the surgical therapy of choice. Resection has the advantage over collapse therapy of removing the major foci of disease, leaving the body with the less formidable task of dealing with the residual disease.

(5) *Drainage of Pus.*—Apart from the drainage of an empyema, this method has little application now, though in the past tuberculous lung cavities were treated by catheter drainage (Monaldi), or open external drainage (cavernostomy).

Management.—All cases should be treated with bed rest and chemotherapy for several months before any active measures are undertaken. In many instances prolonged treatment will result in complete arrest of the disease; in others a tuberculous cavity, a positive sputum, or bronchial damage requires more active treatment. Surgical measures are almost

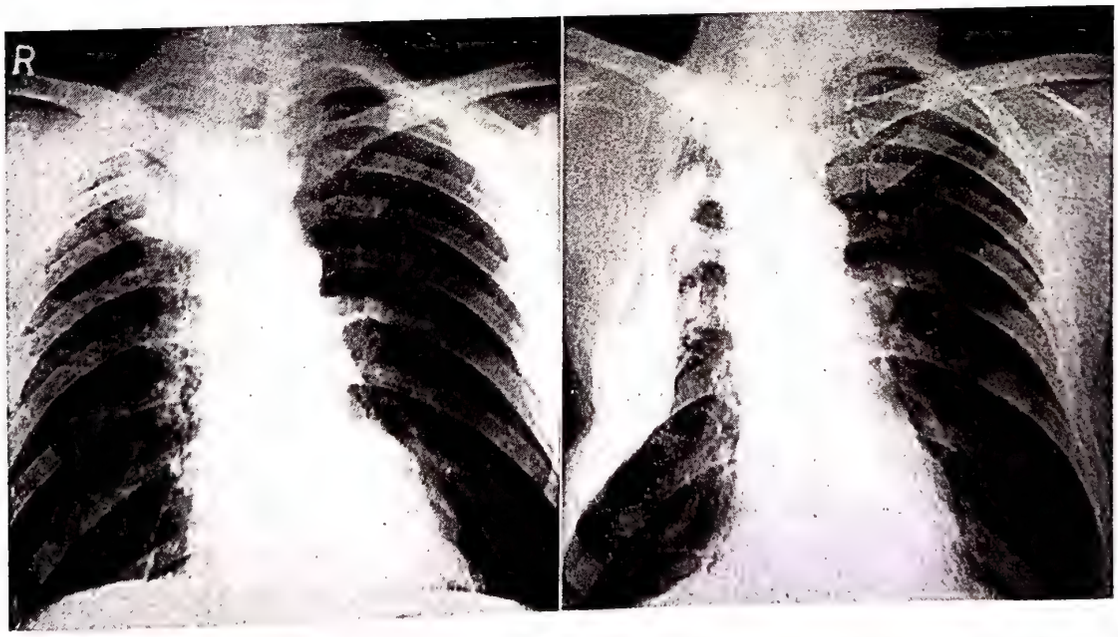

FIG. 784.—Chronic tuberculous cavity at the right apex.

FIG. 785.—Same case as in fig. 784 after thoracoplasty.

entirely employed for dealing with residual lesions which persist after adequate conservative treatment. Resection is the treatment of choice in nearly 90 per cent. of all cases requiring surgical aid. Thoracoplasty is

Vincenzo Monaldi, Contemporary. Director, Tuberculosic Clinic, University of Naples, Italy.

employed only when the risks of resection are unduly high or the disease too widespread for safe removal.

Apart from the failures of medical treatment and the persistence of unstable foci, resection is indicated in patients with destroyed lobes, in tuberculous bronchiectasis and in large solid lesions (tuberculoma). Where there is an empyema as well, surgical treatment will probably be required.

Thoracoplasty.—This has been the standard method of treatment employing major collapse therapy. The operation is now performed infrequently owing to the greater efficiency and safety of lung resection. It is mainly used for cavities in the upper lobe associated with a persistently positive sputum and resistant organisms (figs. 784 and 785), especially where extensive disease makes resection too hazardous.

The aim of the operation is to relax the diseased area from all sides so that it will retract concentrically towards the hilum. Lateral relaxation is produced by removal of the upper ribs whilst apical relaxation is achieved by separating the lung from the apex and the mediastinum. The original operation was introduced by Sauerbruch and consisted of removal of ribs only (lateral thoracoplasty), but this operation has been replaced by Semb's modification which includes apicolysis in addition to rib removal.

Lung Resection.—Since the introduction of streptomycin, resection of tuberculous lesions has been widely practised and has given good results. The operation has the advantage of removing the greater part of the diseased tissue, in leaving no external deformity, and disturbing respiratory function very little. But it cannot be safely employed in those with extensive disease. Before embarking on resection it is necessary to determine by tomography and bronchography whether the lung and bronchi to be left behind are free from disease. Pre-operative bronchoscopy is advisable, and if active tuberculous bronchitis is discovered, resection should be delayed until it is controlled by further chemotherapy. At operation it is advisable to remove all the obvious tuberculous disease, although small healed nodules may be safely left behind (fig. 786). The remaining lobes must be prevented from over-expanding either by temporary phrenic paralysis or by performing a small apical thoracoplasty. Over-distention of the lobe is likely to cause reactivation of dormant foci. It is unwise to carry out a resection if the organisms are resistant to all antibiotics.

FIG. 786.—Upper lobe of left lung (surgical specimen) showing large cavity at apex (upper arrow) smaller cavity below and tuberculous pneumonia.

Other Measures.—Minor collapse procedures, such as artificial pneumothorax, phrenic paralysis, and pneumoperitoneum and variations of the operation of thora-

Ernst Ferdinand Sauerbruch, 1875–1951. Successively Professor of Surgery at Zurich, Switzerland, and at Munich and Berlin, Germany.
Carl Boye Semb, 1895–1971. Professor of Surgery, University of Oslo.

coplasty, such as extra-pleural pneumothorax and plombage, have been rendered obsolete by the continued efficiency of chemotherapeutic agents.

POST-OPERATIVE PULMONARY COMPLICATIONS

The pulmonary complications of general surgery are the cause of serious morbidity and an appreciable mortality, and yet they can be largely prevented by adequate pre-operative and post-operative care.

Predisposing Factors.—(1) *Type of Operation.*—Operations on the upper abdomen and on the upper respiratory tract are more commonly implicated than others, but no operation is exempt. Operations for septic conditions are more prone to be followed by complications.

(2) *Sex.*—Males are more commonly affected than females.

(3) *Age.*—Complications are particularly frequent in the very young and the elderly.

(4) *Chronic Bronchitis.*—Chronic bronchitis is an important predisposing condition.

(5) *Smoking.*—Probably through the production of chronic bronchitis, heavy smokers are more prone to complications than non-smokers. Morton records 60 per cent. of complications occurring in heavy smokers and less than 10 per cent. in non-smokers.

(6) *Anæsthetic.*—The anæsthetic plays some part though this is less than is usually thought. Trauma to the tracheo-bronchial tree should be avoided, and prolonged post-operative unconsciousness is undesirable.

(7) *Pain.*—Post-operative pain is an important factor as it restricts coughing and deep breathing.

(8) Lack of mobility in bed and dehydration predisposes to venous stasis and thrombosis.

(9) Abdominal distension due to paralytic ileus (Chap. 48).

Excessive Bronchial Secretions

Abnormal bronchial secretions account for the majority of the chest complications of surgery. Many patients are a little 'chesty' following even the most trivial operation. This 'normal' post-operative bronchitis, however, may lead to very serious and perhaps fatal sequelæ unless adequately controlled.

Preventative Measures.—Adequate time should be devoted to preparing patients for operations of election. This can usefully be done in a regular pre-operative clinic where breathing exercises and coughing instruction is given, dental sepsis is attended to and bronchitis treated by antibiotics. A routine chest X-ray may reveal unsuspected tuberculous or other lesions. Smoking of cigarettes should be forbidden for several days before operation.

The following complications may be encountered, but it should be realised that one may merge into another, or neglect of one frequently leads to the production of more serious conditions.

(1) *Bronchitis.*—This is the commonest complication and is important in that it is often the precursor of more serious lesions. It may arise *de novo* or represent an exacerbation of a pre-existing bronchitis. The attack may vary considerably from a simple post-operative cough with mucopurulent sputum to severe suppurative bronchitis. Signs in the lungs are generalised, and there are no radiographic changes to be seen.

(2) *Bronchopneumonia* (Aspiration Pneumonia).—This is usually a sequel to the above. Patchy consolidation occurs with more profound systemic changes. The commonest organisms are *Hæmophilus influenzæ* and pneu-

Hugh John Vivian Morton, Contemporary. Anæsthetist, Hillingdon Hospital, Uxbridge, Middlesex, England.

mococci but cross-infection with ward organisms such as drug-resistant staphylococci and *P. pyocyaneus* may occur. Their presence should be sought by microscopy and culture of the sputum. Signs are more localised and bronchial breathing may be heard. Radiographs will reveal patchy mottling.

(3) *Atelectasis.*—This is produced by occlusion of a bronchus by viscid secretions of mucus or pus and is usually a sequel to bronchitis. The obstruction leads to absorption atelectasis of the involved lobe. Secondary invasion of the lobe by pathogenic organisms results in particularly serious changes. Depression of the cough reflex by pain or sedation and poor ventilation are important predisposing factors. Atelectasis usually occurs after the second post-operative night, frequently following heavy sedation. Secretions accumulate during sleep, and by morning have blocked the bronchus. The patient does not feel quite so well and there may be slight fever, tachycardia and breathlessness. Cough and sputum may not be obvious as the latter cannot be expectorated. Signs consist of restricted movement of the affected side of the chest with diminished breath-sounds and impaired percussion note over the affected lobe. Radiography will reveal the dense opacity of the atelectatic lobe.

(4) *Lung Abscess.*—This usually follows bronchopneumonia or atelectasis, and is often the result of ineffective early treatment. It is a particularly serious complication often resulting in spreading suppuration throughout the lung by organisms which are by then often resistant to all drugs.

(5) *Empyema.*—This is an occasional complication of any of the above; its management is no different from the average case.

Treatment.—*Prophylactic.*—At the conclusion of an operation the tracheo-bronchial tree should be aspirated if any secretions are suspected. Early return of consciousness and the cough reflex are desirable. Subsequently coughing and breathing exercises combined with regular rolling of the patient from side to side are desirable. Pain should be controlled by repeated small doses of analgesics of which pethidine (50–100 mg.) is the most useful, as it does not depress respiration.

The Established Case.—It is important to encourage the expectoration of sputum by all possible means. Much can be done by the physiotherapist and the nurse, whilst steam inhalations and saline expectorants help to loosen the sputum. When the secretions cannot be adequately removed naturally, they must be removed by catheter suction. If the simpler measures are not soon effective *bronchoscopy* should be carried out. This can readily be performed in the ward if the patient is too ill to move. It should be performed with minimal local anæsthesia so that the cough reflex is preserved. A careful and unhurried clearance of the whole bronchial tree should be the aim. Bronchoscopy usually results in the aeration of an atelectatic lobe, but the condition may recur and further bronchoscopies be required. In such cases it is often preferable to perform a *tracheostomy*, particularly when secretions are profuse or the patient dyspnœic. Tracheostomy by reducing the ' dead space ' greatly improves the efficiency

of respiration; it also provides easy access for repeated and atraumatic aspiration of the tracheo-bronchial tree. In addition to post-operative complications it has an important place in the management of severe chest injuries, head injuries, bronchopneumonia and poliomyelitis.

Subphrenic Abscess (Chap. 46).

Broncho-pleural Fistula

This complication is one peculiar to thoracic operations involving resection of lung tissue. Several factors may be involved in its production.

(1) Poor surgical technique in closing the bronchus (sutures too tight or imperfectly placed).

(2) Infection or infiltration of the bronchial stump (pyogenic, tuberculous or malignant).

(3) Indifferent healing (elderly and debilitated patients, and after deep X-ray therapy).

Symptoms usually appear towards the end of the first week after operation; fever and blood-stained sputum are the first signs. Subsequent developments depend on the size of the fistula.

A small leak allows air to enter the pleural cavity producing a pneumothorax and collapse of the lung whilst pleural fluid enters the bronchial tree giving rise to a persistent cough with much thin blood-stained sputum.

A larger fistula may give rise to serious flooding of the bronchial tree and the development of a tension pneumothorax.

Treatment.—The first essential when a fistula is suspected is to anticipate and prevent flooding of the bronchial tree by early aspiration of fluid from the pleural cavity and by nursing the patient with the affected side down.

A small leak may be controlled by repeated aspirations or by temporary tube drainage until the fistula heals.

Larger fistulæ should be treated at an early stage by re-opening the chest and resuturing the bronchus. The suture line should be reinforced by a pedicled intercostal muscle graft. If the pleural cavity is already infected, however, it is better to drain the pleura and carry out bronchial repair at a later date.

Pulmonary Embolism (see p. 162).

Between 2 and 3 per cent. of all hospital deaths are due wholly, or in part, to pulmonary embolism. The condition is by no means limited to surgical wards. The clot most commonly originates in the veins of the calves, thighs or pelvis. Two types of venous lesions occur:

(1) *Thrombophlebitis.*—The thrombosis is secondary to infection or trauma. There is a marked inflammatory reaction and the resulting clot is firmly adherent to the vessel wall and is rarely dislodged.

(2) *Phlebothrombosis.*—Clotting is secondary to venous stasis and there is no inflammatory reaction in the veins. The clot is soft and insecurely attached to the vessel wall. Detachment of the clot is easy, particularly as the condition is often unsuspected and movements uninhibited (p. 163).

Clinical Features.—Pulmonary embolism is the most dangerous com-

plication of phlebothrombosis. Much depends on the size of the embolus. *Small emboli* may be silent but the cumulative effect of many such episodes leads to a reduction in the pulmonary vascular bed resulting in pulmonary hypertension. Patients require permanent anticoagulants. *Medium emboli* lodge in branches of the pulmonary artery and result in pulmonary infarction without any hæmodynamic disturbances. Classically the onset is abrupt with pain in the chest, dyspnœa, and hæmoptysis. Chest radiographs reveal a triangular infarcted segment. Signs of venous thrombosis may or may not be present. Anticoagulants should be administered without delay and the patient immobilised for one week. Recurrent emboli are frequent. *Large emboli* lodge in the main pulmonary artery or one of its major branches. They produce serious hæmodynamic disturbances and may be rapidly fatal. Confusion with coronary thrombosis is easy but an E.C.G. is often of diagnostic value, showing right ventricular strain in pulmonary infarction. A massive pulmonary embolus may produce immediate death from ventricular fibrillation or complete obstruction of the circulation. Such cases often have an urgent desire for a bed-pan but are dead before one is produced. Those who survive complain of severe præcordial pain, tightness in the chest, and marked dyspnœa. Shock is marked and the patient becomes grey and cold with a rapid, feeble pulse, low blood pressure, and raised venous pressure. Death may occur at any moment, but the longer the patient survives the better are his prospects of recovery.

Management of Massive Pulmonary Embolism.—Patients fall into one of two categories:

(*a*) Those who succumb within 2 hours of the embolism, and

(*b*) Those who survive this critical period.

In the former group cardiac arrest is frequent and closed cardiac massage will be required. This may serve to dislodge the clot and permit a limited pulmonary circulation. There is insufficient time to mount cardio-pulmonary bypass and pulmonary embolectomy with temporary inflow occlusion should be attempted.

In the second group a reasonable though precarious cardiac output is maintained and there is time to carry out essential investigations, to transfer the patient to a special centre or prepare cardio-pulmonary bypass. Confirmation of the diagnosis is essential by angio-cardiography before definitive treatment is started. The cardiac catheter is left in the pulmonary artery and 600,000 units of streptokinase is injected followed by 100,000 units hourly for 72 hours. Improvement is likely in cardiac output within 6 hours. Thrombolytic therapy should be continued for 3–4 days in favourable cases. If deterioration sets in, pulmonary embolectomy should be performed. Heparin should not be used with fibrinolysins.

Pulmonary Embolectomy (Trendelenburg Type).—The pulmonary artery is exposed through a left fourth space thoracotomy. Several stay sutures are placed on either side of the proposed incision in the pulmonary artery. A clamp is placed across the base of the pulmonary artery and aorta through the transverse sinus. The pulmonary artery is incised and clot removed with a sucker. Both branches of the pulmonary artery must be explored with the sucker end. After 90–120 seconds of

Friedrich Trendelenburg, 1844–1924 (see footnote, p. 71). Described pulmonary embolectomy in 1908. The operation was first performed successfully by Martin Kirschner (see footnote, p. 338) in 1924.

occlusion the arteriotomy is controlled with a clamp and the occlusion clamp across aorta and pulmonary artery removed.

Pulmonary Embolectomy with Bypass.—Anæsthesia is not started until the pump is primed, the surgical staff scrubbed and all in readiness.

A mid sternal splitting incision gives quick access to the heart. A large venous tube is inserted into the right atrium and arterial return effected through a small incision in the ascending aorta. Bypass is then established and the pulmonary artery opened and clot removed with sponge forceps or a sucker. Careful exploration of the pulmonary arteries on both sides should be carried out and all fragments of clot removed.

Venous Thrombectomy.—Removal of residual clot by a Fogarty catheter is advocated by many surgeons to reduce the likelihood of further emboli and to help re-establish a normal circulation in the affected limb. Ligation or plication of the inferior vena cava is advocated by some to prevent further emboli reaching the lungs (p. 165).

LUNG TRANSPLANTATION

Transplantation of the lung has been successfully carried out on many occasions but to date the longest survivor died 10 months after the operation. Many technical problems such as ischæmia at the bronchial suture line and stenosis of the vascular anastomoses remain to be solved. In addition, the problems of rejection are not fully solved. The main indication for transplantation are patients dying from extensive emphysema and fibrosing alveolitis. (See Chapter 59).

THE DIAPHRAGM

Herniation of an abdominal viscus through the diaphragm into the chest may occur through a congenital or acquired defect; the former occur at certain well-recognised points (fig. 787) and are due to a failure of fusion of the various elements which make up the diaphragm. Such herniæ usually have a well-defined sac and adhesions are uncommon. Other congenital malformations may be present.

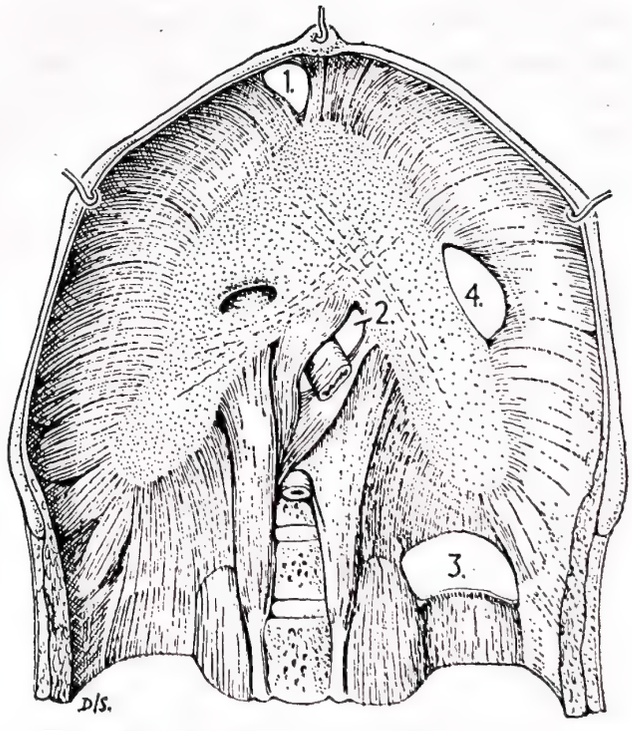

FIG. 787.—The usual sites of congenital diaphragmatic herniæ. 1. Foramen of Morgagni. 2. Œsophageal hiatus. 3. Foramen of Bochdalek (pleuro-peritoneal hernia). 4. Dome.

The acquired group are either traumatic or post-operative. They may occur anywhere in the diaphragm and extensive adherence to surrounding structures is usual. Stomach, small or large bowel, omentum or spleen are commonly found occupying the hernia. Liver and kidney are less frequently seen.

Symptoms may only occur when either obstruction or strangulation supervene. Many patients, however, complain of vague dyspeptic symptoms but if the hernia is large, especially in children, respiratory embarrassment may occur. In infants a diaphragmatic hernia is one cause of acute respiratory embarrassment demanding urgent surgical correction. The lung on the affected side is often hypoplastic.

Thomas J. Fogarty, Contemporary. Assistant Professor of Surgery, Stanford University, San Francisco, California, U.S.A.

Surgical repair is recommended in all cases in order to avoid serious complications. Access is best obtained through a low thoracotomy incision. The sac is excised and the defect is repaired by a double row of non-absorbable sutures. Occasionally reinforcement with fascia lata is required. In infants and small children with large hernias there may be difficulty in accommodating the abdominal viscera in the abdomen.

(1) **Eventration.**—This condition is due to defective development of the whole or part of the muscle of the diaphragm; the latter consists of a sheet of fibrous tissue covered with pleura and peritoneum. The thin, flaccid diaphragm is raised and immobile. Symptoms are uncommon and the condition is usually discovered on routine X-ray. If respiration is embarrassed plication is indicated.

(2) **Œsophageal Hiatus Hernia.**—This is the commonest of congenital abnormalities but may also occur as an acquired condition in the middle-aged or elderly. It is considered on p. 766.

(3) **Hernia through the Foramen of Morgagni.**—The defect lies between the sternal and costal attachments of the diaphragm; it is more common on the right side (fig. 788).

(4) **Hernia through the Foramen of Bochdalek** (Pleuro-peritoneal Canal).—The canal may remain open with free communication between the abdominal and pleural cavities. The hernia in such instances has no sac and the abdominal organs move freely in the chest, sometimes nearly filling the hemithorax and displacing the heart to the opposite side. More commonly the canal is covered by pleural or peritoneal membranes but muscle is absent, and in these cases the hernia has a sac and is usually smaller.

FIG. 788.—Colon occupying a Morgagni hernia. *(Dr. Oliver Smith, Birmingham.)*

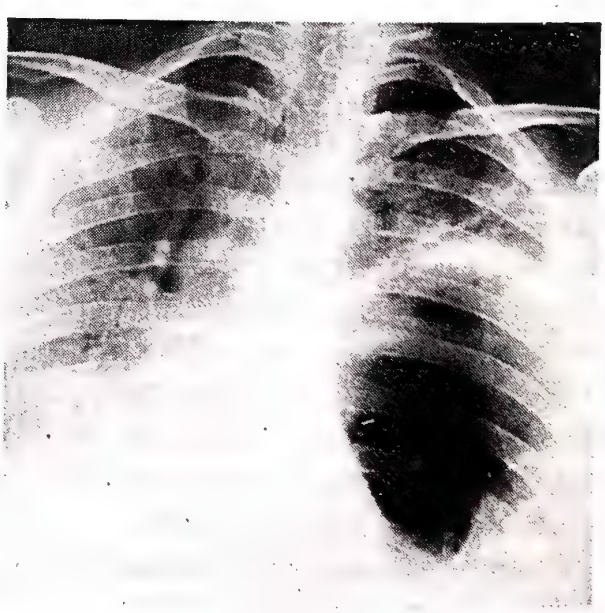

FIG. 789.—A large traumatic diaphragmatic hernia due to a penetrating thoraco-abdominal wound with a retained foreign body.

(5) **Hernia through the Dome.**—These are usually left-sided and may occur anywhere in the diaphragm. They are commonest, however, at the junction of the muscular and tendinous portions.

Giovanni Battista Morgagni, 1682–1771. Professor of Anatomy, Padua, Italy, for 56 years; from 1715 until his death in his 90th year.
Victor Alexander Bochdalek, 1801–1883. Professor of Anatomy, Prague, Czechoslovakia.

(6) **Traumatic Diaphragmatic Hernia.**—The diaphragm may be torn directly by a missile (thoraco-abdominal wound) (fig. 789) or ruptured by severe lower thoracic or abdominal compression (crush injury) without an external wound.

The defect may occur anywhere in the diaphragm in the former instance, but with crush injuries the dome is usually torn. Herniation may occur immediately or be delayed for some considerable time. A peritoneal sac is not present and adhesions between the lung and the herniated viscera always occur. Dyspeptic and obstructive symptoms are common and strangulation occasionally occurs.

Repair of the hernia should always be undertaken.

(7) **Post-operative Diaphragmatic Hernia.**—Occasionally herniation follows thoraco-abdominal operations, particularly those involving an intra-thoracic œsophagogastric anastomosis. Herniation may occur around the new hiatus or through the sutured diaphragm. Great care should be taken in suturing the diaphragm to the stomach or jejunum in these cases, whilst the diaphragm is best closed with a reasonable overlap of the edges and with two rows of sutures.

Diagnosis may be extremely difficult as there are many other causes of vomiting, pain, etc., in the post-operative period. Radiography is often of little use as the suspected area is obscured by effusion, etc.

An early exploration is advisable if the condition is suspected.

MEDIASTINAL TUMOURS

The term ' tumour ' covers a wide variety of conditions which are often difficult to distinguish, but precise diagnosis is not of great practical importance as the majority of innocent ' tumours ' require removal, and those which are not amenable to surgery, e.g. secondary carcinoma, lymphosarcoma, lymphadenoma and reticulosis, are usually readily recognised. Innocent ' tumours ' should be removed owing to the risks of malignant degeneration or compression or involvement of the mediastinal structures. The most important feature in differential diagnosis is the position of the tumour in the mediastinum, and a useful practical classification is as follows :

(1) **Anterior Mediastinal Tumours**
- Retrosternal goitre.
- Thymic tumours and cysts.
- Persistent or enlarged thymus.
- Teratoma.
- Pleuro-pericardial cyst.

(2) **Posterior Mediastinal Tumours**
- Neurogenic tumours (neurofibroma, ganglioneuroma).
- Foregut cysts (paratracheal, para-œsophageal cyst, gastric cyst of mediastinum).
- Œsophageal hiatus hernia with thoracic stomach.

(3) **Tumours arising anywhere in the Mediastinum**
- Lymphadenopathies (these are often multifocal and the lesions are characteristically lobulated). Secondary carcinoma, tuberculous adenitis, lymphadenoma, reticulosis, and sarcoids are the commonest varieties.
- Lymphogenous cysts.
- Lipoma.
- Fibroma.

Diagnosis in the difficult lymphadenopathies can often be made by a scalene node biopsy or mediastinoscopy.

The majority of the solitary lesions require operative removal if serious complications are to be avoided.

Retrosternal Goitre (p. 597).—This produces an anterior mediastinal tumour, often of characteristic shape and distribution. It is frequently bilateral though usually larger on one side. The tumour has a broad base superiorly which merges and cannot be separated from the tissues of the neck on radiological examination. Calcification is not uncommon as the tumour has probably been present for many years. This is one of the few tumours which compress the trachea (scabbard trachea).

Removal through a cervical incision is usually possible, and only occasionally is a sternal-splitting approach required.

THE THYMUS

Anatomy.—The gland originates as a diverticulum of the third and sometimes the fourth pharyngeal pouch on each side. Epithelial in origin, it soon assumes a lymphoid character. The body of the thymus consists of two lobes closely applied to one another in the middle line, overlying the upper part of the pericardium and the great vessels, and extending upwards into the base of the neck. Each lobe is overlapped by pleura, and above this level has a slender pole passing to the isthmus of the thyroid. The blood supply of the gland is derived mainly from the internal mammary arteries. After puberty, the thymus commences to atrophy, and is replaced by fat, but even up to, and after, the age of fifty, the gland still contains a considerable amount of characteristic lymphoid tissue with epithelial elements, notably Hassall's corpuscles.

The Thymus and Immunity.—Most of our knowledge about the relationship of the thymus to immune processes is derived from observations made on thymectomised young mice and other mammals. Immunologically-active lymphocytes first appear in the thymus and are later seeded in other conglomerations of lymphoid tissue. Early thymectomy results in a depletion or absence of these cells in the body. In addition there may be depletion in Immunoglobulin levels and some antibody responses are decreased or delayed. The thymectomised mice will accept homograft transplants with little or no evidence of rejection.

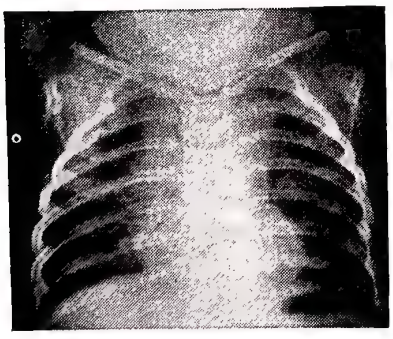

FIG. 790.—Enlargement of the thymus in infancy. (*Professor Carl Krebs, Aarhus, Denmark.*)

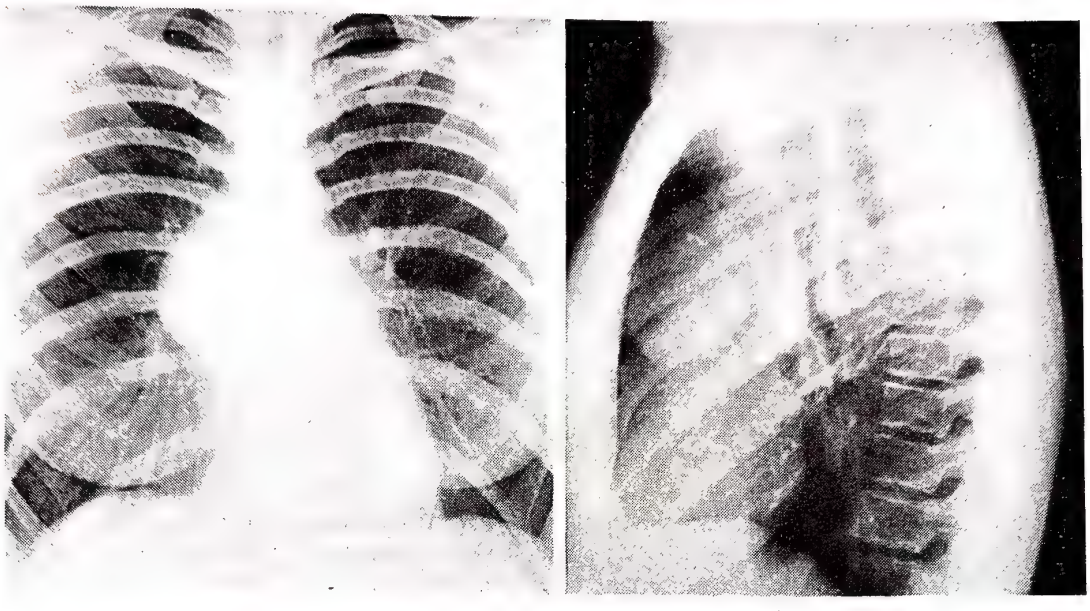
Hyperplasia of the thymus occurs in toxic goitre, acromegaly, in some cases of Addison's disease, after castration, after bilateral adrenalectomy, and in myasthenia gravis. In infancy the gland may be enlarged (fig. 790). In the past this condition was called '*status thymo-lymphaticus*', and thought to be an explanation of sudden death under anæsthesia in children. This theory is no longer acceptable. Enlargement of the gland in infants may compress the trachea causing stridor and wheeziness (thymic asthma). Symptoms usually subside spontaneously but if severe and persistent, treatment with radiotherapy or surgery may be required.

Tumours of the thymus are not uncommon. Classification is difficult, but Thompson and Thackray describe three main histological types: (1) Epithelial. (2) Lymphoid. (3) Teratomatous. The epithelial type is the commonest. Cyst formation, lobulation by fibrous tissue, necrosis, and calcification are sometimes seen. Between 10% and 20% of thymic tumours are associated with myasthenia. Conversely, about 15% of myasthenics are found to have a thymic tumour; half are invasive and malignant and associated with severe and intractible disease; the

Arthur Hill Hassall, 1817–1894. General Practitioner, Microscopist and Chemical Analyst, Kensington, London.
Robert Edward Mervyn Thompson, Contemporary. Reader in Bacteriology, Middlesex Hospital, London.
Alan Christopher Thackray, Contemporary. Professor of Morbid Histology, Middlesex Hospital, London.

remainder are histologically indistinguishable from normal thymic tissue and are non-invasive and do not appear to influence the severity of the myasthenia nor its response to treatment. Thymic tumours occupy the anterior compartment of the superior mediastinum. The majority of tumours are discovered by routine radiography. They are not dense radiologically unless calcified and are thus not visible on postero-anterior radiographs unless large enough to project beyond the mediastinal contour. In the lateral film they may be visible in the normally translucent area of the



(*a*)

(*b*)

FIG. 791.—(*a*) PA and lateral radiograph of thymic cyst. The mass occupies the anterior superior mediastinum. (*b*) Thymic carcinoma. Note that mass is visible on both sides of the mediastinum.

anterior superior mediastinum (fig. 791(*a*)). Tumours visible on both sides of the normal mediastinal contour are likely to be invasive and malignant (fig. 791(*b*)). A few may produce signs of superior mediastinal obstruction.

Removal of the tumours is advised in the majority of patients owing to the very real risks of progressive growth and the development of invasive characteristics. The tumour is approached by a sternal-splitting incision which gives excellent access and facilitates complete removal. In those instances where the lesion is invading the surrounding structures widely a histological diagnosis should be obtained before starting radiotherapy. This can be achieved by an anterior mediastinal exploration through a small incision in the second intercostal space.

Myasthenia Gravis.—In this disease the transmission of motor-nerve impulses at the neuromuscular junctions is blocked by interference with the action of the transmitter—acetylcholine—upon the muscle fibres.[1]

Clinical Features.—The disease occurs in both sexes and commences, as a rule, in early adult life. The essential symptoms are profound fatigue after modest exertion, and transient paresis of voluntary musles. Muscles supplied both by the cranial and spinal nerves are affected, the extrinsic ocular muscles being involved most constantly. Usually ptosis (fig. 792), a squint, and diplopia are the first symptoms. Later manifestations are drooping of the mandible, with weakness of mastication and difficulty in swallowing. The voice becomes weak, and in some cases death occurs within a few months from involvement of the muscles of respiration. Usually the disease runs a chronic progressive course, but partial remissions occur. The reflexes remain normal, and there is no sensory loss. Occasionally myasthenia gravis complicates primary thyrotoxicosis. Should a patient with myasthenia gravis become pregnant, remission of symptoms during pregnancy often occurs.

FIG. 792.—Myasthenia gravis. Before neostigmine. *(Arthur Makey. F.R.C.S. London.)*

FIG. 793.—Myasthenia gravis. One hour after neostigmine. *(Arthur Makey, F.R.C.S., London.)*

Confirmatory Tests.—(1) Edrophonium chloride (Tensilon), 10 mg intravenously relieves signs and symptoms of myasthenia in 1 minute though they usually return in 10 minutes. Tensilon is only used diagnostically in this way because it has such a short action. Alternatively 2 mg neostigmine and 0·65 mg atropine can be given but the response is delayed for ½–1 hour (figs 792 and 793). (2) The affected muscles often show the myasthenic reaction—fatigue with faradic, but not with galvanic, stimulation.

Radiography, particularly a lateral radiograph, of the superior mediastinum should always be undertaken. In 15% of cases a thymic neoplasm is revealed. Apart from tumours, there is no X-ray evidence of thymic enlargements in myasthenic patients.

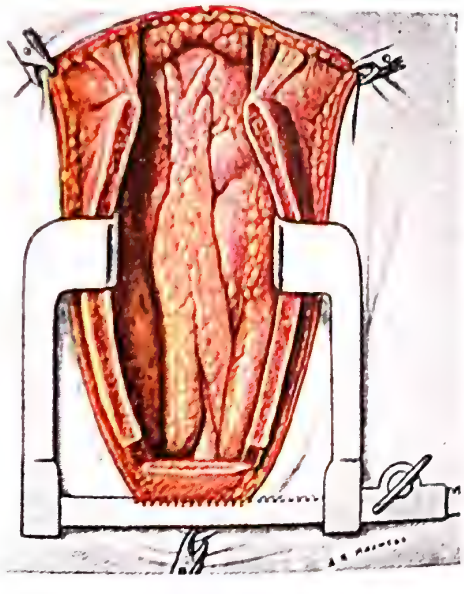


FIG. 794.—Exposure of a tumour of the thymus by splitting the sternum. *(Sir Geoffrey Keynes, F.R.C.S., London.)*

Treatment.—Medical.—Orally, from 4 to 15 tablets (15 mg. each) of neostigmine can be given in the twenty-four hours. They should be so spaced as to enable meals to be taken without difficulty in mastication. Pyridostigmine (mestinon) is a related longer-acting compound which can be used in combination with, or instead of, neostigmine. It is particularly valuable for nocturnal administration. In critical cases neostigmine may be given in a slow drip infusion. Oral potassium salts given in large dosage (12 g

[1] At a postgraduate course in 1934, Mary Walker, a Scottish doctor working in London, learned that physostigmine counteracts curare, and gave the former to a myasthenic patient. Luckily this patient was spared the side-effects (vomiting). This breakthrough met with fierce opposition, but she was vindicated by the successful series of Dr. L. P. E. Laurent, Physician, West London Hospital (who had reported remission during pregnancy—above), and the introduction of prostigmine (neostigmine) which has less side-effects.

Sir Geoffrey Langdon Keynes, Contemporary. Consulting Surgeon, St. Bartholomew's Hospital, London.

per day) are often beneficial. Ephedrine and Guanidine may also be of benefit. Atropine should be administered if bowel activity is increased by the anti-cholinesterase drugs.

Surgical Treatment.—Thymectomy is advised for those patients who are not adequately controlled by medical measures and especially for the more severe cases. Best results are obtained in younger patients especially females with a short history and in these the indications are less strict. The operation, however, should not be denied the elderly male patient with a long history if medical management is proving difficult.

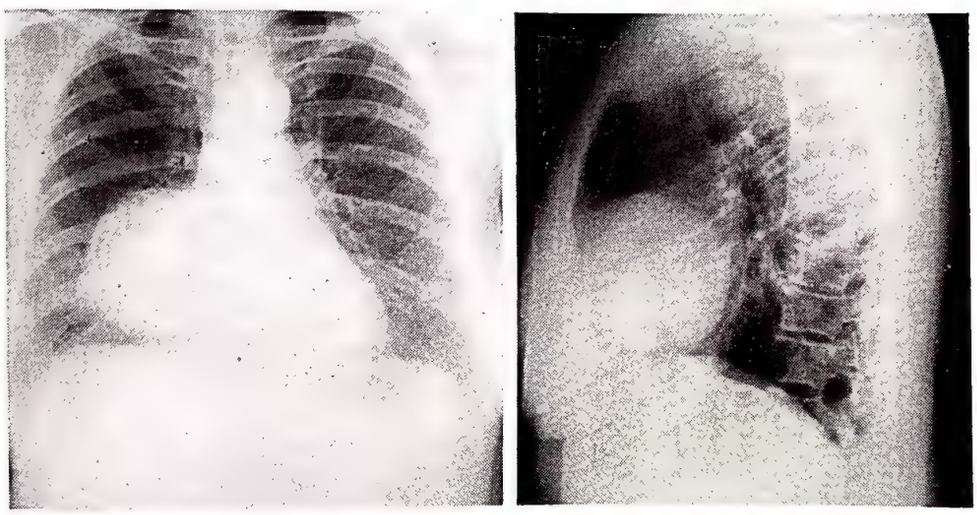
Thymectomy.[1]—Muscle relaxants are currently advised by many anæsthetists on the basis that 24 hours of artifical ventilation after operation has many advantages and permits the clinician to omit all drugs during this period.

The gland is best approached by a vertical full sternal splitting incision. The pleural cavities should be avoided if possible but if opened an intercostal drainage tube should be inserted at the end of the operation and connected to an under-water seal.

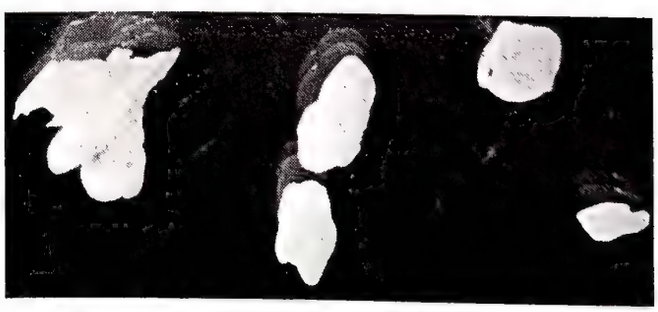
The gland is readily found as it is usually larger than normal. It is dissected carefully from its surroundings and removed in its entirety. The thymic vein passes directly backwards from the posterior aspect of the thymus to the left innominate vein and should be carefully displayed and divided after ligation. The mediastinum and the pleural cavity should all be drained for at least 24 hours.

All patients, where relaxants have been used, must be ventilated until medical therapy has been re-started and muscle power returned.

Results of Treatment.—The operation mortality is approximately 5%. Complete remission is obtained in nearly 50% of favourable cases (young females with a short history) whilst many of the remainder are able to manage more satisfactorily on smaller doses of drugs. In the older age group the results are less dramatic and are often delayed. In patients with invasive thymic tumour the results may be disappointing even when the tumour has been totally excised.



(*a*)



(*b*)

FIG. 795.—(*a*) PA and lateral radiograph of patient with a mediastinal teratoma. The tumour lies anteriorly and with a pedicle attached beneath the aortic arch. (*b*) X-ray of excised tumour showing formation of teeth.

[1] Alfred Blalock, 1899-1964. Professor of Surgery, Johns Hopkins University, Baltimore, was the first to perform thymectomy successfully for myasthenia gravis in 1939.

Pre-operative radiotherapy is only occasionally employed at the present time being usually reserved for the acute case with a radiologically visible tumour.

Teratoma.—The commonest 'inclusion' tumour is the teratoma; true dermoid cysts are only occasionally encountered. The tumours are almost always situated anteriorly with a pedicle attached deeply beneath the aortic arch (fig. 795). They are often slightly lobulated and may project into either side of the chest. Irregular areas of calcification, bone or tooth formation are sometimes seen.

Rapid increase in size without malignant change is sometimes associated with pregnancy. Occasionally a positive Aschheim Zondek test is obtained in non-pregnant patients. Infection and malignant transformation are not uncommon complications. Removal is indicated in all cases, and is best carried out through a wide lateral thoracotomy.

Mediastinal Cysts.—These are usually developmental in origin and may be associated with the trachea, bronchi, or œsophagus (foregut cyst), pericardium (pleuro-pericardial, spring-water cyst), or lymph nodes (lymphogenous cysts).

They are characteristically low-tension cysts and so may alter their shape with posture, respiration or after the induction of an artificial pneumothorax.

Foregut cysts are likely to become infected and may rupture into the trachea, œsophagus, lung or bronchus. Removal is desirable.

Neurogenic Tumours.—These have already been considered under chest-wall lesions (p. 696). They consist of neurofibromas arising from the intercostal nerves and ganglioneuromas from the sympathetic chain. They lie posteriorly in the costovertebral gutter. Occasionally they extend through the intervertebral foramen into the spinal canal (dumb-bell tumours). Malignant change may occur.

Selmar Aschheim, Contemporary. Formerly Honorary Professor of Gynæcology, University of Berlin.
Bernhard Zondek, 1891–1966. Professor of Obstetrics and Gynæcology, Hadassah Medical School, Hebrew University, Jerusalem, Israel.
Aschheim and Zondek described this test for pregnancy in a joint paper in 1928.

CHAPTER 39

THE HEART AND PERICARDIUM

SPECIAL METHODS OF INVESTIGATION

MODERN cardiac surgery demands precise methods of investigation to provide accurate anatomical and physiological details of the various cardiac abnormalities. It is only when such information is available that a precise diagnosis can be made and surgical treatment planned. The most important available methods are :

(1) **Radiology** (standard techniques and fluoroscopy). Such examinations provide details of the cardiac contour and variations in size of the chambers; it also provides information about the pulmonary circulation.

(2) **Angiocardiography** (figs. 796 and 797).—The injection of 76% Urografin in doses of 1 ml. per kg. is used to outline the chambers of the

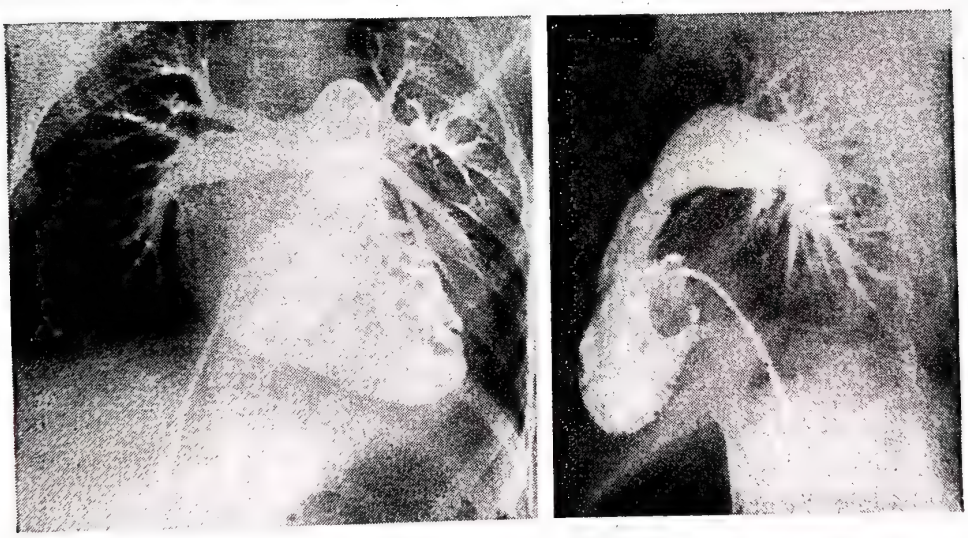


FIG. 796.—Normal angiocardiogram showing the right side of the heart and pulmonary arteries.

heart and great vessels and films can be taken at frequent intervals during the passage of the opaque material through the heart. Important anatomical information concerning the size and shape of the heart chambers, the presence of a shunt or of obstruction or incompetence of a valve may be provided. The aorta and pulmonary arteries and their branches will also be outlined. Ciné-angiography gives a dynamic picture of the circulation through the heart and is especially suitable for demonstrating valvar regurgitation.

(3) **Cardiac Catheterisation.**—A fine catheter is introduced through a vein or an artery into the heart where its passage can be followed by fluoro-

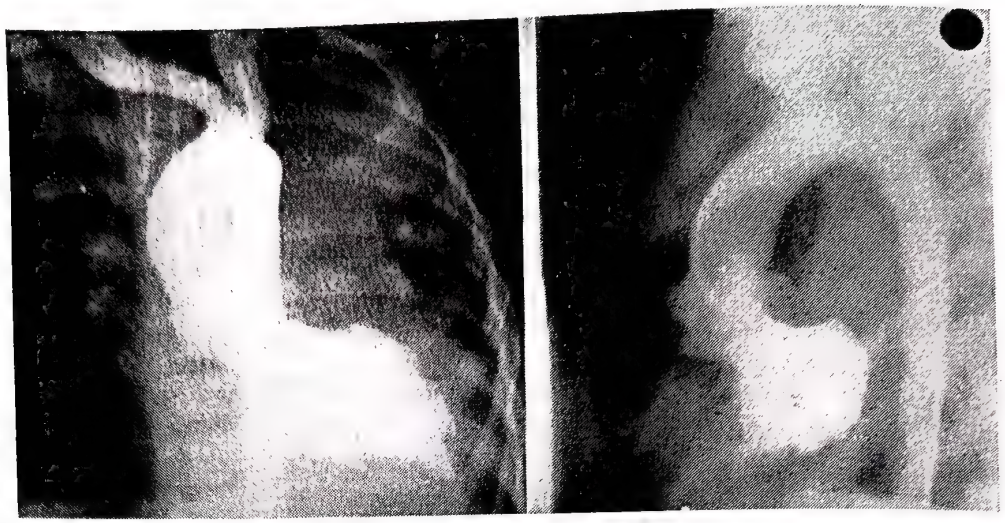

FIG. 797.—Normal angiocardiogram showing the left side of the heart and aorta.

scopy and blood samples and pressure tracings recorded. This investigation supplies functional as well as anatomical data (fig. 798).

(4) **Dye Dilution Studies.**—Injection of tracer dyes (Evans' Blue, Coomassie Blue) can be made into the chambers of the heart during cardiac catheterisation and the appearance of the dye in the systemic circulation recorded by an ear oximeter. The time of appearance of the dye and the mode of its disappearance provides valuable information about the presence of shunts or valve incompetence.

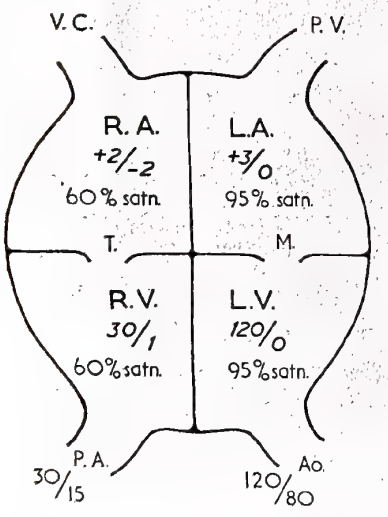

FIG. 798.—Normal intracardiac pressures and oxygen saturations.

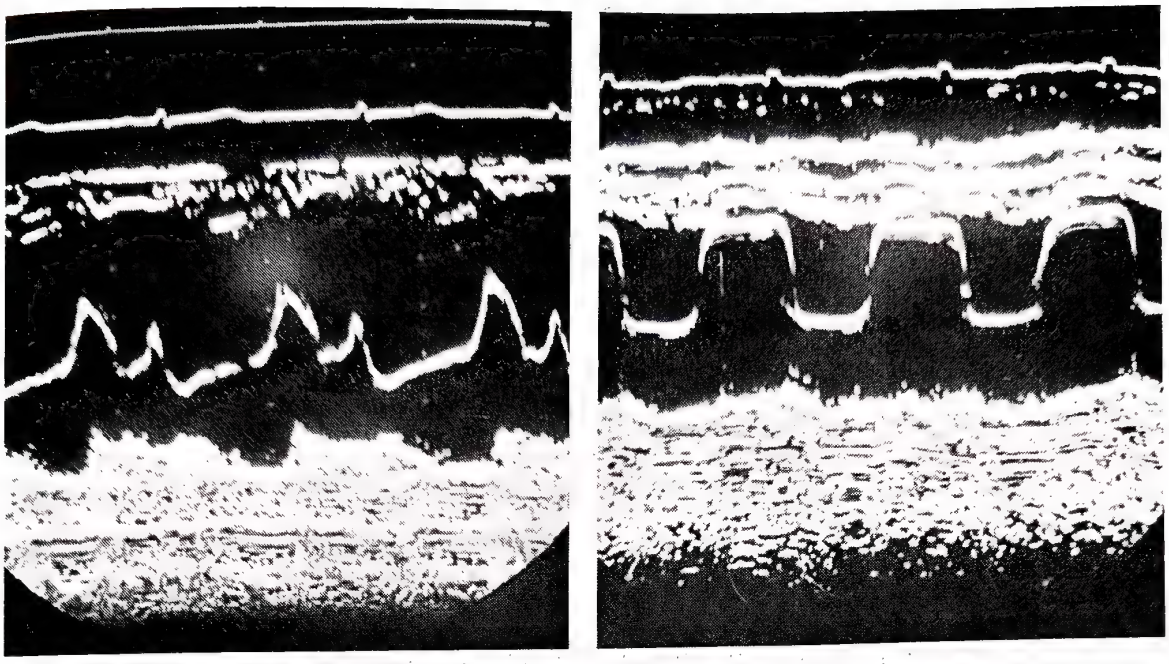
(5) **Echocardiography.**—Beams of high speed ultrasound waves are directed through the heart. Whenever the vibrations cross a boundary or interface, vibrations will be reflected back to the transmitting source provided the reflecting surface lies at right angles to the original beam. By accurate placing of the transmitter the movements of the aortic leaflet of the mitral valve, the anterior and posterior walls of the heart and the ventricular septum can all be recorded and important information obtained (fig. 799 (*a*) and (*b*)). Thickening, calcification and poor mobility of the anterior mitral cusp can be clearly demonstrated and indications for closed or open mitral valvotomy determined from this investigation alone thus avoiding the need for cardiac catheterisation and angiocardiography. Similarly pericardial effusions and atrial tumours can be diagnosed with certainty. Further applications of this technique are being actively explored.

CARDIO-RESPIRATORY RESUSCITATION

In cardio-thoracic emergencies the heart and lungs should be considered as one unit: where there is circulatory failure, both pulmonary and cardiac



(*a*) (*b*)

FIG. 799.—Movements of anterior leaflet of mitral valve as recorded by ultrasound, (*a*) normal cusp. (*b*) mitral stenosis. The flat top of the tracing indicates absence of mitral valve closure during diastole. (*D. Gibson, London.*)

support will be required. Although in the early stages of a crisis only one element may be affected, its failure very rapidly implicates the other. Thus, respiratory failure rapidly leads to cardiac arrest and vice versa.

Circulatory failure is common in civil life—electrocution, drowning, asphyxia, poisonous gases and major trauma account for many cases. In addition, circulatory arrest may occur in any hospital department. It is more commonly associated with major surgical procedures especially those performed for cardiac conditions, but minor operations and diagnostic procedures are not immune. If lives are to be saved, it is essential that the mechanism of production and the methods of correction of circulatory arrest should be clearly understood. Not only should vulnerable departments be supplied with the necessary basic instruments for dealing with the emergency, but both medical and nursing personnel should be thoroughly familiar with the procedure of resuscitation.

Causes of Cardiac Arrest.—The following are the factors usually responsible for cardiac arrest :

(1) **Anoxia.**—Myocardial anoxia is probably the most frequent and important precipitating cause of arrest. It can be produced by a variety of means, such as respiratory obstruction, serious hæmorrhage, a sudden severe fall in blood pressure or coronary air embolism. Hæmorrhage from the heart is always more serious than that from the peripheral circulation owing to a marked decrease of cardiac output and rapid fall in blood pressure. Most cardiac manipulations produce a temporary fall in blood pressure, but if they are repeated or prolonged, severe and irreversible changes may develop.

(2) **The State of the Myocardium.**—A healthy myocardium will stand moderate manipulation and anoxia without ill effect, but a diseased myocardium has less reserve, and relatively minor disturbances may cause failure.

(3) **Toxic and Irritating Drugs.**—Certain drugs have a direct depressing or irritating action on the myocardium whilst others affect it indirectly through the circulation. In the latter group, the vasodilators are the most important; these include many anæsthetic agents, procaine, etc. Chloroform, cyclopropane and adrenaline may produce cardiac irregularities, whilst marked excess of potassium may lead to cardiac arrest.

Types of Cardiac Arrest.—Sudden acute cardiac failure may be produced by:

(1) **Circulatory Obstruction.**—By a massive pulmonary embolism, air embolism, or accidental occlusion of one of the main vessels.

(2) **Asystole.**—This is usually due to severe myocardial depression. The heart beat becomes slow and feeble and finally stops. The myocardium is flabby, dilated, and cyanosed.

(3) **Ventricular Fibrillation** is usually associated with an irritable heart as a result of manipulation, trauma or drugs. In such cases, the myocardium is less depressed and more likely to recover than in the former group.

Management of Cardiac Arrest.—Speedy recognition is essential if the circulation is to be restored before irreversible damage has been done to the brain. Diagnosis is based on three signs (*a*) absent carotid pulse (*b*) absent or gasping respiration (*c*) dilated pupils. Disappearance of the pulse is the most important sign. If the carotid pulse cannot be felt, cardiac arrest must be assumed and appropriate action taken. If the circulation can be restored within five minutes of cessation, recovery is possible, but it is unlikely after an interval of ten minutes.

Vulnerable departments should prepare a simple chart outlining essential procedure for guidance to both medical and nursing staff.

Management is divided into two phases:

(*a*) **Emergency.**—These measures are carried out by the man on the spot and consist of *mouth to mouth ventilation* and *closed cardiac massage*. These can both be performed by one operator in the ratio of one breath to ten chest compressions, but are more efficiently carried out by two. (Full technical details are available in all first-aid manuals.) These two measures should be continued without interruption until a heart beat or spontaneous respirations return or until expert help arrives. If performed effectively, the vital organs can be kept alive for a few hours by these measures alone.

(*b*) **Subsequent Management.**—Further management depends on the arrival of expert help and appropriate equipment (endotracheal tubes, ventilating apparatus, cardiograph, electrical defibrillator and thoracotomy set).

1. *Ventilation:* At the earliest possible moment an endotracheal tube should be passed and mechanical ventilation started.

2. *Cardiograph:* Electrocardiographic monitoring should be provided as soon as possible in order to determine the type of cardiac arrest (asystole or ventricular fibrillation) and demonstrate any signs of recovery.

3. *Cardiac massage:* Closed massage should be continued until cardiography is available. Further action depends on the type of rhythm.

(*a*) If ventricular fibrillation is present, attempt external defibrillation. If this is unsuccessful, give an intravenous or intracardiac injection of 100 mg. lignocaine or 250 mg. of procaine amide, or 5 ml. of 10 per cent. calcium

chloride, and attempt defibrillation after an interval of two to three minutes with continued cardiac massage. As a last resort expose the heart and carry out open massage and drug administration.

(*b*) If asystole has developed, inject 10 ml. of 1:10,000 adrenaline or 0·01 mg. isoprenaline into heart. This should induce ventricular fibrillation in which case proceed as in 3(*a*) above. If there is no response, open the chest and carry out open massage with further injections of adrenaline or isoprenaline.

(*c*) **Open Cardiac Massage.**—The chest should be opened through the fifth intercostal space on the left side by an intercostal incision extending from the sternum to the axilla. The wound does not bleed as there is no circulation. The only instrument required to permit bi-manual massage is a rib-spreader, but should this not be immediately available massage is quite possible with one hand. Massage is most efficient with two hands with the pericardium widely opened. One hand should be placed above and the other below the ventricular mass, and massage should be carried out with the flat of the hand and fingers rather that with the finger-tips. The rate should be about 50 times per minute, though this is guided by the need for a sufficient pause to permit diastolic filling. Massage should always be carried out gently as considerable damage to the myocardium is possible if excessive force is used. The object of cardiac massage is to improve the tone of the myocardium, to increase the coronary flow, and ensure a supply of oxygenated blood to the nervous centres. The arrested heart is distended, flaccid, and cyanosed, but after massage it should become smaller, firmer, and pinker. When tone has returned, attempts should be made to obtain normal beating.

4. *Correction of Metabolic Acidosis:* All patients develop acidosis after cardiac arrest and its presence may prevent resuscitation. Sixty ml. of an 8·4 per cent. solution of sodium bicarbonate (1 mEq. per ml.) should be given intravenously as soon as possible and further doses administered to restore the pH to normal levels (p. 96).

Later Management.—After the restoration of normal rhythm and a normal blood pressure, a careful watch should be maintained in case of recurrence. Adequate steps should be taken to correct any metabolic acidosis. The main late complications are related to cerebral and renal damage resulting from the period of circulatory arrest. If return of consciousness is delayed, cerebral dehydration as described on p. 405 should be carried out. Total body hypothermia with reduction of temperature to 32°C. may help to limit cerebral damage (p. 406). If renal activity is impaired, the measures described under renal anuria (Chap. 53) should be instituted.

THE SCOPE OF CARDIAC SURGERY

Operative treatment of cardiac abnormalities is advancing steadily, particularly with the advent of new techniques for controlling the circulation. The procedures can be, for practical purposes, placed in one of three groups :

(1) **Extracardiac Operations.**—These are carried out on the main vessels outside the heart or on the pericardium. The ventricles or atria are not directly interfered with so that cardiac function is not unduly disturbed. Examples include ligation of a patent ductus, excision of coarctation, systemic-pulmonary anastomoses, resection of aneurysms, pericardectomy and certain operations for ischæmic heart disease.

(2) **Closed Intracardiac Operations.**—These are blind intracardiac procedures performed by instrument or finger and controlled by touch. Access is obtained to the interior of the heart through either the ventricular or atrial walls or through the base of one of the great vessels. Cardiac action is interfered with to some extent so that irregularity of heart action is liable to be encountered. Mitral valvotomy is the only closed procedure still used regularly.

(3) **Open Cardiac Operations.**—The desire of every surgeon is to operate with safety under direct vision on the open and motionless heart. The following procedures have come near to achieving this goal :

(*a*) *Extra-corporeal Circulation.*—Several clinically proven heart-lung machines are now in regular use. Basically each consists of a pump and an oxygenator. Blood is withdrawn from the venæ cavæ, passed through the oxygenator and returned into the arterial circulation through the femoral artery or ascending aorta (fig. 800). The blood is thus diverted completely from the heart and lungs but a good supply of well oxygenated blood is made available to the vital organs. Heart-lung machines provide the surgeon with periods for intracardiac surgery of between two or three hours with safety. By the use of an extra-corporeal circulation many complicated cardiac anomalies can be corrected and such conditions as ventricular septal defects, Fallot's tetralogy (p. 747) and valvar abnormalities are being so treated.

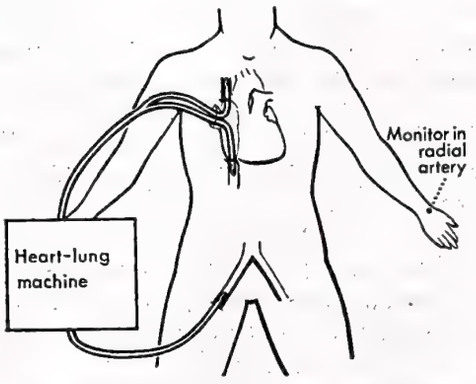


FIG. 800.—Orthodox cannulation for heart lung machine.

(*b*) *Hypothermia.*—By cooling the body to 29 to 30° C. the basic oxygen requirement of vital organs is so reduced that they can withstand periods of up to ten minutes of complete circulatory arrest without suffering irreparable damage. This time is sufficient to enable the surgeon to correct straightforward conditions such as atrial septal defects and pulmonary valve stenosis, but the technique is used less frequently as the efficiency and ease of operation of heart-lung machines increase.

The desired temperature is obtained either by cooling the whole body (surface cooling) by immersion in cold water or by cooled blankets; alternatively the blood alone can be cooled (veno-venous cooling) by cannulation of both venæ cavæ, removing blood from the superior cava, passing it through a cooling chamber and returning it to the inferior cava.

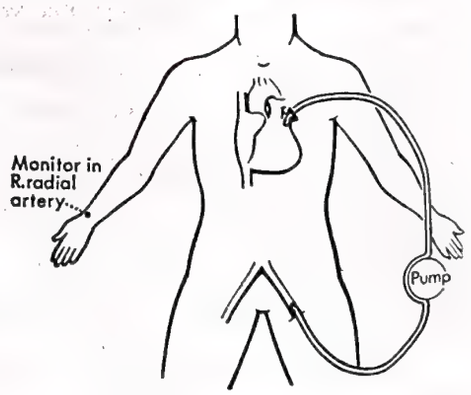

FIG. 801.—Left heart by-pass.

(*c*) *Deep Hypothermia.*—It is possible by cannulating each side of the heart separately to reduce the body temperature to 10° C. or lower. The heart fibrillates at about 25° C., but the circulation is maintained by separate pumps in each circuit until the desired temperature is reached. The patient's own lungs are used for oxygenating the blood. At these low temperatures the circulation can be safely stopped for forty-five to sixty minutes.

(*d*) *Left Heart By-Pass.*—Left atrio-femoral or left heart by-pass is a useful technique which facilitates operations on the thoracic aorta. The left atrium is cannulated and blood diverted with a pump into the femoral artery (fig. 801). The aorta can now be cross-clamped and the left ventricle continues to supply the head and upper extremities with blood whilst the by-pass caters for the lower limbs and abdominal viscera.

THE PERICARDIUM

Cardiac Tamponade.—A rapid accumulation of fluid in the pericardial sac will compress the heart and prevent diastolic filling; this results in an increase of the venous pressure and a reduction of the cardiac output. Occurring rapidly (e.g. after injuries or cardiac surgery), it produces a shock-like state and if not relieved may prove fatal. The cardiac dullness and silhouette are enlarged and the heart sounds weak; the jugular venous pressure is raised and the pulse may be paradoxical (weaker on inspiration). Immediate relief can be obtained by aspiration but, if symptoms recur, pericardial exploration will be required.

Aspiration of the Pericardium.—The pericardium should be explored with a short-bevelled needle introduced alongside the xiphoid process in an upward and backward direction with the needle at an angle of 45 degrees to the skin. This site has the following advantages:

(*a*) It does not transgress the pleura.

(*b*) It is more likely to encounter fluid which frequently gravitates between the diaphragm and the heart.

(*c*) It is less likely to damage the coronary vessels.

Acute Pericarditis.—Purulent pericarditis is now a rare complication of septicæmia, pyæmia, pneumonia or empyema. Signs and symptoms may be vague, consisting of fever, tachycardia or retrosternal pain. A friction rub may be heard and felt. X-rays may show a large pear-shaped cardiac outline, whilst the electrocardiograph shows a characteristic elevation of the S-T segment. The pericardium should be aspirated and suitable antibiotics injected. Drainage of the pericardium is required if aspirations prove ineffective in controlling the infection.

Chronic Pericarditis (Constrictive Pericarditis; Pick's Disease).—In this condition there is marked thickening, fibrosis and calcification of the pericardium which confines the heart in a rigid inelastic casing preventing it from filling in diastole and emptying in systole. The majority of cases are a sequel to a tuberculous pericarditis, but occasional cases follow purulent pericarditis or a traumatic hæmopericardium.

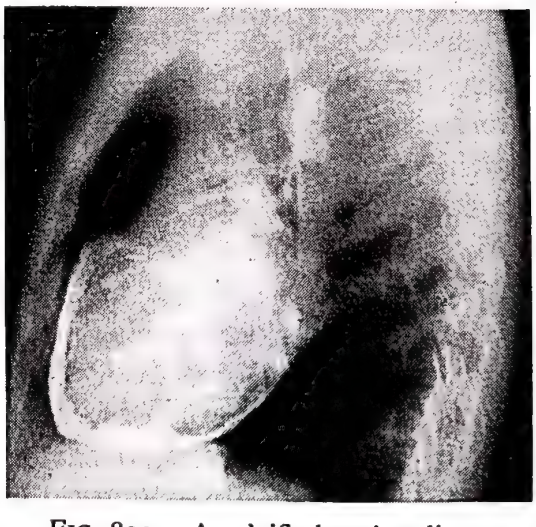

FIG. 802.—A calcified pericardium.

Hæmodynamics. — Decreased diastolic filling leads to an accumulation of blood on the venous side. The jugular veins are engorged, pleural effusions may occur, the liver is enlarged, and ascites and œdema of the ankles may appear. On the arterial side, the blood pressure is low with a small

Friedel Pick, 1876–1926. Professor of Laryngology, Prague, Czechoslovakia. Described this disease in 1896.

pulse volume due to a reduced cardiac output. Fluoroscopy shows decreased or absent cardiac pulsation and pericardial calcification is commonly seen (fig. 802).

Treatment.—Surgical removal of the constricting pericardium is the only effective treatment; this will allow the heart to fill and empty normally.

The patient should be prepared by salt and water restriction, diuretics, and aspiration of pleural or ascitic fluid. At operation (pericardectomy) it is essential to remove the thickened pericardium from the ventricles, but thickened or calcified plaques covering the atria or venæ cavæ should also be removed (Holman).

CONGENITAL HEART DISEASE

Approximately six babies in every thousand live births have a congenital cardiac abnormality. Many are severe and complicated so that survival beyond a few weeks or months is unlikely. Of those who do survive infancy, the expectation of life is often markedly reduced so that surgical correction is desirable wherever possible.

The lesions are divided into those associated with a normal arterial oxygen saturation (acyanotic group) and those with reduced saturation (cyanotic group).

Acyanotic Congenital Heart Disease

I. PATENT DUCTUS ARTERIOSUS

This is one of the commonest abnormalities, accounting for 15 per cent. of all types. It may occur as an isolated condition (simple patent ductus) or as part of a more complex abnormality (complicated patent ductus). The mechanism of normal closure of the ductus and the causes of patency are not fully understood.

Hæmodynamics—The ductus connects the left pulmonary artery with the aorta just distal to the origin of the left subclavian artery. As the pressure is higher in the aorta than in the pulmonary artery, blood will flow from the former into the latter vessel. As much as 10 to 20 litres of blood per minute, representing two to four times the normal cardiac output, can flow through a patent ductus. On the systemic side, the systolic blood pressure rises and the diastolic pressure falls, producing a water-hammer or collapsing pulse. The amount of blood in the lungs is markedly increased and the pulmonary vessels are dilated (pulmonary plethora) and their pulsation increased (hilar dance). The additional circulation of blood through the lungs and the left side of the heart results in left ventricular hypertrophy.

Clinical Features.—Many cases are only discovered on routine examination in childhood, but a minority give rise to cardiac failure during the first year. Soon after birth, when the pressures in the pulmonary and systemic circuits are nearly equal, only a systolic murmur is audible and diagnosis is difficult. As the child grows, the difference between pressures increases and the typical continuous machinery murmur develops; this is best heard in the second and third spaces to the left of the sternum. Breathlessness on exertion and retardation of growth may be present in childhood, but symp-

Emile Frederic Holman, Contemporary. Professor of Surgery Emeritus, Stanford University, San Francisco, California, U.S.A.

toms are often absent until complications ensue. Fluoroscopy shows enlargement of the left ventricle with markedly enlarged pulsatile pulmonary arteries. The diagnosis is usually obvious from the presence of the continuous murmur, an increased pulse pressure with a water-hammer pulse, and the X-ray findings. Atypical cases should be investigated by cardiac catheterisation.

Complications.—(1) *Cardiac Failure.*—This is the most important complication especially in infants and probably accounts for one-third of the deaths. Failure is preceded by progressive cardiac enlargement.

(2) *Bacterial Endocarditis.*—Before the advent of antibiotics this was a frequent and fatal complication accounting for one-third of all deaths. Chemotherapy now permits control of the majority, but relapse is likely unless the ductus is ligated.

Prognosis.—The outlook for a simple patent ductus is difficult to determine. The disease is common in children and rare in adults. It is unlikely that a patent ductus ever closes spontaneously, and it must be assumed that some patients die from cardiac failure in early adult life.

Treatment.—The results of surgical closure are so satisfactory and the mortality rate is at such a level (less than 2 per cent.) that ligation can be recommended in all cases. Recanalisation is rare. Division and suture is practised by Gross and others in order to reduce the risks of recanalisation, but is probably only necessary for the short wide ductus which cannot be safely ligated.

The operation is carried out through a left-sided postero-lateral incision through the fourth space. The mediastinal pleura is incised over the aortic arch and the vagus nerve and its recurrent branch are retracted posteriorly. The areolar tissue is removed from the surface of the ductus and the latter gently mobilised by blunt dissection. Occlusion is achieved by using two stout non-absorbable ligatures placed at either end of the ductus with a transfixion ligature between (Blalock).

II. COARCTATION OF AORTA

Narrowing of the aorta may occur at any site, but, in the vast majority of cases, the stenosis lies immediately beyond the origin of the left subclavian artery in close relationship to the ductus or ligamentum arteriosum. The lesion accounts for 6 per cent. of all congenital cardiac anomalies.

Two main types are described according to the relationship of the ductus to the coarctation:

(1) **Post-ductal Type. Adult Coarctation.**—Sixty per cent. of all cases are of this type. The ductus is patent in a minority and enters the aorta above the coarctation. The stenosis is abrupt with an internal lumen of 1 to 2 mm. Externally the aorta shows a characteristic indentation.

(2) **Pre-ductal Type. Infantile Coarctation.**—Here a patent duct enters the aorta below the coarctation. Unoxygenated blood may pass from the pulmonary artery into the aorta and thence to the lower trunk and extremities. These areas are cyanosed, whilst the head, neck and upper extremities are pink (differential cyanosis). The stenosed aortic segment may be long and include one or more of the great vessels. Forty per cent. of patients have other cardiac lesions. The mortality in the first year of life is considerable.

Clinical Features.—The obstruction results in hypertension above and

Robert Edward Gross, Contemporary. Ladd Professor of Children's Surgery, Harvard University, Boston, Massachusetts, U.S.A.
Alfred Blalock, 1899–1964. Professor of Surgery, Johns Hopkins University, Baltimore, Maryland, U.S.A.

hypotension below the constriction with collateral vessels linking the two areas. Symptoms can be divided into three groups :

(1) Those of hypertension above the block; headaches, irritability, excessive heart action, throbbing and pulsation in head and neck.

(2) Those due to hypotension below the block; cold legs and intermittent claudication.

(3) Complications secondary to hypertension; left ventricular failure, intracranial hæmorrhage, rupture of the aorta.

Characteristically there is marked pulsation of the carotid and subclavian arteries with evidence of left ventricular enlargement. Systolic murmurs are frequently audible over the præcordium and elsewhere over the thorax, due usually to the collateral vessels, although sometimes caused by associated aortic valve disease. Blood pressure in the arms is considerably elevated. Collateral vessels can be seen and felt over the thorax, particularly in the scapular region. Femoral, dorsalis pedis and posterior tibial pulses may be absent or weak. The femoral pulse, if present, is delayed when compared with the radial. Oscillometry reveals defective pulsation in the lower limbs. X-rays show evidence of left ventricular enlargement, a prominent ascending aorta and an absent or abnormal aortic knuckle (fig. 803).

FIG. 803.—Coarctation of aorta showing a prominent ascending aorta, double aortic knuckle and rib notching.

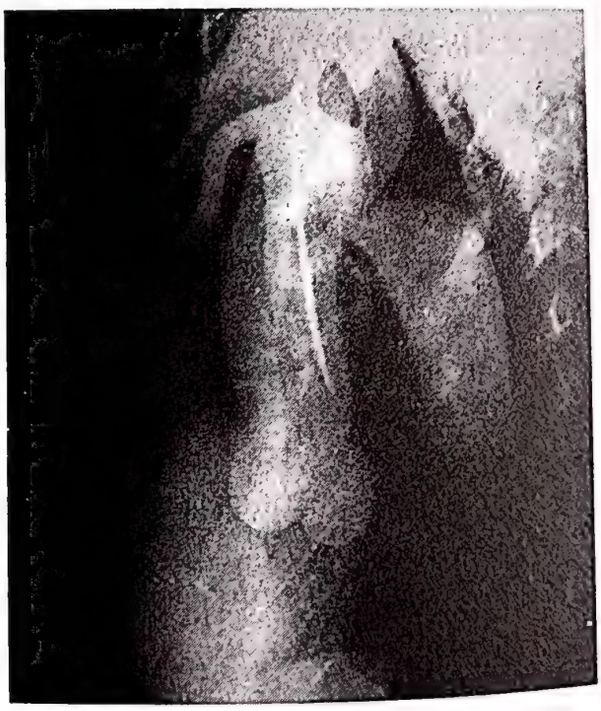

FIG. 804.—Coarctation of aorta. Aortogram showing the stenosis and the marked collateral vessels.

Notching of the ribs due to large tortuous intercostal vessels is seen in adults but rarely in children.

Investigations.—Venous angiocardiography or retrograde aortography (fig. 804) are employed to demonstrate the actual site and type of the coarctation, but these investigations are by no means essential pre-operatively if an aortic graft is available at the time of operation.

Prognosis.—The condition is a serious one and it is estimated that very

few patients survive beyond the age of forty-five years; the majority die from the effects of hypertension.

Treatment.—Both Crafoord and Gross independently in 1945 demonstrated that the stenosis could be excised and an end-to-end anastomosis safely performed. The operation is now a well-accepted one and the mortality should not be above 10 per cent. In the majority, excision with an end-to-end anastomosis is possible. Occasionally a graft is required to bridge a wide defect in cases with a long hypoplastic segment or with a post-stenotic aneurysm. Aortic homografts were originally employed but they calcify and narrow with age and have been superseded by grafts of crimped Teflon or Dacron (p. 134). All children and young adults should be operated upon. The results in children are excellent with the blood pressure usually returning to normal. In adults the blood pressure rarely falls to normal levels but the reduction is nevertheless important; symptoms are relieved and the risks of serious or fatal complications reduced.

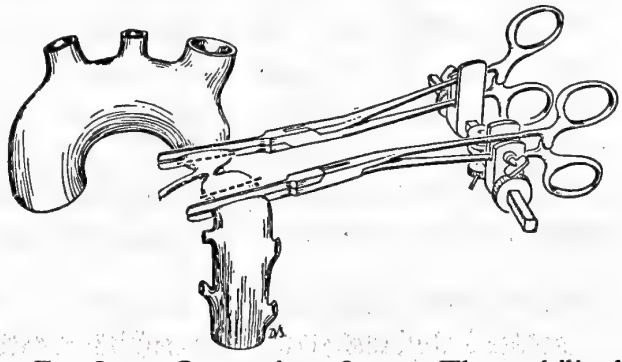

FIG. 805.—Coarctation of aorta. The mobilised aorta is clamped prior to excision and anastomosis. The clamps are held in position with the adjustable Brom's Vice.

The operation is carried out through a left postero-lateral incision through the fourth intercostal space. The large anastomotic vessels in the chest wall are ligated. The aorta is mobilised widely both above and below the constriction, great care being taken not to injure the large thin-walled intercostal and mediastinal vessels arising from the distal segment. The ligamentum arteriosum is divided: the aorta is clamped above and below the constriction and the latter excised (fig. 805). An end-to-end anastomosis is performed using a fine (000 or 0000) eversion suture. The clamps should be released slowly and any leak from the suture-line controlled by pressure.

Results of the Operation.—The over-all mortality rate for all cases is under 10 per cent., but in children it is considerably lower. A normal blood pressure in both upper and lower limbs is usual in children; in adults some elevation in blood pressure usually persists, but the pressure in the lower limbs often rises above that in the upper limbs and the femoral pulse is no longer delayed. Relief of symptoms is the rule.

III. CONGENITAL VALVAR ABNORMALITIES

Developmental abnormalities can occur with any of the valves, resulting in stenosis, regurgitation or combined lesions. Less frequently obstruction may occur in the subvalvar region.

Stenotic lesions in the pulmonary or aortic valves are commonest (all other varieties are rare). Classically the commissures are fused to form a dome-shaped valve with a small central orifice. Bicuspid valves and other complex varieties are not uncommon. The stenotic valve produces an ejection systolic murmur and thrill and evidence of Right (pulmonary stenosis) or Left (aortic stenosis) Ventricular Hypertrophy.

Both lesions can be corrected by open operation with heart-lung bypass with good results. The operation of closed pulmonary valvotomy (Brock) is rarely employed now.

Gerard Brom, Contemporary. Academisch Ziekenhuis, Leiden, Holland.
Russell Claude Brock (Lord Brock of Wimbledon), Contemporary. Director, Department of Surgical Sciences, Royal College of Surgeons of England, London.

IV. ATRIAL SEPTAL DEFECT

Defects of the septum between the atria account for 7 per cent. of congenital cardiac anomalies; they allow blood to flow from the left to the right atrium (L–R shunt) so that the right side of the heart and lungs are overfilled whilst the left side receives less blood than usual. Although the deformity may cause little disability during childhood and early adult life, it is a serious condition with troublesome symptoms appearing in middle life associated with the onset of atrial fibrillation.

Signs are due to over-filling and -activity of the right side of the heart and lungs. The right ventricle is palpably enlarged and active. The pulmonary arteries are dilated and actively pulsatile (hilar dance) and increased flow produces a pulmonary systolic murmur. The second heart sound is widely split due to bundle branch block. The E.C.G. shows right bundle branch block and right ventricular hypertrophy.

Closure of the defect is readily performed by direct suture under vision with the aid of hypothermia or extracorporeal circulation.

The more complicated atrial defects (ostium primum: atrio-ventricular canal) can be corrected but the risks of operation are higher.

V. VENTRICULAR SEPTAL DEFECT

Isolated defects of the ventricular septum are one of the commonest congenital lesions (22 per cent.). In addition, they occur frequently as part of certain complex anomalies (Fallot's tetralogy, transposition, etc.).

The defect is usually 1 to 3 cm. in diameter, most often situated in the fibrous part of the septum close to the aortic and tricuspid valves.

The defect allows the passage of blood from the left to the right ventricle resulting in over-filling of the right heart, pulmonary plethora and hypertension.

The lesion is a serious one, over 50 per cent. of patients dying during the first few months of life.

The defect can be repaired with the aid of an extracorporeal circulation or deep hypothermia using either direct sutures or inserting a patch of Dacron or pericardium.

The operative mortality is 10 per cent., and the most serious complications are due to the production of complete heart block or incomplete closure of the defect. In infants a stout ligature can be applied around the pulmonary artery (pulmonary banding) to restrict the flow of blood into the lungs. Closure of the defect and removal of the pulmonary artery band is carried out at a later date.

Cyanotic Congenital Heart Disease

The cyanotic heart lesions include a number of different abnormalities, the commonest of which is Fallot's tetralogy (fig. 806). The abnormalities are multiple and complex and often difficult to determine accurately, but all have central cyanosis due to an intracardiac shunt from the right to the left side. From the surgical point of view the state of the pulmonary cir-

Etienne Louis Arthur Fallot, 1850–1911. Professor of Medicine, Marseilles, France.

culation is by far the most important consideration. If this is defective (pulmonary ischæmia), then surgical means can be taken to improve it and thereby increase exercise tolerance and decrease cyanosis. If, however, the lungs are overfilled (pulmonary plethora), or the pressure considerably raised (pulmonary hypertension) it may be difficult or impossible to carry out a corrective procedure with safety. The exact type of surgical procedure will depend on obtaining accurate anatomical details of the abnormality by angiocardiography and cardiac catheterisation.

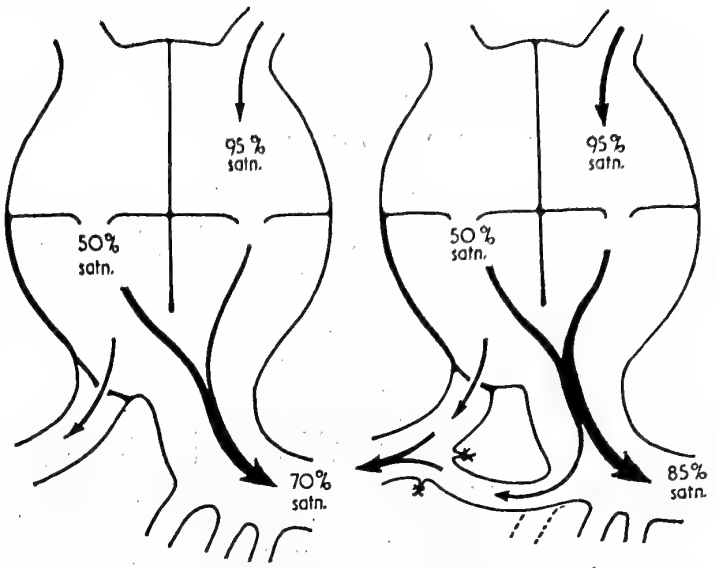

FIG. 806.—Hæmodynamics of Fallot's tetralogy before and after Blalock's operation. Note the ventrivular septal defect, the over-riding aorta, pulmonary stenosis and right ventricular hypertrophy which make up the tetralogy (cf. fig. 798).

Fallot's Tetralogy

This is the commonest of the cyanotic conditions and accounts for about 10 per cent. of all cases of congenital heart disease.

The tetrad originally described by Fallot in 1888 consists of (1) stenosis of the pulmonary tract; (2) a ventricular septal defect; (3) an aorta which straddles the ventricular defect and over-rides both ventricles and (4) right ventricular hypertrophy.

The patient is usually undersized and mentally retarded, with central cyanosis and finger clubbing. The heart is small and quiet and there is a systolic murmur and thrill in the pulmonary area. All degrees of severity are encountered from those who are only cyanosed with exercise, to others who are deeply and permanently cyanosed in whom the arterial oxygen saturation rarely rises above 60 per cent. The mortality in infancy in this latter group is considerable, but those of less severity may survive into adult life.

All patients require careful investigation with cardiac catheterisation, angiocardiography and dye studies to provide accurate anatomical details of the lesion and indicate the most favourable type of operation.

Fallot's Tetralogy is capable of complete surgical correction and this should be the aim in every case. However, in the very young and in those patients with hypoplastic right ventricular outflow tract some surgeons advise a palliative anastomotic operation designed to increase the pulmonary blood flow, to improve the patient's clinical condition and perhaps help the hypoplastic outflow tract to develop. Definitive total correction would then be carried out at a later date.

(1) **Anastomotic Procedures.**—These aim at increasing the blood flow to the lungs by creating a shunt between the aorta or one of its branches and the pulmonary artery. The Blalock operation is the most popular and consists of an anastomosis between the left subclavian artery and the left pulmonary artery

A left posterolateral thoracotomy through the fourth space gives good access. The left pulmonary artery is mobilised and doubly clamped as it lies in the lung hilmn. The left subclavian artery is fully mobilised and divided near the first rib. The proximal end of the subclavian is then anastomosed to the upper border of the pulmonary artery (fig. 807). A continuous thrill can be felt over the anastomosis on releasing the clamps.

Alternative anastomotic procedures are available where a Blalock operation cannot be done or in infants. Descending aorta—left pulmonary artery (Potts), ascending aorta—right pulmonary artery (Waterston–Cooley) or superior vena cava—right pulmonary artery (Glenn) are those most frequently employed.

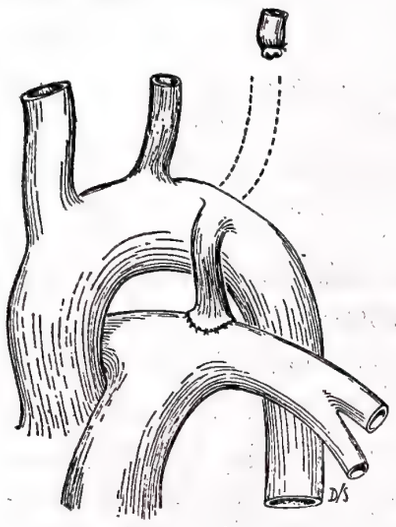

FIG. 807. — Subclavian-pulmonary anastomosis (Blalock) for Fallot's tetralogy.

(2) **Complete Correction.**—This should be considered in every case but may be deferred in infants and the more severe examples where palliative anastomotic procedures are performed initially.

The operation is carried out under cardio-pulmonary bypass with additional hypothermia. The ventricular septal defect is closed with a Dacron patch. The pulmonary valvar and infundibular obstruction is relieved and an out-flow tract patch of Dacron inserted to enlarge the tract if necessary.

The operative mortality is about 10%. The results of total correction are dramatic and gratifying. Long term follow-up demonstrates continued good health.

TRANSPOSITION OF THE GREAT VESSELS

After Fallot's tetralogy this is the next most common cause of cyanotic congenital heart disease. The aorta arises from the right ventricle and the pulmonary artery from the left ventricle. The greater and the lesser circulations are thus separated and life is only possible if there is a communication between the two through an atrial or a ventricular defect or a patent ductus arteriosus. Death in the neonatal period is common due to inadequate communications between the circuits.

The child is deeply cyanosed and severely incapacitated. The lungs may be plethoric or oligæmic depending on associated pulmonary stenosis. Diagnosis is confirmed by cardiac catheterisation and angiocardiography.

Management in infancy is aimed at improving the shunting between the circuits by creating or enlarging an atrial defect. This is effected in infants by rupturing the septum with a balloon catheter passed transvenously through the foramen ovale (Balloon Septostomy: Rashkind). Alternatively, portions

Willis John Potts, 1895–1968. Surgeon, Children's Memorial Hospital, Chicago, Illinois, U.S.A.
David James Waterston, Contemporary. Surgeon, Hospital for Sick Children, Great Ormond Street, London.
Denton A. Cooley, Contemporary. Professor of Surgery, Baylor University, Houston, Texas, U.S.A.
William W. L. Glenn, Contemporary. Professor of Surgery, Yale University, New Haven, Connecticut, U.S.A.
William Jacobson Rashkind, Contemporary. Surgeon, Children's Hospital, Philadelphia, Pa., U.S.A.

of the septum can be excised by the technique of Blalock and Hanlon. If the child survives the first year with or without surgical aid a more radical correction can be contemplated, either by an ingenious transposing of the atria developed by Mustard, or a re-alignment of the arteries as described by Rastelli.

ACQUIRED HEART DISEASE

Inflammatory and degenerative changes are responsible for the majority of the acquired lesions of surgical interest although cardiac injuries and tumours constitute a small but important group. Rheumatism has a predilection for the aortic and mitral valves, syphilis for the aortic valve and aortic wall, whilst degenerative lesions are frequent in the aortic valve, coronary vessels and myocardium.

Mitral Stenosis

Mitral valvulitis is the commonest sequel of rheumatic carditis. The original attack of rheumatism may be so mild as to pass unnoticed. Only half the patients with mitral stenosis give a history of rheumatic fever or chorea. The condition affects women more frequently than men, and symptoms are commonest during the third and fourth decades.

Pathology.—The cardiac manifestations of rheumatism are widespread with involvement of all three layers, but it is mainly the mitral and aortic valve involvement which leads to later disturbances. The essential lesion is the Aschoff nodule. These produce swelling and roughening of the valve cusps and fibrin is deposited on the roughened surfaces. Later organisation with fibrosis and calcification may occur. As a result the valve leaflets become fused, thickened, rigid and immobile. All grades are encountered from simple fusion of the commissures and mild fibrosis (but with preservation of mobility) to grossly calcified, fixed and functionless valves. The valve orifice is oval or slit-like with an average opening of 1 cm. in its long axis in those patients submitted for operation.

Clinical Features.—These can be considered briefly under four headings:

(1) Those due to a low cardiac output: tiredness, shortness of breath on exertion, a small volume pulse and pale, cold extremities.

(2) Those due to disturbances of the pulmonary circulation: exertional dyspnœa, pulmonary œdema, nocturnal dyspnœa or asthma, hæmoptysis and bronchitis.

(3) Those due to failure of the right ventricle: congestive failure heart with engorged veins, large liver, ascites and œdema.

(4) Systemic embolism from clot dislodged from the left atrial appendage.

In all cases a full cardiological examination and investigation are required, not only to confirm the diagnosis but to determine the presence or absence of other cardiological abnormalities (fig. 808).

Indications for Operation.—Every case of mitral stenosis with symptoms which are beginning to cause inconvenience should be carefully considered from the point of view of operation.

The following factors will influence any decision regarding surgical treatment:

(1) **Active Carditis.**—Any suggestion of active rheumatic carditis constitutes an

Cyril Rollins Hanlon, Contemporary. Professor of Surgery, St. Louis University Hospitals, Missouri, U.S.A.
William T. Mustard, Contemporary. Associate Professor of Cardiovascular Surgery, Hospital for Sick Children, Toronto, Canada.
Gian Carlo Rastelli, 1934–1970. Consultant in Cardiovascular Surgical Research, Mayo Clinic, Rochester, Minn., U.S.A.
Karl Albert Ludwig Aschoff, 1866–1942. Professor of Pathology, Freiburg, Germany. Described the Aschoff nodule in 1904.

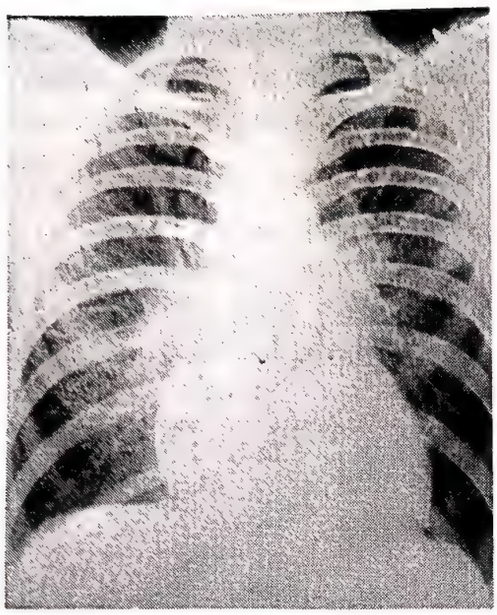

FIG. 808.—Mitral stenosis showing enlargement of the 'pulmonary bay' and the pulmonary arteries.

absolute, but temporary, contraindication to surgical treatment. Such evidence as fever, a raised E.S.R., unexplained tachycardia, unexplained recent cardiac enlargement, and a recent history of respiratory infection and joint pains all call for a postponement of operation.

(2) **Age.**—The ideal age for operation lies between twenty and fifty; below twenty the chances of further rheumatic activity are appreciable, and surgery should be delayed if practicable, but should never be withheld in severe cases. Over the age of fifty it is important to make sure that symptoms are due to mitral stenosis and not the result of myocardial ischæmia, hypertension, bronchitis and emphysema, etc.

(3) **Other Valve Abnormalities.**—Aortic stenosis, aortic incompetence, and mitral incompetence may be associated with mitral stenosis. They produce left ventricular hypertrophy which does not occur with uncomplicated mitral stenosis. Diagnosis and assessment in these cases with multiple valve lesions is sometimes extremely difficult and may require elaborate investigations. Where mitral stenosis is the dominant lesion, mitral valvotomy should be carried out, but if other valvular lesions are playing a significant part in the dynamics and symptomatology, mitral valvotomy alone may give disappointing results.

(4) **Mobility of the Mitral Valve.**—Best results are obtained when the mitral valve is still mobile where, after valvotomy, reasonable restoration of function can be expected. A mobile valve is suggested by marked accentuation of the first sound at the apex, and the presence of an opening snap. Rigidity is suggested by a poor first sound, the absence of an opening snap and calcification of the mitral valve. Echocardiography (p. 736) provides valuable information about the mobility and thickness of the valve.

(5) **Atrial Fibrillation.**—The operative risks are slightly higher, and the postoperative results slightly inferior in cases with atrial fibrillation. This is probably merely an indication of more severe myocardial damage in these cases.

(6) **Embolism.**—The majority of emboli are associated with atrial fibrillation; they constitute a severe complication and account for a significant number of deaths. Cerebral, aortic bifurcation and femoral emboli are both frequent and serious. Multiple emboli are common and the chances of further emboli increase steeply with each incident. In the majority of instances the clots develop in the left atrial appendage. Valvotomy is urgently indicated to relieve stagnation in the left atrium with the removal of the appendage at the same time.

(7) **Pregnancy.**—Mitral valvotomy should always be considered in cases where symptoms of mitral stenosis are aggravated by pregnancy. Mild cases can usually be nursed through pregnancy without difficulty, though there are risks of pulmonary œdema and serious pulmonary hæmorrhage even in these cases. More severe cases within the first three months of pregnancy can be treated by abortion or valvotomy, but after three months mitral valvotomy is preferable to termination of the pregnancy. After the seventh month of pregnancy, the chances of continuing to term are reasonable with rest, etc., and mitral valvotomy can be deferred until after delivery. Sterilisation should never be considered until the possibility of relief by valvotomy has been fully explored.

(8) **Size of Heart.**—The size of the heart, and particularly the size of the right ventricle, indicates the degree of strain thrown upon the heart and also the state of the myocardium. Operative risks in patients with large hearts are considerable, and even should a successful valvotomy be performed, subsequent improvement may be disappointing unless the myocardium is capable of considerable recovery.

(9) **Congestive Heart Failure.**—Persistent congestive heart failure is an indication that the heart has broken down completely and is unlikely to improve if a valvotomy is performed. The operative risks are high in this group.

MITRAL VALVOTOMY

Careful pre-operative preparation, with a period of rest, fluid and salt restriction, diuretics and breathing exercises is necessary. All cases should be digitalised as there is a 30 per cent. risk of atrial fibrillation developing in the post-operative period in cases in normal rhythm. Bronchopulmonary infections should be relieved by antibiotics. Patients with a history of embolism and those with pulmonary hypertension should be given oral anticoagulants for several weeks before operation. The anticoagulants should be continued through the operation into the postoperative period. The valvotomy may be done as an open or a closed procedure.

Closed Valvotomy.—A good result from a closed valvotomy can be expected where the valve is mobile and neither thickened nor calcified. Regurgitation should be absent and the patient in sinus rhythm. The operation is carried out through a left antero-lateral thoracotomy. The valve is split with an expanding dilator (Tubbs) inserted through a stab wound in the apex of the left ventricle with the right index finger inserted into the left atrium through its appendage to control the split. The appendage is amputated at the end of the procedure to minimise risk of embolism.

Open Valvotomy.—This is carried out with the aid of cardiopulmonary bypass through a sternal splitting incision. The mitral valve is exposed with an incision in the atrial groove. The fused commissures are carefully incised. The valve is tested for competence by filling the left ventricle with blood. If adequate relief of stenosis is not possible or if regurgitation is produced, the valve should be excised and replaced with a prosthesis.

In the post-operative period the most troublesome complications are :

(1) Systemic embolism.
(2) Suppurative bronchitis.
(3) Cardiac failure.
(4) Pulmonary embolism.
(5) Disorders of rhythm.

All peripheral vessels should be palpated at the end of operation to exclude embolism. Occlusion of one of the major vessels should be treated by immediate embolectomy (p. 143); involvement of smaller vessels is treated by antispasmodics (papaverine, Priscol) and by keeping the affected part locally cool and producing reflex vasodilatation by warming the rest of the body. The majority of emboli occur at the time of operation; late embolism is uncommon.

Active breathing and coughing exercises are started early and full mobility in bed is encouraged. Bronchitis should be treated vigorously with postural coughing and antibiotics. A close watch is kept on the fluid balance; if water retention occurs, if the venous pressure rises or if pulmonary œdema is imminent, diuretics should be given.

Troublesome tachycardia may develop and is usually a sign of underdigitalisation. Small repeated doses of digoxin intravenously will usually control it. Ventricular ectopics may be caused by a low serum potassium

Oswald Sydney Tubbs, Contemporary. Formerly Cardiothoracic Surgeon, St. Bartholomew's Hospital, London.

(hypokalæmia). If confirmed, small doses (10–20 mEq.) are given slowly intravenously.

Results of Treatment.—The operative mortality in reasonable cases should not be above 5 per cent., representing the accidents and irreducible hazards of the operation (cerebral embolism, cardiac arrest, auricular tears). Good results are obtained in 75 per cent. of all cases. The majority of the poor results are due to the production of mitral incompetence. About 2 per cent. of patients per annum develop signs of re-stenosis. A second valvotomy should be carried out in favourable cases. In patients with a rigid or calcified valve or where there is additional mitral regurgitation valve replacement is recommended.

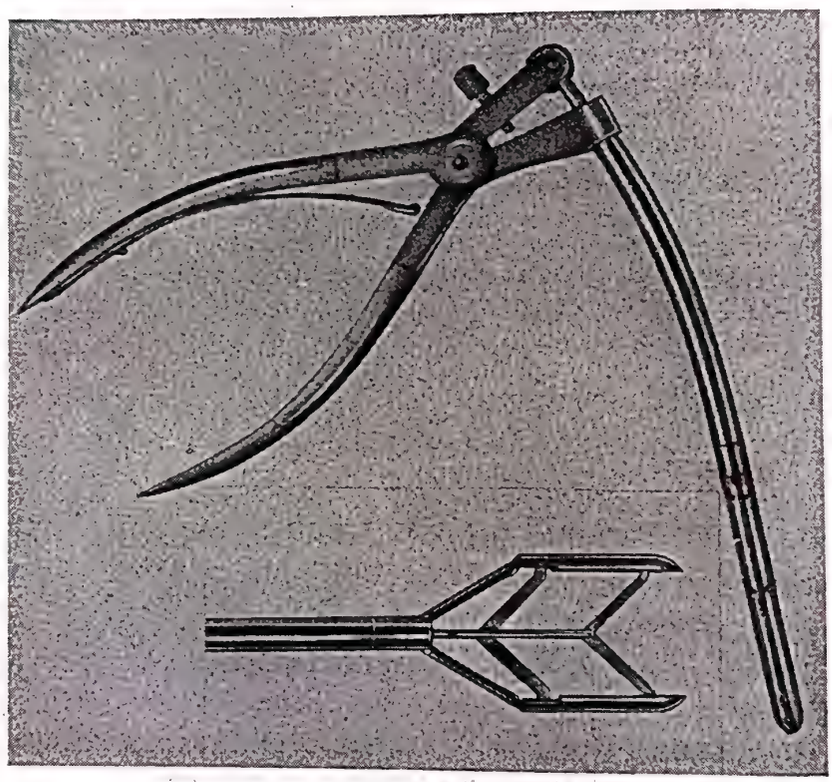

FIG. 809.—Transventricular adjustable mitral valve dilator. (*Tubbs.*)

Mitral Regurgitation

This may occur as an isolated lesion or more commonly in association with stenosis. A proportion complicate valvotomy for mitral stenosis and the remainder are developmental in origin.

The lesion impedes the forward flow of blood from the left ventricle leading to left ventricular hypertrophy and pulmonary venous congestion.

Repair of an incompetent valve by annular plication (Wooler) is possible provided there is good cusp mobility and normal chordæ tendinæ. Otherwise excision of the valve and replacement is necessary.

Mitral Valve Replacement.—The approach is similar to that for open valvotomy. The valve and subvalvar papillary muscles and chordæ are excised. A prosthesis is sewn securely into the rim of the valve with multiple mattress sutures. Mechanical valves of the ball valve (Starr) or disc valve (Björk) type are commonly used. Porcine aortic valve heterografts mounted

Geoffrey Hubert Wooler, Contemporary. Thoracic Surgeon, General Infirmary, Leeds, England.
Albert Starr, Contemporary. Professor of Surgery, University of Oregon, Portland, Oregon, U.S.A.
Viking Olaf Björk, Contemporary. Cardiac Surgeon, Karolinska Sjukhuset, Stockholm.

on a metal frame are being used increasingly. Long term anticoagulation is required for mechanical valves to reduce the risks of thrombo-embolism. The operative mortality is 10% and the long term results are good provided that the heart has not failed prior to replacement.

Aortic Valve Disease

The aortic valve may be affected by developmental, inflammatory or degenerative processes, resulting in stenosis, incompetence or combined lesions.

Aortic Stenosis.—The obstruction impedes the forward flow of blood from the left ventricle producing angina, syncope and effort dyspnœa. The left ventricle is hypertrophied and a coarse systolic murmur and thrill are discernible in the aortic area. The arterial pulse is slow-rising and sustained (anacrotic or plateau pulse) and the pulse pressure is small.

The lesion is serious; children are liable to sudden death and adults with symptoms have a life expectancy of only a few years.

Surgery, with the aid of extracorporeal circulation, plays an important role in the management of the condition. *Open valvotomy* with division of fused commissures is often possible in children. *Valve replacement* will be required for grossly destroyed or heavily calcified valves.

Aortic Regurgitation.—A leaking aortic valve produces considerable left ventricular dilatation in addition to hypertrophy. Symptoms are similar to those of aortic stenosis. In addition to an aortic systolic murmur, a diastolic murmur is audible along the left sternal edge. The pulse is characteristically quick rising (Corrigan or water-hammer) with a high systolic and low diastolic pressure resulting in a large pulse pressure.

Isolated cases are capable of correction by suture (tears) or patching (perforations), but the majority are best treated by excision and replacement.

FIG. 810. — Starr-Edwards ball valve aortic prosthesis.

Aortic Valve Replacement.—This is carried out with the aid of heart lung bypass through a sternal splitting incision. The valve is exposed with an incision in the aortic root after cross-clamping the aorta. The coronary arteries are cannulated and perfused by the heart-lung machine to protect the myocardium from ischæmia. Alternatively the heart can be cooled to 15° C. The valve is carefully excised and calcium dissected from the valve ring. The prosthesis is sutured to the valve ring with interrupted mattress sutures. The surgeon has a choice of mechanical valves—Starr Ball Valve (fig. 810) or Bjork Disc Valve, a free homograft (Ross and Barrett Boyes) or mounted heterograft.

Cardiac Tumours

Tumours of the heart are relatively uncommon; they may occur in the ventricle or atrium. The commonest is the myxoma of the atrium

Sir Dominic John Corrigan, 1802–1880. Physician, Jervis Street Hospital, Dublin. Described the water-hammer pulse of aortic incompetence in 1832.
Donald Nixon Ross, Contemporary. Thoracic Surgeon, Guy's Hospital, London.
Sir Brian Barratt-Boyes, Contemporary. Thoracic Surgeon, Auckland, New Zealand.

(80 per cent. of all tumours) and of these the majority (75 per cent.) occur in the left atrium.

Left atrial myxomas simulate mitral stenosis; they obstruct the flow of blood through the left atrium producing pulmonary venous engorgement and hypertension. Systemic embolism and postural syncope are important symptoms.

The condition simulates mitral stenosis but is distinguished from it by a shorter and more progressive history, evidence of toxicity (fever, raised E.S.R., anæmia) and disturbances of plasma proteins and by ultra-sound (echo-cardiography, p. 736).

The lesion can be demonstrated by angiography, and can be completely removed with the aid of an extracorporeal circulation.

Disorders of Rhythm

Heart block or complete atrio-ventricular dissociation may occur as a manifestation of certain congenital cardiac lesions, as a complication of ischæmic heart disease or the result of surgical treatment of ventricular or allied defects. In all cases, the atrial impulse fails to reach and stimulate the ventricle owing to interference with the conduction of the bundle of His. The ventricles beat independently at a rate of 25 to 50 per minute.

The dangers of this situation are three-fold:

(*a*) The slow rate impairs cardiac output and may lead to heart failure.

(*b*) A sudden slowing or cessation of the beat may produce syncope or death (Stokes-Adams attacks).

(*c*) A sudden change from sinus rhythm to heart block may produce syncope.

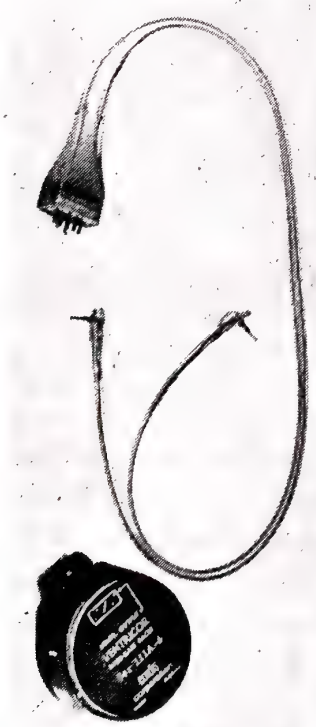

FIG. 811.— Battery-operated implantable pacemaker.

Although the ventricular rate can sometimes be increased by sympatheticotonic drugs, of which ephedrine and iso-propyl noradrenaline (iso-prenaline) are the most effective, the response to both drugs becomes less with continued use.

Artificial electrical pacemakers have been designed to stimulate the heart at any desired rate. These can be *wholly external* using electrodes applied to the surface of the chest; *wholly internal* with a small implantable battery operated pacemaker (fig. 811), which is buried in the abdominal wall and connected to the myocardial surface by wire electrodes, or *combined internal and external.* In the latter the apparatus is external and the heart is stimulated either by a catheter electrode passed along the external jugular vein into the right ventricle, or by wire electrodes attached to the surface of the ventricle. Artificial pacemakers are designed to work for about three years but failure of the battery, leads or electrodes may occur at any time and demand earlier replacement.

Wilhelm His (Junior), 1863–1934. Professor of Medicine, Berlin. Described the atrio-ventricular bundle in 1893.
William Stokes, 1804–1878. Regius Professor of Medicine, Dublin. Described this condition in 1846, and drew attention to the cases reported by Adams in 1827.
Robert Adams, 1791–1875. Regius Professor of Surgery, Dublin.

Ischæmic Heart Disease

Atherosclerosis of the coronary arteries occurs with increasing frequency in Western civilisation. Between 1951 and 1975 the proportion of deaths in England and Wales due to ischæmic heart disease rose from 10·5% to 26·0% of the total.

Narrowing of the coronary arteries deprives the myocardium of oxygen. When severe enough, chest pain is produced (angina = claudication). Total occlusion results in death of myocardial tissue (infarction = necrosis). Angina thus indicates a serious deprivation of myocardial blood supply which may lead to infarction and death if allowed to progress.

Surgery has a role to play both in the relief of angina by revascularisation of the myocardium and in the management of the complications of infarction.

Full investigations including coronary arteriography are needed before surgery can be considered. A trial of medical therapy including the use of β blockers is desirable before resorting to surgery.

Aorto-Coronary Bypass Graft.—Here a length of autogenous saphenous vein is used to circumvent a narrowed coronary artery. Proximally it is attached to the ascending aorta and distally to the coronary artery beyond the occlusion (fig. 812). Up to five grafts may be required to nourish all ischæmic areas. The main indication for bypass grafting is the relief of angina which cannot be controlled by medical means. Coronary arteriography must show a blocked or stenosed coronary artery near its origin with normal vessel beyond the occlusion. Left ventricular function must be good.

The mortality rate is 3–5% and 80–90% obtain relief of angina.

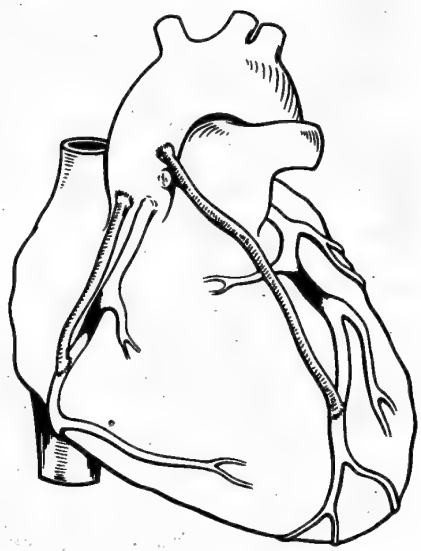

FIG. 812.—Diagrammatic representation of double coronary vein graft to obstructed right coronary artery and left anterior descending.

Left Ventricular Aneurysm.—Myocardial infarction results in death of muscle. Healing is by scar tissue. The scar may stretch and form an aneurysm. The presence of an aneurysm adversely effects the function of the heart and results in heart failure. Fibrin is deposited on the walls of the aneurysm and may be dislodged as an embolus. The aneurysm should be resected under cardiopulmonary bypass and the left ventricle reconstituted by suturing the edges of the aneurysm together.

The operative risks are approximately 10% and prospects of long term survival are quite good.

Other Complications of Infarction.—The interventricular septum or the papillary muscles supporting the tricuspid or mitral valves may be damaged after infarction. Rupture of the septum (acquired VSD) and papillary

muscle dysfunction (mitral or tricuspid regurgitation) may result. Either lesion seriously affects cardiac function but both can be corrected surgically.

AORTIC ANEURYSMS

The surgery of the aorta has made considerable strides since the introduction of aortic grafts and the advent of hypothermia and methods of cardio-pulmonary by-pass. It is now possible to occlude the aorta with safety for reasonable periods, and to bridge considerable defects, so that the two chief deterrents to reconstructive aortic surgery have largely disappeared.

Aortic aneurysms due to syphilis or degenerative changes may be fusiform, saccular (fig. 813) or dissecting. The diagnosis may be straightforward, but is often notoriously difficult, although angio-cardiography has provided a useful diagnostic procedure.

FIG. 813.—Saccular aneurysm of the ascending aorta.

Treatment of Aneurysms.—Insertion of Colt's umbrella and Blakemore's wire and wrapping of aneurysms in polythene has been entirely superseded as methods of treatment by more direct procedures made possible by the use of heart-lung by-pass or left atrio-femoral by-pass. (p. 741).

(1) *Excision and Repair. Aneurysmorrhaphy (Matas).*—Applicable to smaller saccular aneurysms. Consists of excision of the sac with direct suture of the neck. Not applicable to fusiform aneurysm or saccular aneurysms with a wide neck (fig. 814 and also fig. 146).

(2) *Excision and Grafting.*—This involves excision of the aneurysm and adjacent aorta and its replacement with a prosthesis (woven, crimped Dacron) (fig. 815). Heart-lung by-pass is required for aneurysms of the ascending aorta or aortic arch, but the simpler left atrio-femoral by-pass is all that is required for aneurysms of the descending thoracic aorta.

FIG. 814. — Saccular aneurysm. Excision and repair.

(3) *Excision and Plastic Repair.*—The aneurysm is excised and the aortic

George Herbert Colt, 1878–1957. Surgeon, Royal Infirmary, Aberdeen, Scotland.
Arthur Hendley Blakemore, Contemporary. Associate Professor of Surgery, Columbia University College of Physicians and Surgeons, New York, U.S.A.
Rudolph Matas, 1860–1957. Professor of Surgery, Tulane University, New Orleans, Louisiana, U.S.A. (see footnote, p. 138).

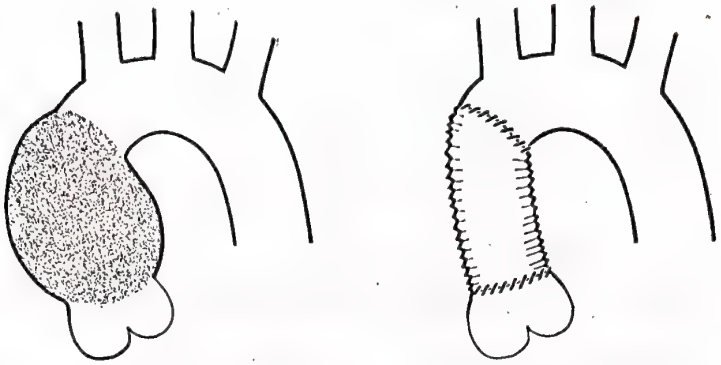

FIG. 815. — Fusiform aneurysm of the ascending aorta. Excision and grafting.

defect is repaired by an insert of woven Dacron (fig. 816). This method is applicable to saccular aneurysms of the aortic arch and avoids the elaborate anastomoses required for replacement of the arch.

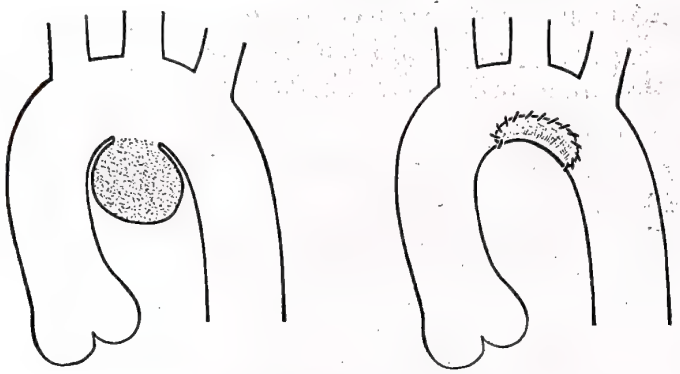

FIG. 816. — Aneurysm of the aortic arch. Localised excision and plastic repair.

Dissecting Aneurysms.—These are produced by a split in the intima and internal portion of the media, allowing blood to enter the media and extend both distally and proximally resulting in a double lumen aorta. The aneurysms may rupture externally or into the pericardium with fatal

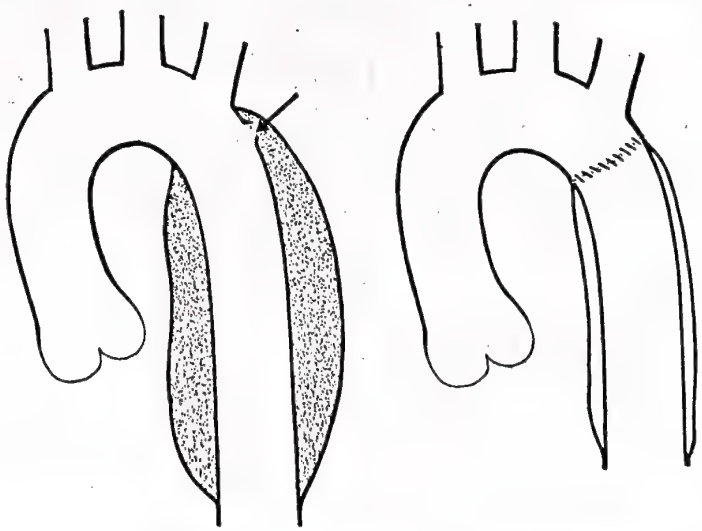

FIG. 817.—Dissecting aneurysm of the descending aorta. Excision of area of rupture and reconstitution of the aorta. The arrow indicates the site of the intimal tear.

results, may undermine and dislodge the attachments of the aortic valve, producing aortic incompetence or occlude vital branches of the aorta (carotid, renal, etc.) with serious consequences. Dissection may be related to systemic hypertension or defective aortic wall as in Marfan's disease.

Bernard Jean Antonin Marfan, 1858–1942. (*See footnote, p. 268.*)

The lesion is a serious one with a high mortality within a few days of onset, but a minority survive for some years. In the early stages dissection may be limited by the use of hypotensive drugs. Operative treatment with excision of the point of entry and re-anastomosis offers some hope of limiting further dissection by allowing blood to clot in the outer lumen (fig. 817). Some form of by-pass circulation is necessary.

Road accident chest injuries are another cause of partial or complete aortic rupture, usually in relation to the origins of the major ascending branches, and requiring the use of an artificial by-pass for repair or replacement with a Dacron graft.

Dysphagia Lusoria[1] (Vascular Rings).—Abnormal development of the aortic arch and its branches (e.g. double aortic arch, right subclavian arising from descending aorta) may result in obstruction of the trachea and œsophagus by vessels which surround them both in front and behind. The anomaly may pass unnoticed, but occasionally in children severe dyspnœa, stridor and dysphagia may develop and require urgent treatment. Occasionally symptoms only occur later in life due to enlargement of the vessels.

A barium swallow reveals a posterior indentation of the œsophagus by the abnormal vessel. If symptoms are severe, thoracotomy should be performed and the abnormal vessel divided or transposed.

---

[1] Lusus = game, sport or jest. Condition originally described as ' Lusus naturæ '—a jest or sport of nature.

CHAPTER 40

THE ŒSOPHAGUS

Surgical Anatomy.—The œsophagus is a fibromuscular tube 25 cm long occupying the posterior mediastinum and extending from the cricopharyngeal sphincter to the cardia of the stomach; 4 cm of this tube lies below the diaphragm. The musculature of the upper one-third is mainly striated, giving way to smooth muscle below. It is lined by squamous epithelium which is replaced by specialised epithelium at the level of the hiatus similar to gastric mucosa but without oxyntic and peptic cells (fig. 818). This specialised mucosa lines the lower 3 cm. The parasympathetic nerve supply is mediated by the vagus through an extrinsic and intrinsic plexus. The intrinsic plexus has no Meissner's network which is present elsewhere through the alimentary canal, and Auerbach's plexus is present only in the lower two-thirds.

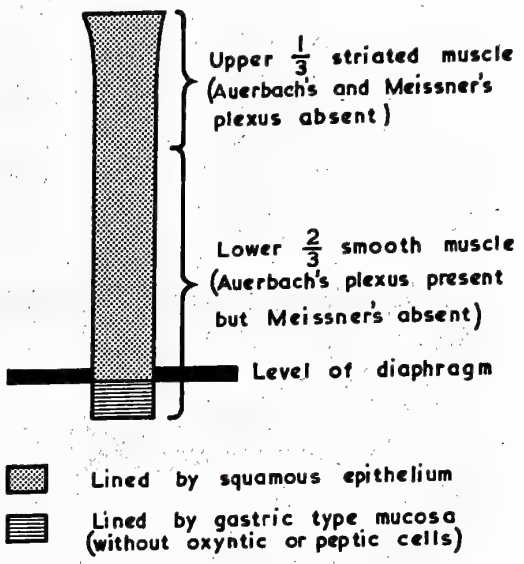

FIG. 818.—The anatomical structure of the œsophagus.

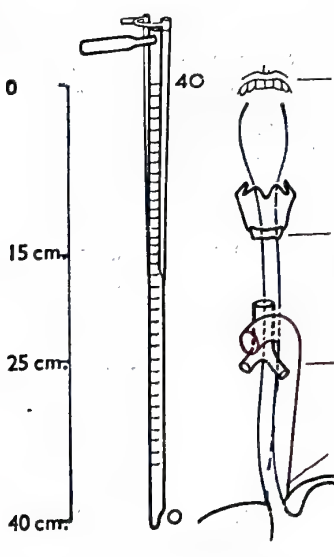
There are three physiological constrictions in this tube with distinct lesions at each level as shown in fig. 819. The figures 15, 25 and 40 are very important to the œsophagoscopist. They represent the situations of anatomical narrowing where difficulty may be experienced in the passage of instruments and where foreign bodies may be arrested. They are also the sites of election for innocent strictures and for carcinoma of the œsophagus.



COMMON LESIONS OF OESOPHAGUS

	Neoplasms	Strictures	Arrest of foreign bodies	Miscellaneous
cricopharyngeal constriction	carcinoma	traumatic strictures.	F. B.	pharyngeal pouch, webs.
aortic and bronchial constriction	carcinoma	peptic or traumatic strictures, congenital stenosis.	F. B.	atresia, traction diverticulum, dysphagia lusoria.
diaphragmatic and "sphincter" constriction	carcinoma	peptic strictures.	F. B.	oesophagitis, (hiatus herniation) achalasia, scleroderma.

FIG. 819.—Common lesions at various levels of the œsophagus. An œsophagoscope is drawn to the left of the diagram. (*L. R. Celestin, F.R.C.S., Bristol.*)

Physiology.—Swallowing is accomplished by two mechanisms, 1, *oropharyngeal*, which is voluntary, and 2, *œsophageal*, which is involuntary.

Georg Meissner, 1829–1905. Professor of Physiology, Göttingen, Germany.
Leopold Auerbach, 1828–1897. Professor of Neuropathology, Breslau, Germany. (Now Wroclaw, Poland.)

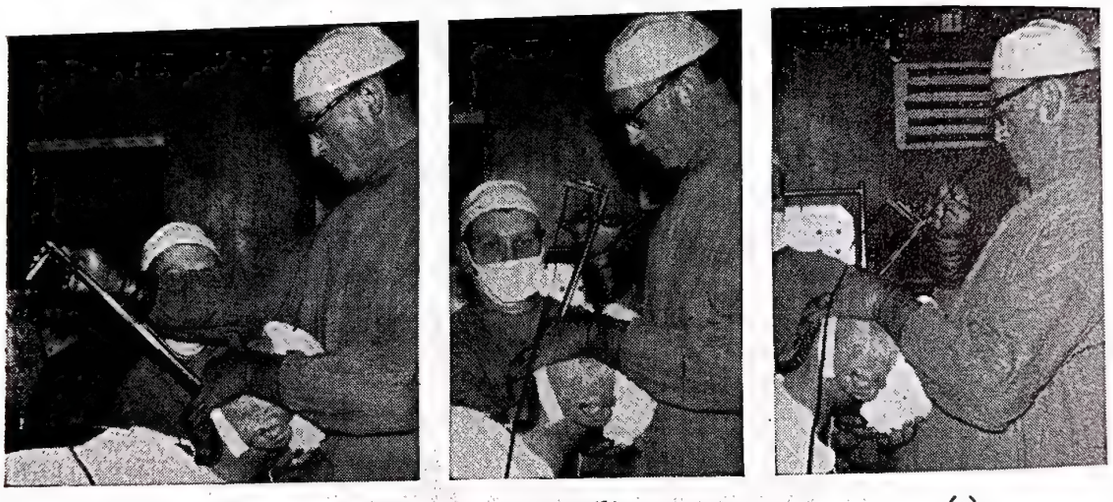
INVESTIGATION OF THE DISEASES OF THE ŒSOPHAGUS

The œsophagus being inaccessible by palpation the history is of special importance but the physical signs are of lesser value.

Dysphagia is the term used to describe difficulty (not pain) in swallowing; there are two types—oropharyngeal and œsophageal. The type of dysphagia is important. It may be dysphagia for solids or fluids, intermittent or progressive, precise or vague in its appreciation. *Pain* may be present. Painful dysphagia is usually due to œsophagitis. *Regurgitation*—it is important to record the volume, contents, presence of blood or bile and the reaction to litmus. Loss of weight, anæmia, cachexia and change of voice are also important symptoms.

Radiography is a most valuable investigation. A *straight film* will show an opaque foreign body and the site of its arrest (figs. 823, 824). A *barium swallow* is essential: screening will show the motility and films, taken as necessary, will delineate size, distortion or the presence of a space-occupying lesion. It is important to take a film with the patient in the prone head-down position to assess the degree of regurgitation.

Œsophagoscopy is essential. Endotracheal anæsthesia with a short-acting relaxant permits of easy access. The key to safety lies in the correct position of the patient on the table. A sandbag is placed behind the third dorsal vertebra in the supine position. An assistant holds the head and controls its position during the various manœuvres of the tube (fig. 820). Every stage must be accomplished under *direct vision*—at no time must the instrument be passed blindly.



(*a*) (*b*) (*c*)

(*d*)

(*e*)

FIG. 820.—Œsophagoscopy. (*a*) With the patient's shoulders slightly raised and neck fully flexed, the œsophagoscope is guided by the endoscopist's left hand over the dorsum of the tongue to the posterior pharyngeal wall. (*b*) The head is slightly extended and the instrument has been passed under vision behind the endotracheal tube. The tip of the instrument is now behind the cricoid cartilage and on levering the larynx forwards the crico-pharyngeal fold is seen. (*c*) As the head and neck are gradually extended the instrument is advanced under vision. The mid-thoracic œsophagus is now being inspected. (*d*) The head and neck are now completely extended and the œsophagoscope has advanced until the 40-cm mark is opposite the upper incisor teeth. At this level the cardia normally comes into view but in this case the œsophageal carcinoma (*e*) is seen.

(*Norman C. Tanner, F.R.C.S., London.*)

Adequate suction and a good light are very important. After œsophagoscopy the patient should have nothing to drink for twelve hours. If there is any fever or pain within thirty-six hours of the procedure, massive doses of penicillin should be given. This will usually prevent the development of a retro-pharyngeal cellulitis or mediastinitis from a perforation (p. 763) which is a possible complication.

Motility Studies.—Since the work of Code these have come to play an important part in diagnosis. A unit made up of three tubes with open tips or small water-filled balloons is swallowed by the patient. The tubes (or balloons) are spaced at 5 cm apart and each is attached to a pressure transducer. In this way it is possible to record pressure changes in the viscus during swallowing and to see if peristalsis is propagated normally. It has perhaps its greatest use in the diagnosis of diffuse spasm (presbyœsophagus, fig. 844) scleroderma (p. 774) or the lesser degrees of hiatal hernia (Earlam).

CONGENITAL ABNORMALITIES

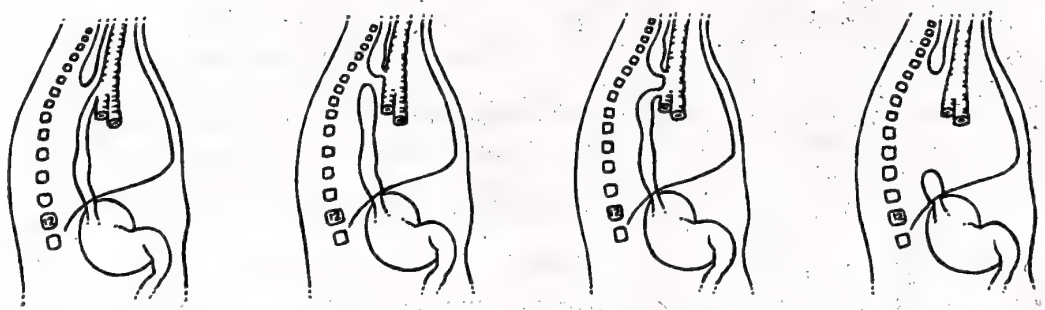
Well-known abnormalities are:

1. Atresia with or without tracheo-œsophageal fistula.
2. Stenosis.
3. ' Short ' œsophagus with hiatus hernia.
4. Dysphagia lusoria.

Congenital atresia of the œsophagus is usually associated with a tracheo-œsophageal fistula. Referring to fig. 821, it will be seen that in 85 per cent. of cases it is the *lower* pouch that communicates with the trachea.

It is highly important to be cognisant of this abnormality, because its recognition within forty-eight hours of birth, and subsequent surgical correction, is the only hope of survival.

Clinical Features.—The new-born babe regurgitates all its first, and every feed. Saliva pours, almost continuously, from its mouth. This is



(*a*) 85 per cent. (*b*) 2 per cent. (*c*) 1 per cent. (*d*) 12 per cent.

FIG. 821.—Congenital œsophageal atresia. (*a*) Lower pouch opening into the trachea. (*b*) Upper pouch opening into the trachea. (*c*) Both pouches opening into the trachea. (*d*) Both pouches ending blindly. Usually the mid-œsophagus is missing entirely.

the sign of œsophageal atresia—to no other condition does this phenomenon appertain. Attacks of coughing[1] and cyanosis are liable to occur on feeding. The abdomen becomes distended (dilatation of the stomach), due to air swallowed from the tracheal fistula (fig. 821 (*a*)).

Clinical Confirmation of the Diagnosis.—A No. 10 soft rubber catheter is introduced into the œsophagus through the nose. Should an obstruction be encountered about 10 cm from the nostril, the diagnosis is practically certain.

Radiological Confirmation.—On no account should barium emulsion be given in these cases. Injection of 1 ml. of lipiodol down the catheter will demonstrate the obstruction. During this examination the supine position is advised, because in the rare event of the atresia belonging to categories (*b*) or (*c*), the medium is less likely

[1] In type (*a*) the patient coughs up frothy mucus, perhaps tinged with bile.

Charles F. Code, Contemporary. Professor of Physiology, The Mayo Clinic, Rochester, Minnesota, U.S.A.
Richard John Earlam, Contemporary. Surgeon, The London Hospital, London.

to enter the trachea. In all cases the lipiodol should be aspirated after the radiograph has been taken. Another radiographic finding of significance is air in the stomach and jejunum, which is indicative of a communication between the lower pouch and the trachea.

Pre-operative Treatment.—Surgical intervention is urgent. Aspiration pneumonia is nearly always present and penicillin should be given. Everything by mouth is forbidden.

Operation.—The best approach is through a right-sided thoracotomy incision at the level of the fifth intercostal space (fig. 822). The azygos vein having been divided between ligatures, the upper segment of the œsophagus is located by a catheter within it, and freed gently from the surrounding structures. Having been separated from the trachea, the lower segment is transected just sufficiently far from the abnormal communication to permit the opening in the trachea to be closed. An opening is made into the blind upper segment and anastomosis carried out between this opening and the lower segment.

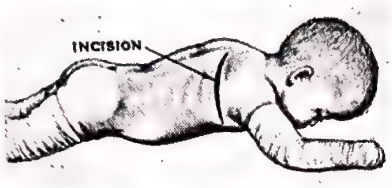


FIG. 822. — Thoracotomy for congenital œsophageal atresia.

Post-operative Care.—A special nurse skilled in aspirating the pharynx, and an oxygen tent-incubator are highly desirable.

Prognosis.—Aspiration pneumonia with acid digestion of the lungs and infection superadded is exceedingly likely to supervene when there has been delay in making the diagnosis. Added to this there is a danger of post-operative leakage from the anastomosis into the pleural cavity, a disaster that is minimised by freeing the distal segment for a considerable distance and thus decreasing tension. These dual complications result in a mortality approximating 40 per cent.

Œsophageal Stenosis.—This is a congenital organic narrowing of the lumen of the œsophagus and is a cause of dysphagia. Commonly it occurs at the same site as atresia and is treated by dilatation. Those in the lower one-third are usually not congenital but due to such conditions as œsophagitis, ulceration or achalasia.

Congenital Short Œsophagus (p. 766).

Dysphagia Lusoria or **Œsophageal Compression by an Abnormal Artery** is discussed on p. 758.

FOREIGN BODIES IN THE ŒSOPHAGUS

All manner of swallowed foreign bodies have become arrested in the œsophagus: coins, pins, and dentures (fig. 823) head the list. When the object contains radio-opaque material, an urgent X-ray examination is called

FIG. 823.—False teeth impacted in œsophagus. (*The late Dr. James F. Brailsford, Birmingham.*)

FIG. 824.—Damson-stone outlined by barium, indicated by the arrow.

FIG. 825.—An 'old' penny in the œsophagus as seen through an œsophagoscope.

for. The presence of a non-opaque foreign body in the œsophagus can often be confirmed by a barium swallow (fig. 824). Whenever possible the patient should be screened before œsophagoscopy is undertaken.

The foreign body having been visualised (fig. 825); and, if necessary, manipulated into a favourable position, it is grasped with suitable forceps introduced through the œsophagoscope. The œsophagoscope, together with the forceps still grasping the foreign body, is then gently withdrawn.

INJURIES

Perforation of the œsophagus can result from the inexpert use of an œsophagoscope or a gastroscope; usually the beak of the instrument is thrust through the thin posterior wall of the pharynx just above the cricopharyngeal sphincter or the wall is crushed between the shaft of the instrument and a rigid, osteoarthritic cervical spine. Perforation just above an œsophageal stricture can occur from œsophagoscopy or bouginage. It also can result from removal of a piece of growth for biopsy, but probably the most frequent cause of perforation is a sharp foreign body plus instrumentation to remove it.

Often the perforation goes unrecognised by the œsophagoscopist until general distress and great pain on swallowing saliva or fluid, and dyspnœa, become apparent. In such circumstances the possibility of a tear should be considered at once. An X-ray is essential; this discloses the presence of air in the mediastinum, the pleural cavity, or in the neck which may be palpable (surgical emphysema). In doubtful cases the radiograph should be repeated after the patient has swallowed a small quantity of lipiodol. When the wall of the œsophagus has been perforated, urgent operation under antibiotic cover is indicated. When the cervical œsophagus has been ruptured, an incision along the anterior border of the sternomastoid (usually the left), with lateral retraction of the carotid sheath, gives access to the site of perforation (fig. 826), which is closed in two layers. If the mid or lower œsophagus is involved, thoracotomy must be performed. In non-malignant cases timely suture is usually followed by recovery.

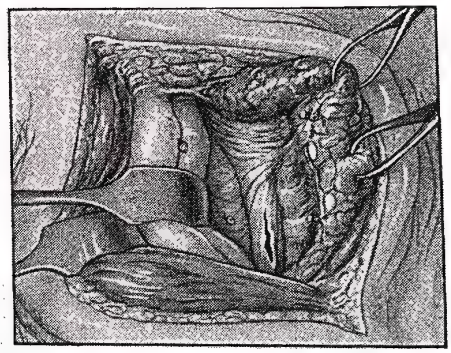

FIG. 826.—Exposure of a tear in the cervical œsophagus. In this case there was surgical emphysema on the right side of the neck.

When the symptoms are delayed, and radiography is negative, the perforation is in all probability a very small one. In this case massive antibiotic treatment with parenteral feeding is usually successful.

Burns and scalds of the œsophagus from swallowing corrosive fluid, if not rapidly fatal, are often the precursor of a dense stricture. The surgeon's aim should be to minimise the contracture of the inevitable scar and this is best achieved by the use of hydrocortisone and antibiotics. As soon as the patient's general condition permits, gastrostomy is performed. About a week later it is advisable to ascertain the extent of the damage by œsophagoscopy performed with great gentleness.

It is wise to prohibit bouginage for at least three weeks. More than 70 per cent. are controlled by dilatation. The remainder should have resection of the stricture and colon replacement if necessary. The enormous improvement in the outcome of burns and scalds of the œsophagus is due chiefly to the introduction of antibiotics, cortisone, and to the development of œsophageal surgery.

SPONTANEOUS RUPTURE OF THE ŒSOPHAGUS

Ætiology.—Instead of the cricopharyngeus relaxing, as is usual during vomiting, it contracts. The pressure within the œsophagus rises so steeply that the organ bursts at its weakest point. The condition is similar to the linear tears of the cardia in the Mallory-Weiss syndrome (p. 808).

Pathology.—The necropsy findings[1] are remarkably constant. There is a longitudinal tear 1 to 4 cm. in length in the posterior wall of the extreme lower end of the œsophagus, nearly always on the left side. Following perforation, the mediastinum becomes filled with air and gastric contents. Usually about six hours later the pleural membrane gives way, and air and gastric contents gush into the pleural cavity.

Clinical features are also remarkably constant. Following a meal, vomiting occurs. During vomiting, agonising pain is experienced in the thorax, followed by dyspnœa. Board-like rigidity similar to that accompanying perforation of a gastric or duodenal ulcer is often present. Soon surgical emphysema appears in the suprasternal notch; it spreads up and around the neck. Crepitus is often detected here within one hour after rupture. Hyper-resonance and absence of breath-sounds over one lung indicate a pneumothorax. The pain is so intense that even i.v. morphine fails to relieve it.

Radiography.—In very early cases no abnormality is demonstrated; after a few hours mediastinal emphysema is seen; in later cases a hydro-pneumothorax is present.

Paracentesis Thoracis.—Several hours after the perforation, when the extravasated fluid in the mediastinum has ruptured into the pleural cavity, if a hollow needle is inserted into the chest, air and liquid vomitus, acid in reaction, are withdrawn.

Treatment.—Recovery has followed immediate thoracotomy, opening widely the mediastinum, suture of the perforation, and closure of the thorax with drainage. Supportive fluid therapy must be given before, during, and after the operation.

ŒSOPHAGEAL DIVERTICULUM

Pulsion diverticulum is rare, and occurs where a blood vessel enters the œsophagus. The majority are associated with neuro-muscular incoordination which is the cause of occasional dysphagia (fig. 844).

ŒSOPHAGEAL VARICES

The lower end of the œsophagus is one of the principal regions where the portal and systemic venous systems anastomose. Dilatation of these anastomotic channels occurs in portal hypertension (Chap. 43) and is a cause of hæmatemesis. The treatment of œsophageal varices is considered in Chap. 43.

PARALYSIS

The passage of food along the gullet is dependent entirely upon involuntary muscular peristalsis. When the neuromuscular mechanism of deglutition is paralysed, as occurs occasionally, notably as a complication of tetanus or diphtheria, ingested material is regurgitated. In established cases the difficulty must be overcome by feeding through a stomach tube.

ŒSOPHAGITIS

This may be *acute*—following burns or scalds, infective (spreading from the pharynx), or peptic, sometimes from the trauma of an indwelling stomach tube; or *chronic*—the most important cause is reflux, either of acid or alkaline juices; the latter following œsophago-duodenostomy or œsophago-jejunostomy without a Roux-en-Y loop.

Ætio-Pathology.—The changes are maximal at the lower end of the œsophagus. Essentially there is loss of epithelium with replacement by bleeding granulation tissue. Although the symptoms are experienced by day the damage is done by night when the recumbent position allows the peptic juices to flow into the œsophagus. As soon as inflammation of the epithelium occurs, there is vagal hyperactivity so that the longitudinal muscle contracts and draws the cardia more and more up into the thorax and also hyperacidity is increased. Thus a vicious circle of œsophagitis—longitudinal

[1] Spontaneous rupture of the œsophagus has been found at necropsy in cases of severe head injury and other cerebral lesions, doubtless due to vomiting and retching.

César Roux, 1857–1934. Professor of Surgery and Gynæcology, Lausanne, Switzerland. (*See footnote p. 825.*)

muscle spasm—upward displacement of the cardia—increased regurgitation ensues. It is likely that the reflux œsophagitis so often encountered during pregnancy is due to a temporary sliding hiatus hernia resulting from increased intra-abdominal pressure; after delivery the hernia usually reduces itself, but it sometimes recurs apart from pregnancy later in life.

Clinical Features.—Reflux œsophagitis is the commonest affection of the œsophagus, but its manifestations are not always clear-cut.

Pain.—In the majority, pain is the presenting symptom. At first, it is retrosternal and later may radiate between the shoulder blades, down either arm or up the side of the neck to the ear. This referred pain may simulate angina and is an expression of the sympathetic innervation. It tends to occur when the patient lies down to sleep and keeps him awake (in contradistinction to the pain of duodenal ulcer which wakes the patient from a sound sleep at about 2 a.m.). It is relieved by sitting upright and sometimes by taking alkalis.

Heartburn with regurgitation of bitter fluid is very common.

Dysphagia.—A complaint that food sticks in the region of the lower œsophagus is a fairly frequent symptom of œsophagitis. It occurs long before any stenosis has developed, and is probably an indication of œdema and spasm. Later, dysphagia is constant and becomes progressively worse as the stenosis develops.

Occult blood is present in the stools in a large percentage of cases.

Secondary anæmia is not uncommon. The œsophagitis may only be uncovered when a routine search is made for the cause of such anæmia.

Diagnosis.—A barium swallow X-ray of the œsophagus reveals no characteristic sign until stenosis commences. *Œsophagoscopy* is essential in order to make the diagnosis. On examination, the mucous membrane of the lower end of the œsophagus is velvety, scarlet, and bleeds readily. Additional white areas of desquamating epithelium may also be seen in the inflamed area. Later one or more ulcers are present (Barrett's ulcers) (fig. 827) and progressive cicatrisation with narrowing of the terminal part of the œsophagus occurs. The *treatment* is that of the cause, notably that of hiatus hernia (p. 768).

HIATUS HERNIA

TYPES	Sliding or œsophago-gastric	85%
	Rolling or paraœsophageal	10%
	Mixed or transitional	5%

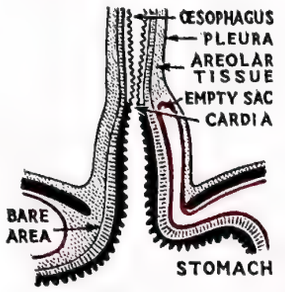

FIG. 828. — Sliding œsophageal hiatus hernia. (*After N. R. Barrett, F.R.C.S., London.*)

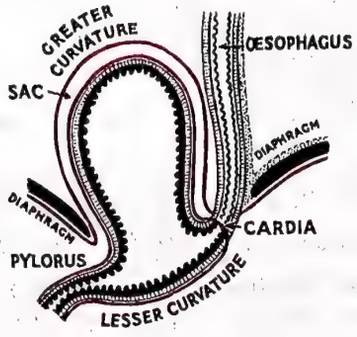

FIG. 829.–Para-œsophageal hernia.

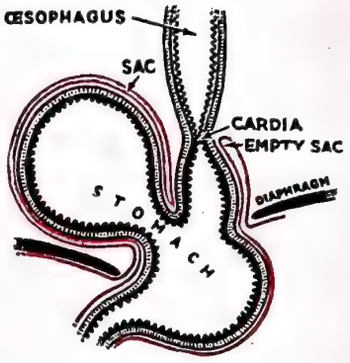

FIG. 830.—Mixed hiatus hernia.

Ninety-eight per cent. of diaphragmatic herniæ (p. 729) occur through the œsophageal hiatus. Sir Astley Cooper was the first to insist that œsophageal hiatus hernia was acquired, and not congenital. While probably this is true in the majority of cases, the fact is that it may occur in early infancy, and rapidly proceed to stricture and œsophageal shortening, a condition erroneously described as ' congenital short œsophagus '.

Sliding Hiatus Hernia

Anatomy of Cardiac Sphincter.—There is undoubtedly a functional intrinsic sphincter-like mechanism at the cardia although it cannot be demonstrated anatomically. This is expressed as a zone of high intra-luminal pressure which prevents regurgitation from the stomach. This important function is maintained by four factors: 1, the valvular effects of the œsophago-gastric angle (fig. 831); 2, the pinch-

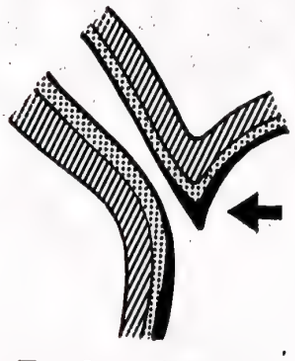

FIG. 831.—The valvular mechanism of the cardia.

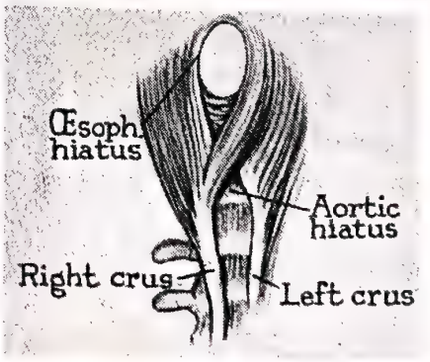

FIG. 832.—The right crus forms the entire musculotendinous diaphragmatic ring around the œsophagus.

cock action of the right crus (fig. 832); 3, the ' rosette-like ' folds of the gastric mucous membrane at the cardia; 4, the presence of a length (about 4 cm) of intra-abdominal œsophagus (p. 768). Certain gastro-intestinal hormones may affect sphincter tone.

Sir Astley Paston Cooper, 1768–1841. Surgeon, Guy's Hospital, London.

Mechanism of Herniation.—The hernia is small, and usually remains so. The cardiac orifice and a portion of the stomach immediately adjacent pass into the posterior mediastinum, carrying with them a small peritoneal sac applied to the left side of the stomach. The right side of the hernia is derived from the ' bare area ' of the stomach, and consequently is bereft of peritoneum (fig. 828). Branches of the left gastric artery supplying the prolapsed stomach also pass through the hiatus. The sac is always empty, and its fundus lies opposite the junction of the prolapsed stomach (lined by columnar epithelium) and the œsophagus (lined by squamous epithelium). It should be noted that the prolapsed stomach, with its columnar-celled epithelium (black) hangs from the œsophagus proper like a supradiaphragmatic bell. In a less common variety there is massive herniation upwards of the stomach.

The final result is that the phreno-œsophageal ligaments are stretched and the cardio-œsophageal junction is distorted.

Ætiopathology of Herniation.—There are several factors in the development of this hernia:

1. Muscular degeneration of increasing age.
2. Increased intra-abdominal pressure as in large ovarian cysts, pregnancy, increasing weight and the wearing of tight corsets. Trauma may be an initial factor.
3. Increase of fatty tissue in the hiatus with decreased elasticity of the crus as occurs in obese women.
4. Once regurgitation is established, œsophageal spasm and later even œsophageal fibrosis will pull more and more stomach into the chest.

Clinical Features.—These are similar to those of reflux œsophagitis (see p. 764). The majority of the patients are over fifty years of age, and women are slightly more often affected than men. A duodenal or gastric ulcer may be present as well. Gall stones, diverticulosis coli and hiatus hernia are not uncommonly associated (Saint's triad, Chap. 44). An aspiration pneumonitis may develop.

Hiatus Hernia in Infants

Hiatus hernia with œsophagitis occurs in infants. The outstanding clinical feature is effortless vomiting of small amounts, often blood-tinged, starting soon after birth.

Radiography.—In order to demonstrate a sliding hiatus hernia radiologically, technique is important. During the course of a routine barium meal the patient is turned into a semi-prone position on the right side and the table tilted into a 20° Trendelenburg position. In the case of a true hiatus hernia, barium will regurgitate into the hernia without the aid of any additional pressure (fig. 833). If there is no regurgitation from the hernia into the œsophagus, there are usually no symptoms and no treatment is necessary.

FIG. 833.—A large sliding hiatus hernia.

Œsophagoscopy reveals varying degrees of inflammation of the lower end of the œsophagus (p. 760). The most valid sign of a hiatus hernia is reflux of gastric juice through the cardia, best seen during œsophagoscopy under surface anæsthesia. Furthermore the cardia will open on inspiration, whereas it normally closes and descends.

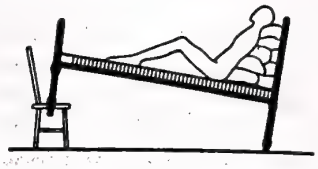
Differential Diagnosis.—Now that the prone head down position is routine in all barium meals, hiatus hernia and reflux are a not infrequent finding. Above the age of 60 years about 50 per cent. of all patients coming

Friedrich Trendelenburg, 1844–1924. Professor of Surgery, Leipzig, Germany (see footnote p. 71).

for a barium meal examination have a demonstrable hiatus hernia at some time or other (Airth). One must therefore be vigilant lest cholelithiasis, peptic ulcer, or diverticulitis be overlooked in a patient with an incidental hiatus hernia.

Factors which influence Treatment

In all cases medical treatment should be tried and faithfully followed. Many cases do not need surgery, and it is unwise to advise operation in the absence of definite indications. Operation undertaken in patients who are obese or who have chronic bronchitis often gives unsatisfactory results.



Medical Treatment.—The principles to be followed are:

1. The patient must sleep in a semi-recumbent position propped up with pillows and with the lower end of the bed raised on a chair. Five out of six patients benefit from lying on the left side at night.
2. He must avoid heavy work, lifting weights and excessive bending.
3. Six small, non-bulky meals should be taken daily, instead of three; food should be masticated thoroughly, and eaten slowly. The maintenance of the upright position after meals is sometimes of benefit.
4. Mucaine and Antacids such as Nulacin may control symptoms.
5. If the patient is obese, reduction of weight is very important.
6. Correction of anæmia.

Especially when the patient is old or follows a sedentary occupation, these simple measures may bring about and maintain such a remarkable improvement that the question of operation can be postponed indefinitely. In other circumstances operation should be advised.

Medical Treatment in Infancy.—The first injunction is to nurse the baby in an upright position, and the second is to thicken the feeds, giving semi-solid diet as soon as possible. The most practical method of maintaining the sitting position is by an almost legless chair made of plaster of Paris, which can be used both in the cot and the perambulator. Some children lose all symptoms when they start to walk; some of the remainder will require surgery.

Indications for Surgery

1. Severe symptoms which cannot be controlled medically or which interfere with patients' occupation.
2. Complications such as stenosis, hæmorrhage and œsophagitis.
3. Associated lesions such as gallstones, ovarian cysts and pyloric ulcers which should be dealt with in their own right.

Operative Treatment.—There are two approaches in common use—abdominal or thoracic. The guiding principle of surgical repair is to ensure a length of at least 4 cm. of intra-abdominal œsophagus and to prevent this segment from returning to the chest. The positive intra-abdominal pressure of inspiration closes this segment of gullet thus preventing the reflux of gastric juice into the thoracic œsophagus (Keen).

The choice between the abdominal and thoracic operation is vexed. If the case is not complicated by œsophagitis it may be approached from below. This approach makes any gall-bladder and duodenal surgery much easier; it is not anything like such a difficult procedure and avoids intercostal neuralgia which so often follows the thoracic approach. If severe shortening of the œsophagus is present the thoracic approach should be used.

Abdominal Approach—Fundo-plication. Nissen—almost by accident—found that wrapping the fundus of the stomach around the lower 5 cm of the

Graham Robertson Airth, Contemporary. Radiologist, Southmead Hospital, Bristol, England.
Gerald Keen, Contemporary. Thoracic Surgeon, Royal Infirmary, Bristol, England.
Rudolph Nissen, Contemporary. Formerly Professor of Surgery, Istanbul, Turkey, and Basle, Switzerland.

œsophagus produced a very effective valve. A left upper abdominal incision is made in the line of the left margin of the rectus abdominis and the left lobe of the liver is mobilised to expose the cardia. A transverse incision at the hiatus is then made to expose the lower œsophagus and the crura. It is important to clear the abdominal œsophagus for 5 to 7·5 cm both behind the œsophagus and along the upper part of the lesser curve. The fundus of the stomach is freed, its anterior aspect is brought round behind the œsophagus and sutured anteriorly (fig. 834). Splenectomy may be required. Some believe that vagotomy with a drainage operation (p. 802) is advisable; this view is not widely shared. The operation is best carried out with a large stomach tube in position in order to prevent narrowing of the œsophagus. Lesions of the stomach, duodenum, gall bladder and colon may be dealt with at the same time.

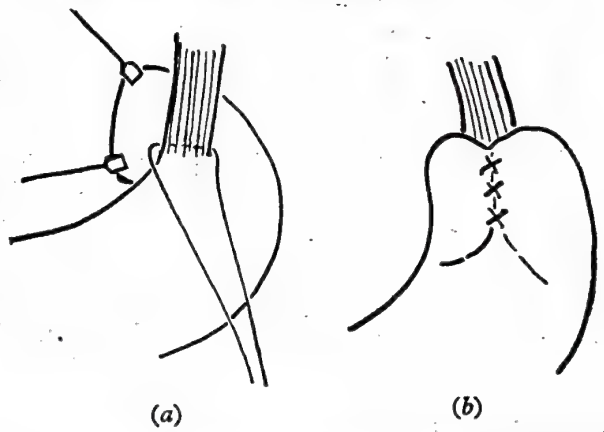


FIG. 834.—(*a*) Mobilisation of the gastric fundus with tissue forceps and a rubber catheter round the œsophagus. (*b*) Plication of the gastric fundus.

Thoracic Approach. — With the patient lying on the right side, an incision is made parallel to the left 8th rib and the chest is entered by subperiosteal stripping of the upper border of this rib. The pleura over the hiatus and lower œsophagus is incised and the œsophagus mobilised. In the presence of peri-œsophagitis and fibrous œsophageal shortening, it may be necessary to mobilise it as high as the aortic arch. If this is not done, it may be difficult to reduce the hernia and where the hernia is repaired under the condition of a taut fibrous œsophagus, recurrence is certain. A rubber catheter is placed around the cardia to act as a retractor and helps to pull the herniated stomach back into position below the diaphragm. During this procedure, the phreno-œsophageal ligament is exposed and divided. The stomach is freed from the hiatus and the large fatty bursa at the cardia should be cleaned from the œsophagus and stomach. Then firm sutures attach the free medial border of the phreno-œsophageal ligament deeply to the pre-aortic fascia. The chest must be closed with underwater drainage. Over 50% recur within two to three years but symptomatic improvement may persist after recurrence.

Treatment of Complications. Stricture and Penetrating Ulcer.—Here the choice is:

1. The stenosed portion is resected and continuity restored by œsophago-gastrostomy or by interposition of a jejunal or colonic conduit.
2. Performing a standard 2/3 Polya type gastrectomy (p. 802) or a vagotomy and pyloroplasty (p. 803). Both these procedures reduce gastric acidity and may be successful in curing the ulcer and stricture.
3. More recently Thal's patch has been gaining in popularity (Pringle). The operation is done through a left thoracotomy incision (fig. 835).
4. Very elderly and frail patients may be fit for regular dilatation only.

Hæmorrhage.—Although chronic œsophagitis can cause a severe iron deficiency anæmia and is an indication for repair, yet severe hæmorrhage is usually due to an accompanying duodenal or gastric ulcer and not from the œsophagus.

Para-œsophageal (' rolling ') hernia.—This is a true hernia into which the greater curvature of the stomach (figs. 829 and 837) or, very rarely, the whole stomach itself ascends into a preformed sac lying in the mediastinum (fig. 829). Acute dilatation or volvulus of the intrathoracic stomach may result in serious symptoms or death and such herniæ are best repaired early.

Clinical Features.—Regurgitant œsophagitis and peri-œsophagitis are not features of this condition since the cardia remains in its normal position (fig. 829). The gastro-œsophageal angle is not disturbed and the competence of the cardia is not

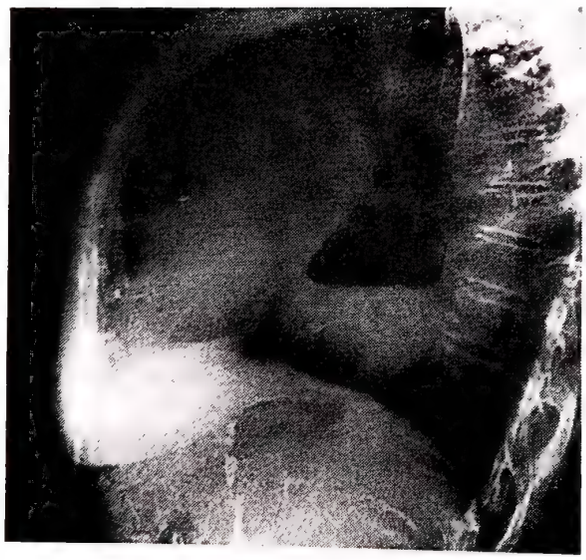

FIG. 836.—Para-œsophageal hernia. A fluid level is seen in the chest.

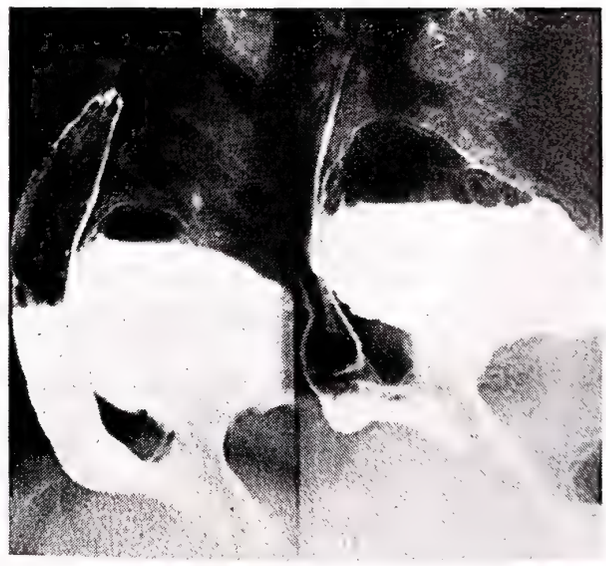

FIG. 837.—Barium study of this case.

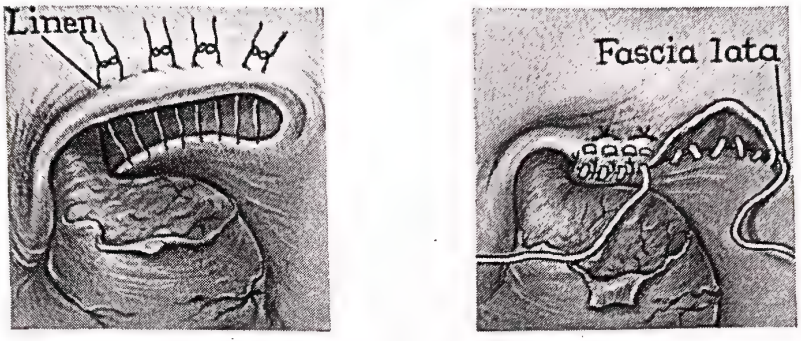
impaired. Symptoms therefore rarely appear until the hernia is large (fig. 829), and they are variable: (*a*) intermittent dysphagia; (*b*) cardiac symptoms due to pressure on the heart; (*c*) occasionally bouts of hiccough form irritation of the phrenic nerve. These symptoms are most frequently due to a recurrent gastric volvulus (p. 827).

Operation.—The muscular fibres of the crus are so attenuated by stretching that the operation described for sliding hernia is usually inapplicable.

For a right-sided hernia the thoracic approach is chosen, because the liver prevents a satisfactory abdominal exposure of the hernial site. In the case of the left side (much more common) the abdominal approach is chosen. The upper abdomen having been opened, a stomach tube is passed by the anæsthetist and all gaseous and fluid stomach

contents are aspirated before reduction of the hernia is undertaken. Reduction having been affected, the hernial sac is usually excised. A very large adherent sac may have to be detached from the stomach, but the intrathoracic portion is left *in situ*.

The hernial orifice is repaired by overlapping (Harrington). The first layer of sutures is of thread (fig. 838(*a*)); the second and third layers are of fascia lata (fig. 838(*b*)).



(*a*) (*b*)

FIG. 838.—(*a*) Repair of a para-œsophageal hernia. First layer of sutures. (*b*) The second and third layers of sutures of fascia lata, so placed as to imbricate the pillars of the hernial orifice. (*After S. W. Harrington.*)

Mixed Hiatus Hernia.—This is a combination of sliding hernia and paraœsophageal hernia (fig. 830).

Clinical Features.—These depend on the degree of angulation of the cardia and the bulk of the paraœsophageal component. If angulation is disturbed and the paraœsophageal component is small, the main symptoms are those of reflux œsophagitis. Alternatively, normal angulation will be associated more with symptoms of a paraœsophageal hernia.

Treatment.—Operative treatment is strongly indicated. For the repair of the hernia some prefer the transthoracic route and others the abdominal route as described on p. 768.

CHRONIC ŒSOPHAGEAL OBSTRUCTION

The causes of chronic œsophageal obstruction can be classified as follows:

Congenital—see p. 761.

Acquired

- Pressure from without
  - Thyroid swelling
  - Pharyngeal pouch (p. 668)
  - Aortic aneurysm
  - Mediastinal
    - Neoplasm
    - Abscess
  - 'Rolling' Hiatal Hernia (p. 769)
- Causes in the wall
  - Stricture
  - Diverticulum
  - Neoplasm
  - Spasm
    - Plummer-Vinson syndrome
    - Achalasia
    - Diffuse spasm
- Causes in the lumen
  - Foreign body

LOCALISED MUSCULAR SPASM

There are two important clinical entities associated with muscular conditions of the œsophagus. One effects the pharyngo-œsophageal junction an is known as the Plummer-Vinson syndrome. The other affects the extreme lower end of the œsophagus and is called cardiospasm, or achalasia.

Stuart William Harrington, Contemporary. Emeritus Professor of Surgery, Mayo Graduate School of Medicine Rochester, Minnesota, U.S.A.
Henry Stanley Plummer, 1874–1937. Physician, Mayo Clinic, Rochester Minnesota, U.S.A.
Porter Paisley Vinson, 1890–1959. Physician, Mayo Clinic, Rochester, Minnesota, U.S.A.

THE PLUMMER-VINSON SYNDROME

This syndrome was first described by Paterson and Kelly in 1919. It is however commonly called after Plummer and Vinson who described it again in 1921. The patient is nearly always a middle-aged woman who comes complaining of difficulty or inability to swallow. Severe retching spells are wont to occur and classically the patient fears choking. Provided the clinician is aware of the existence of the syndrome, thoughtful examination nearly always provides clues to the diagnosis, but not all the following are necessarily in evidence in a given case.

The tongue is usually devoid of papillæ, smooth and pale, but rarely inflamed or sore.

The lips and corners of the mouth are often cracked, giving the mouth a pursed appearance.

FIG. 839.—Spoon-shaped finger-nail.

The finger-nails are brittle, and tend to be spoon-shaped (koilonychia) (fig. 839).

The spleen is enlarged in the same ratio as in other iron-deficiency anæmias.

The bone marrow is devoid of stainable iron stores.

The Blood.—Hypochromic[1] anæmia is always present, the serum iron levels being particularly low. Usually dysphagia precedes the anæmia, which is due to lack of iron and other requirements of a balanced diet.

Achlorhydria is often present, as is usually the case in iron-deficient anæmia.

Dysphagia is due to spasm of the circular muscle fibres at the extreme upper portion of the œsophagus. This is associated with the formation of webs (fig. 840). The mucous membrane is hyperkeratotic in places, and desquamated in others; it is extremely friable and easily traumatised by the passage of an œsophagoscope. In long-standing cases the orifice looks like a mere pin-hole. This lesion is definitely a precarcinomatous condition.

FIG. 840.—Œsophageal web. (*H. Talib, F.R.C.S., Baghdad*)

Treatment.—The dysphagia yields readily to dilatation of the stricture through an œsophagoscope. As always, gentleness must be used; even so, in cases of some standing, bleeding will occur. The administration of tab. ferrous sulphate, 0·3 g t.d.s., together with vitamins, is indicated. Some patients require intramuscular or intravenous iron. Sometimes blood transfusion is necessary. Hyperalimentation with a liquid diet through a gastric aspiration tube helps to bring about regeneration of the desquamated epithelium of the mucous membrane of the œsophagus. Once the anæmia is under control and the patient can swallow an adequate diet, rapid improvement occurs and usually is maintained.

ACHALASIA OF THE ŒSOPHAGUS (*syn.* 'CARDIOSPASM')

Ætiology.—Achalasia is a disease of the œsophagus, the exact cause of which still remains unsolved.

It consists essentially of a failure of integration of the parasympathetic impulses so that œsophageal peristalsis is disorganised, and there is failure of relaxation of the cardia. These result in a *functional* obstruction. An epidemic variety has been described in Breslau and was associated with Vitamin B_1 deficiency on the one hand and trypanosomiasis on the other (Chagas' disease). Stress and emotional upsets are also associated with achalasia.

The œsophagus consists of a dilated tortuous sac above and a narrow neck below. The elements of Auerbach's plexus are defective though ganglia are present (cf.

[1] Hypochromic anæmia is so-called because the red blood-corpuscles contain less hæmoglobin than normal.

Donald Rose Paterson, 1862–1939. Surgeon, Ear, Nose and Throat Department, Royal Infirmary, Cardiff, Wales.
Adam Brown Kelly, 1865–1941. Surgeon, Ear, Nose and Throat Department, Victoria Infirmary, Glasgow, Scotland.
Carlos Chagas, 1879–1934. Professor of Tropical Medicine, Rio de Janeiro, Brazil.

Hirschsprung's disease (Chap. 47) where they are completely absent). There is marked stasis and a retention œsophagitis due to the presence of a foul smelling fluid. Like stasis anywhere, it predisposes to diverticula and it is pre-cancerous.

Clinical Features.—Usually achalasia of the œsophagus occurs in women about forty years of age, but it can occur at any time of adult life and in both sexes. The history is one of progressive dysphagia; there are several special features.

The onset is insidious and, more often than not, the patient seeks relief only after the symptoms have been present for many years. Although the patient says she vomits, on closer interrogation it becomes apparent that there is regurgitation of food, often several hours after the meal. In advanced cases mucus and froth are brought up in considerable quantities. There may be retrosternal discomfort, fœtid flatulence and aspiration pneumonitis. A toxic 'rheumatoid' arthritis may occur.

As a result of the obstruction the patient fails to obtain sufficient nourishment, and consequently remains in a state of continual ill-health, rendering normal activities impossible.

The *radiographic findings* are most important. Characteristic features are:

1. A smooth pencil-shaped narrowing of the lower segment.
2. Dilatation and later tortuosity and recumbency of the lower œsophagus (fig. 841).
3. Lack of a gas bubble in the stomach.
4. Inco-ordinated peristalsis which is hypersensitive to acetyl-choline (when Carbachol 0·25 mg is injected intramuscularly abnormal peristaltic contractions occur).

Œsophagoscopy.—Once the instrument has passed the cricoid cartilage it appears to enter a gaping cave partially filled with dirty water, which laps to and fro with respiratory movement. When the fluid has been aspirated the cardiac orifice is located with difficulty, owing to its contracted state.

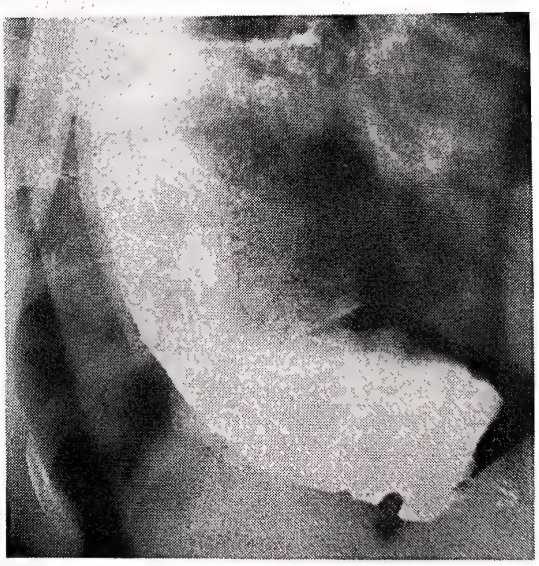


FIG. 841.—Typical appearance after barium swallow in a case of achalasia showing dilatation and recumbency.

Treatment.—The essential is the disruption of the constricting fibres of the cardia either from without by Heller's operation or from within by Plummer's bag.

Operative treatment becomes necessary in at least 20 per cent. of cases.

Heller's Operation (*Œsophagocardiomyotomy*).—Aspiration of the dilated œsophagus is commenced twenty-four hours before operation during which time the patient is on a water diet. The approach may be thoracic or abdominal but the essential procedure is the same. In the abdominal operation a long high left paramedian incision is made. The left lobe of the liver is retracted to the right and the triangular ligament, thus rendered taut, is severed. The stomach is retracted downwards so as to display the abdominal portion of the œsophagus, the peritoneum overlying which is incised, permitting the lower end of the œsophagus to be liberated circumferentially. A soft rubber catheter is passed around the cardia to facilitate retraction. When the

Ernst Heller, Surgeon, St. George's Hospital, Leipzig, Germany.

lower end of the œsophagus has been mobilised sufficiently, a longitudinal incision is made extending 5 cm proximal and 5 cm distal to the constricted portion. The incision is deepened to the mucosa throughout the length of the incision (fig. 842). After its completion, the mucous membrane bulges, as occurs in Ramstedt's operation (p. 790). The rubber sling is removed and the abdomen is closed. The advantage of the thoracic operation is that the myotomy can be carried up much higher on the œsophagus, which it should be in order to obtain the best results.

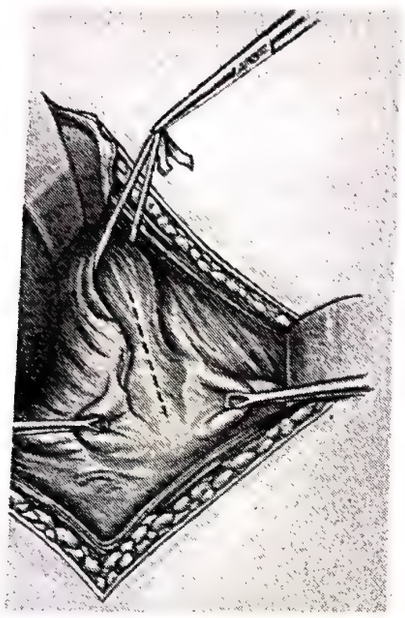

FIG. 842.—Heller's operation, showing the length and position of the incision dividing the muscular coats. (*After P. Thorek, Chicago, U.S.A.*)

In 80 per cent. of cases the results of Heller's operation are most satisfactory; in the remainder, symptoms due to reflux œsophagitis develop and mar the benefits conferred by the operation.

Plummer's Hydrostatic Bag.—A silk thread with a shot on the end is swallowed, and when the shot has entered the stomach, suitable bougies are passed by the 'rail-road' method. Once the narrow neck has been dilated sufficiently, the hydrostatic bag (fig. 843) is inserted. Plummer's bag often succeeds where dilatation fails, because the hydrostatic bag can be distended to a transverse diameter of 5 cm. This ruptures the circular muscle fibres of 'the neck'.

Diffuse spasm (Presbyœsophagus).—In this condition multiple areas of spasm (fig. 844) may be seen throughout the œsophagus ('corkscrew œsophagus'). Like scleroderma, however, it does not proceed to the massive dilatation seen in achalasia. 85% of cases are men over 60 (Flavell).

The condition presents as mild dysphagia with pain on swallowing felt mainly in the root of the neck but may be discovered accidentally during barium meal examination. The patient is usually of a nervous disposition. Treatment is by dilatation.

SCLERODERMA

Œsophageal manifestations of this distressing systemic disease are not uncommon, although the peripheral cutaneous, vascular and arthritic changes are more frequently seen.

The disease has a male:female ratio of 1:2 and is of the collagen variety.

Dysphagia is the commonest gastrointestinal symptom, although other regions of the gastrointestinal tract may be involved and indeed, intestinal obstruction may occur.

FIG. 843.—Plummer's hydrostatic bag *in situ*.

FIG. 844.—Diffuse spasm. A diverticulum is present in the mid-œsophagus.

FIG. 845.—Scleroderma of the œsophagus.

Geoffrey Flavell, Contemporary. Surgeon, The London Hospital, England.

Widespread infiltration of the mucosa of the viscus with fibrous tissue leads to ineffectual contraction and eventually to a suspension of peristalsis and shortening particularly in its distal half (fig. 845). Areas of spasm may occur proximal to this. In its fully developed state surgical replacement of the lower œsophagus may be required.

BENIGN STRICTURES

Compared with obstruction due to carcinoma, simple strictures are rare in this country. As set out in the table on p. 771, the causes of benign stricture are numerous. When consequent upon swallowing corrosive poisons, the strictures are usually multiple, the densest being at the level of the crossing of the left bronchus. The symptom of benign strictures is increasing dysphagia, and the diagnosis is established by a barium swallow X-ray and by œsophagoscopy. *A Schatzki's ring* is a kind of mucosal stenosis situated just above the cardia.

Treatment.—In the established condition treatment consists in dilatation with bougies (see below). In the first instance this should always be carried out under vision; in most cases it is advisable to continue to dilate the stricture at regular intervals under the vision afforded by an œsophagoscope. When the stricture has a very small

Chevalier Jackson's carrot-shaped œsophageal bougie.

lumen a special guide is passed, to the end of which a larger bougie is attached by a screw. By these means nearly all simple strictures can be dilated sufficiently to permit bougies to be passed in the usual manner, but treatment must be continued at regular intervals suited to the individual case for the remainder of the patient's life.

In cases where a bougie cannot be passed from above or threaded along a swallowed string weighted by a small shot, retrograde bouginage can be attempted through a gastrotomy. If this measure is successful, bougies can be passed afterwards in the usual way. In extreme cases, where dilatation of a dense stricture is impossible, colon replacement of the strictured segment is advisable (p. 778.)

In acute corrosion the use of cortisone has been found valuable.

BENIGN TUMOURS

Simple tumours of the œsophagus are exceedingly rare. Usually they are discovered as a space-occupying lesion in a radiograph following a barium swallow, ordered on account of dysphagia. The diagnosis is confirmed by œsophagoscopy with, perhaps, biopsy. Papilloma of the œsophagus is usually solitary, and occurs in the upper third of the organ. Diathermy excision through an œsophagoscope is a satisfactory method of treatment. A polyp with a narrow stalk can be removed with a snare. Occasionally a leiomyoma or a submucous lipoma causing symptoms of dysphagia has been removed successfully by the transthoracic approach. The most difficult benign neoplasm of the œsophagus to treat is a cavernous hæmangioma which, as might be expected, usually gives rise to hæmatemesis. Injection of a sclerosing agent is sometimes successful; in others, partial œsophagectomy is required.

CARCINOMA OF THE ŒSOPHAGUS

Most cases are diagnosed only after œsophageal obstruction has supervened and the tumour has progressed beyond the anatomical limits of the organ. By this time it has usually involved the regional, if not distant, lymph nodes. In spite of modern methods of treatment, only 2 or 3 per cent. of patients with this disease survive for five years after the diagnosis has been made.

The œsophagus is a common site for a carcinoma in men but is exceeded in incidence, by the bronchus, stomach, colon, prostate and pancreas. In

Richard Schatzki, Contemporary. Radiologist, Mount Auburn Hospital, Cambridge, Massachusetts, U.S.A.
Chevalier Jackson, 1865–1958. Professor of Bronchoscopy and Œsophagoscopy, Jefferson Medical College, Philadelphia, Pennsylvania, U.S.A.

Japan, carcinoma of the œsophagus occurs even more frequently, and at a younger age, than in Western races. It may be primary or secondary. The latter is becoming more common with the increased incidence of bronchial carcinoma.

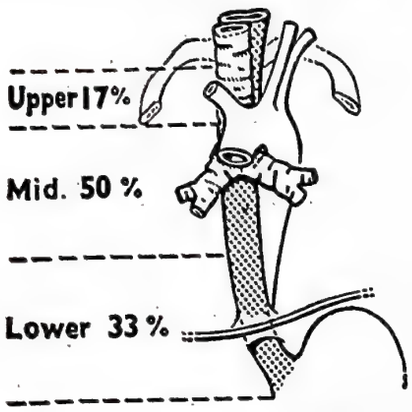

FIG. 846.—The relative frequency of squamous-celled carcinoma in various portions of the œsophagus.

Pathology.—The lesion may be squamous celled or an adenocarcinoma. The latter occurs essentially at the lower end from the lower 3 cm lined by columnar epithelium (fig. 818), or may be secondary to carcinoma of the stomach. The sites of predilection for the squamous-celled growth are the three areas of constriction (fig. 819). The incidence is shown in fig. 846.

Macroscopically three types can be recognised:

1. An annular stenosing lesion usually found at the cardia.
2. An epitheliomatous ulcer with everted edges.
3. A fungating cauliflower-like friable mass.

Spread: (*a*) *Direct.*—This is the main method of spread and the most important to the surgeon. It is both transverse and longitudinal in direction and erodes the muscular wall to invade the important structures of the neck and posterior mediastinum, as well as the lungs and trachea. It may perforate and lead to mediastinitis; rarely it causes massive fatal bleeding from the aorta.

(*b*) *Lymphatic.*—Submucosal lymphatic permeation may lead to satellite nodules away from the main tumour. Similarly, embolic spread to surrounding lymph nodes occurs. From the cervical œsophagus the spread is to the lymph nodes of the supraclavicular triangles. From the thoracic œsophagus metastases pass to the para-œsophageal and tracheo-bronchial lymph nodes, with downward extension to the subdiaphragmatic nodes. In the case of the abdominal œsophagus, spread is to the lymph nodes along the lesser curvature of the stomach, and thence to those around the cœliac axis. In the main, lymphatic metastases occur in a *downward* direction.

(*c*) *By the blood-stream* is exceptional; occasionally metastases occur in the liver or the lungs.

FIG. 847.—Carcinoma of the œsophagus as seen through an œsophagoscope. (*A. Lawrence Abel, F.R.C.S., London.*)

Clinical Features.—Men between forty-five and seventy are the usual victims, their average age being sixty-three. About 28 per cent. of the patients are women, and in them the neoplasm is situated most frequently in the upper third of the œsophagus; their average age is in the late fifties.

The leading symptom—indeed, often the only symptom—of this fell disease is dysphagia. Sometimes, owing to sloughing of a portion of the growth, for a time swallowing becomes easier, but as a rule the difficulty is steadily progressive. Only 40 per cent. of patients report within three

months; too often the patient procrastinates seeking advice until he can no longer swallow milk pudding. By this time the growth must have encircled at least three-quarters of the lumen of the œsophagus and, as might be expected, loss of weight is obvious. Regurgitation (œsophageal pseudo-vomiting) is a fairly common symptom. The regurgitated material is alkaline, mixed with saliva, and possibly streaked with blood. In growths situated in the lower part of the œsophagus, anorexia is sometimes a feature. Pain, if it occurs, is usually a late manifestation, but it is not in itself a contraindication to an exploratory operation.

Radiography after barium emulsion has been swallowed should be carried out in every case of dysphagia. By this investigation the presence of a carcinoma of the œsophagus (fig. 848), or, more usually, the stenosis produced by the neoplasm ('rat tail'), is displayed (fig. 849). Nevertheless, complete reliance must not be placed on the radiological findings, particularly if the examination is negative.

FIG. 848. — Early carcinoma of the œsophagus.

FIG. 849.—'Rat tail' appearance, in advanced carcinoma.

Œsophagoscopy is usually diagnostic. A piece of the tumour must always be removed for histology.

Bronchoscopy should be undertaken when there is a cough with expectoration of large quantities of purulent sputum which suggests involvement of the bronchial tree, and possibly a fistula.

Exfoliative Cytology.—Lavage of the œsophagus and examination of the fluid for malignant cells has led to the discovery of an early carcinoma when radiology and œsophagoscopy were negative.

Treatment.—Dysphagia is a most distressing symptom and somehow it must be relieved. Gastrostomy is an unsatisfactory procedure and is mentioned only to be condemned. Treatment is by operative resection, radiotherapy or by some palliative procedure.

Pre-operative Treatment.—Hourly feeds, as much as the patient can take, of fortified milk (2 eggs, 60 g sugar, 1 teaspoonful salt, 60 g dried milk, and 30 g of butter to 1·0 l of milk) are given. Breathing exercises and, when necessary, postural

drainage are carried out. The patient's teeth, if present, are scrutinised as hygiene of the mouth is most important. Suitable preparations of iron and vitamins are prescribed. Antibiotic therapy is commenced three days before the operation.

Operation.—It is only after the region of the growth has been displayed and the extent of its fixity to surrounding structures ascertained that it is possible to tell if partial œsophagectomy is practicable. As a result of exploration, about 50 per cent. of growths will be found to be irremovable, in which case a short-circuiting operation is performed. If the growth is operable, the methods of procedure are as follows:

(*a*) **Growth at the Cardiac Orifice.**—Through a left thoraco-abdominal approach (fig. 850) a block dissection of the stomach, together with the spleen, omenta, and tail of the pancreas, is undertaken. Restoration of the continuity is by œsophago-jejunostomy, employing a Roux-en-Y anastomosis.

FIG. 850. — Usually the eighth rib is resected subperiosteally. If more room is required, the posterior ends of the seventh, sixth, and fifth ribs are sectioned.

(*b*) **Growth situated in the Lower Third of the Thoracic Œsophagus.**—The operative surgery for such a growth has swung away from the left thoracoabdominal exposure to that used for a **growth in the middle third,** namely an abdominal and right thoracic approach. This trend has been due to the difficulty in securing a sufficient length of growth-free œsophagus for an anastomosis below the arch of the aorta. An abdominal incision is made first, and the greater and lesser curvatures of the stomach fully mobilised from cardia to pylorus, preserving the right gastric and gastro-epiploic vessels. The cardia is freed from its hiatus at this stage and a pyloroplasty is performed. The patient is then turned on to his left side, and the œsophagus approached via a right-thoracotomy at the level of the fifth rib. The vena-azygos is the only structure requiring division. The œsophagus is then fully mobilised after which the stomach is drawn up into the chest. The œsophageal resection extends from 6 cm above the growth right down to the cardia to include a cuff of gastric wall. This gastric defect is closed in two layers, and the highest point of the fundus anastomosed to the cut end of the œsophagus (fig. 851). Debilitated patients may benefit from a two-stage procedure several days apart.

(*c*) **Growth lies in the Thorax above the Arch of the Aorta.**—See Post-Cricoid carcinoma (p. 675).

* * *

Other Methods of bridging the Defect.—The great disadvantage of utilising the stomach as a substitute for the œsophagus is reflux œsophagitis above the anastomotic line. For this reason other methods are being used. The best of these is colon replacement. An isolated segment of the transverse or the right colon, with its blood supply intact, is brought up to connect the stump of the œsophagus to the stomach. An intrathoracic polythene prosthesis has been used but, in general, it has not been found to be satisfactory.

Radiotherapy.—In carcinoma of the upper and mid-œsophagus radiation frequently restores the ability to swallow, although this benefit lasts only a few months. Recent results with penetrating radiation are more encouraging and an increasing number of long-term survivals are being obtained.

Growths of the Upper Third.—The magnitude and severity of extirpation of the œsophagus in this region, and the radio-sensitivity of most of the neoplasms, render radiotherapy the method of choice.

Growths of the Mid Third.—The ^{60}cobalt teletherapy unit emits gamma radiation equivalent to the most powerful super-voltage X-ray machine, and a rotational device has enabled a more uniform dose to be delivered to the growth. In a number of instances, as a result of this treatment, the tumour disappears; however, in spite of improvement in swallowing, the majority of patients soon die of metastases.

Growths of the Lower Third.—Frequently the neoplasm is columnar-celled and less radio-resistant and figures of from 10–15% five-year survival rate are reported.

The results of radiotherapy plus operation appear to be little better than either alone. McKeown, however, found about 30% of his patients surviving after 5 years after excision of a middle-third growth and slightly less living for 3 years after lower-third growth. The operative mortality was about 25% in growths above the lower third.

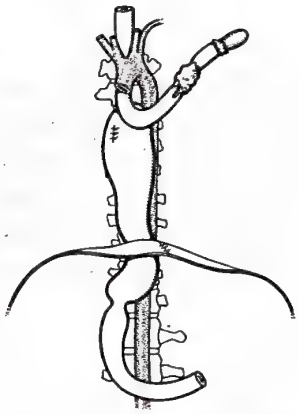

FIG. 851.—Resection of the œsophagus for a growth in its middle third, utilising the mobilised stomach for restoring the continuity of the alimentary tract (semi-diagrammatic).

PALLIATIVE PROCEDURES

When Thoracotomy reveals that the Growth is Irremovable.—If the neoplasm is situated at the cardia, the œsophagus can be divided above the growth, the lower end closed, and œsophago-jejunostomy-en-Y (Roux) performed above the obstruction. When the neoplasm is higher in the thoracic œsophagus, after similar exclusion, the previously mobilised stomach can be anastomosed to the œsophagus above.

When Inoperability is decided upon at a Clinical Examination.—Inoperability is so frequent and the results of heroic surgery so disappointing that a simple palliative procedure assumes an added importance. The introduction of a tube not only allows the patient to take sufficient nourishment by mouth, but relieves him of his one distressing symptom: dysphagia. It also protects him from recurrent aspiration pneumonitis. Neither of these is avoided by a gastrostomy.

FIG. 852.—Celestin tube.

The Souttar tube, made of German silver and pushed blindly into position after dilatation, has now been replaced by safer tubes that are *pulled* into position. The Celestin tube based on physiological considerations consists of a 25-cm shaft carrying an oval barrel-shaped funnel about the size of a bolus. It is pulled into position by a detachable pilot-bougie (fig. 852). The latter is navigated through the growth under direct vision, no dilatation being required. The tip of the bougie is recovered in the stomach via high gastrotomy. The endo-œsophageal tube is then plugged on securely to the bougie and traction applied steadily to the latter so as to draw the tube through the tumour. The tube must be finally left in a comfortable vertical position,

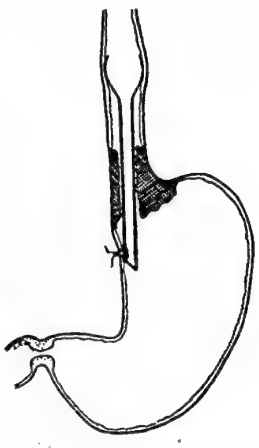

FIG. 853.—Method of fixation of tube.

Kenneth Charles McKeown, Contemporary. Consulting Surgeon, Darlington Memorial Hospital, Darlington, England.

Louis Roger Celestin, Contemporary. Surgeon, Frenchay Hospital, Bristol, England.

even if this means that the funnel lies several inches above the tumour (fig. 853); otherwise ulceration may result. It is then tethered to the lesser curve and any excess cut off. After the operation the patient may be allowed a fairly free diet provided it is chewed very thoroughly, and frequently washed down with aerated water. The tube may also be used in patients receiving high-voltage irradiation, or as a pre-operative measure.

Terminal Complications.—Unresected, the growth causes death in one of the following ways:

1. Progressive cachexia and dehydration.
2. Pneumonia from perforation into some part of the bronchial tree.
3. Mediastinitis from perforation into the posterior mediastinum.
4. Erosion of the aorta (rare).

CHAPTER 41

THE STOMACH AND DUODENUM

SURGICAL ANATOMY

Blood Supply

Arterial Supply (fig. 854).—(*a*) The left gastric artery, the smallest branch of the coeliac axis, runs towards the cardiac orifice and thence along the lesser curvature, from left to right, to join (*b*) the right gastric artery, which arises from the hepatic artery and pursues a course from right to left along the lesser curvature. (*c*) The gastro-duodenal artery is the largest branch of the hepatic artery. It passes behind the first part of the duodenum, where it bifurcates into the superior pancreatico-duodenal artery and (*d*) the right gastro-epiploic artery. (*e*) The left gastro-epiploic artery is the largest branch of the splenic artery. (*f*) Vasa brevia (short gastric arteries) are five to seven small vessels that spring from the splenic artery towards its termination, and are distributed to the fundus of the stomach. An important feature of the gastric circulation is the large number of arterio-venous shunts in the submucosa of the lesser curve. These are opened up by vagotomy.

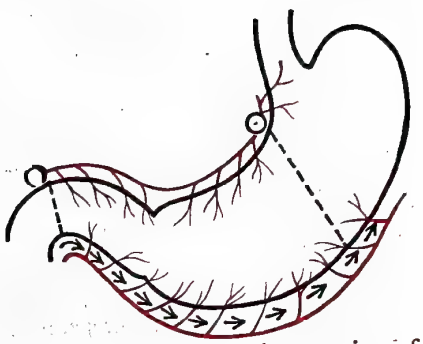

FIG. 854.—The main arteries of the stomach. Circles denote where the R. and L. gastric are divided. Arrows denote place of section of gastro-epiploic arteries. Dotted lines show where stomach is divided in partial gastrectomy.

Veins.—Those corresponding to the right and left gastric arteries terminate in the portal vein. Those corresponding to the left gastro-epiploic artery and vasa brevia join the splenic vein, while the right gastro-epiploic vein empties into the superior mesenteric vein. In the living, the veins of Mayo (fig. 855), are helpful landmarks in distinguishing the pyloric canal from the first part of the duodenum.

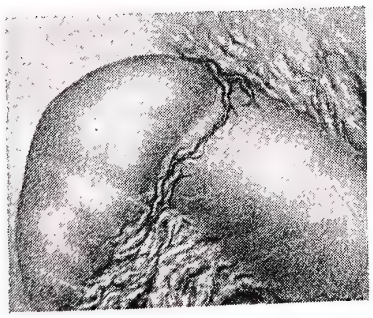

FIG. 855.—The pre-pyloric vein of Mayo.

Lymphatics are described on p. 823 in connection with malignant neoplasms of the stomach with which they are so intimately concerned.

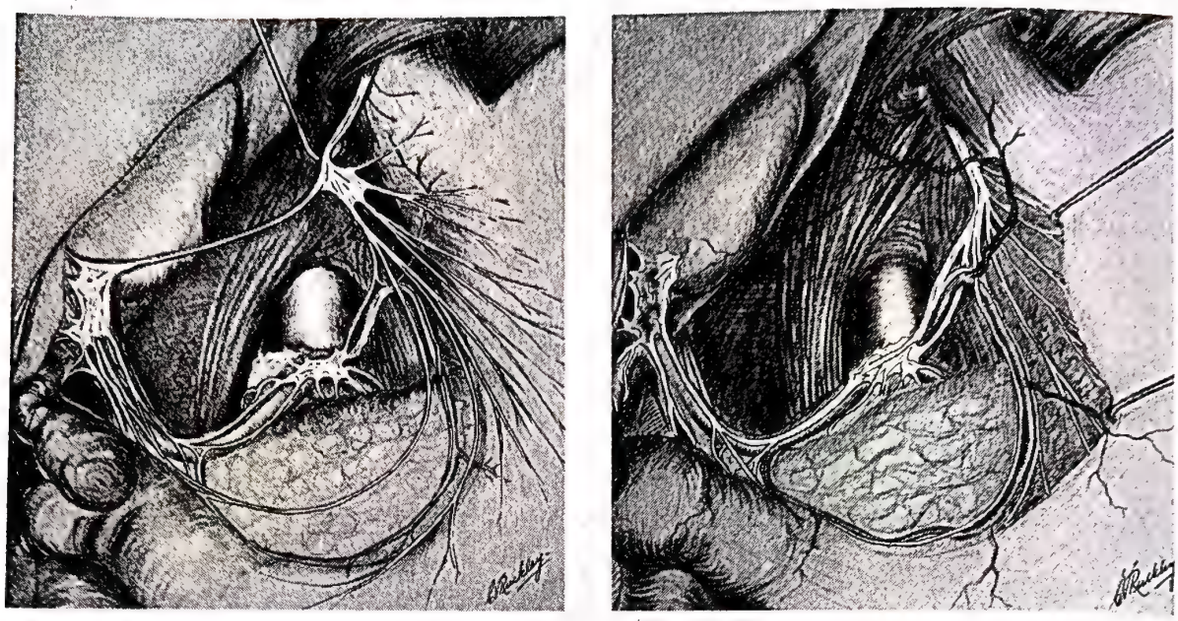
Innervation.—The vagus nerves are the motor nerves of the stomach. Fig. 856 shows the general disposition of the nerves, and their branches. Familiarity with the common distribution and main variations of the nerves is important owing to the swing from total to selective or highly selective vagotomy operation for duodenal ulcer (p. 802).

Histology

Gastric Epithelial Cells lining the stomach are of the columnar type. They are filled with mucigenous granules and are responsible for the lubrication of contents. About a third of them regenerate by mitosis daily. They do not respond to acid secretagogues.

Parietal Cells.—These occur only in the body of the stomach and lie in the gastric crypts. Electron-microscopic studies show many inter-cellular canaliculi which communicate with the crypt lumen. They are responsible for the secretion of isotonic HCl to a pH of 0·9. In a normal adult male the parietal cell population is of the order of 1 billion whilst in about two-thirds of duodenal ulcer cases this may

William James Mayo, 1861–1939. Surgeon, Mayo Clinic, Rochester, Minnesota, U.S.A. The pre-pyloric vein should be called the Vein of Latarget as it was first described by André Latarget (1876–1947), Professor of Anatomy, Lyons, France.



A B

FIG. 856.—A, anterior and B, posterior vagus nerve. Showing distribution to stomach, cœliac, and subhepatic plexuses (*C. V. Ruckley, F.R.C.S., Edinburgh*). The anterior and posterior nerves of Latarjet are seen crossing the pancreas on their way to supply the pylorus. The sympathetic innervation of the organ may carry a proportion of pain transmitting fibres.

be nearly doubled. In the Zollinger-Ellison syndrome (Chap. 45) a four-fold increase has been reported. In gastric ulcer the count is low.

Chief Cells.—These lie mainly in the proximal part of the gastric crypts in the fundic mucosa and are responsible for the secretion of pepsinogen.

Endocrine Cells.—The mid-zone of the gastric mucosa contains G-cells, which synthesise gastrin. G-cells are found mainly in the gastric antrum, and their distribution differs from that of parietal cells on which gastrin acts. The number of G-cells may be increased in duodenal (but not gastric) ulcer patients, and is greatly increased in the condition known as G-cell hyperplasia (Polak).

PHYSIOLOGY OF THE STOMACH AND DUODENUM

The important physiological functions of the stomach and duodenum are secretory and motor. The stomach acts as a reservoir from which food, ingested over a period of minutes, is released over a period of hours after undergoing acid and peptic digestion into the duodenum. In the duodenum, the mixed food and gastric secretions, now known as ' chyme ', are brought to neutral pH by duodenal and pancreatic secretion of bicarbonate, and the osmolarity of the chyme is equilibrated with plasma. In addition, various nutrients stimulate the release from endocrine cells in the duodenal mucosa of polypeptides which modulate the secretory and motor activity of the digestive tract. The rate at which chyme is delivered from the stomach is dependent upon the osmolarity and the fat and caloric content of the chyme through receptors in the proximal duodenal mucosa (Hunt).

Secretion of Gastric Juice

The gastric juice consists mainly of pepsin, intrinsic factors, ions and other organic solutes in dilute hydrochloric acid. Conventionally, three phases of secretion of gastric juice are recognised.

1. **Cephalic.**—This is mediated by vagal activity, both from psychic arousal as demonstrated by Pavlov, and reflexly from antral stimulation (Uvnäs).

2. **Gastric.**—Gastrins are polypeptides differing in secretogenic potency and molecular size, but identical in action (Gregory), which are released from antral G-cells in response to mechanical distension of the antrum, and to meat proteins. After release from the G-cell, gastrin reaches the parietal cell *via* the systemic circulation. Secretion of acid is controlled by negative feedback; when intragastric

Börje Karl Magnus Uvnäs, Contemporary. Professor of Physiology, University of Stockholm, Sweden.
Roderic Alfred Gregory, Contemporary. Holt Professor of Physiology, University of Liverpool.

pH falls below 3, due to acid secretion, the release of gastrin is inhibited. Because of the buffering capacity of a mixed meal, acid output is high for half an hour after eating, but falls thereafter. The role of histamine, long known as a potent stimulus of gastric acid secretion, has been a matter of controversy, but it now seems likely that gastrin acts on the parietal cell through the release of histamine.

3. **Intestinal.**—Prolongation of acid secretion for some hours after feeding was originally ascribed to 'intestinal factors'; but, since a mixed meal is not emptied from the stomach for several hours, it is probably due, for the most part, to prolonged gastrin release from mechanical stimulation of the antrum. The effect of chyme in the intestine on gastric secretion is largely inhibitory in order to preserve the neutral pH of the duodenum. Duodenal acidification provokes secretin release which inhibits gastric acid secretion (Grossman), and other intestinal polypeptides are probably implicated in this regulation.

Pepsin Secretion

The secretion of pepsin is usually coupled to H+ secretion, but may be varied by cholinergic stimuli and by polypeptide hormones.

Gastric Mucus

The gastric mucosa is covered and lubricated by this viscid secretion, which is composed of mycopolysaccharides. As with pepsin, its secretion may be evoked by vagal stimulation on feeding. Its pH is alkaline, and it has considerable buffering capacity (up to 80 mmol/l, Hollander).

Gastric mucus forms a physiological barrier which protects the mucosa from mechanical damage and the effects of gastric acid. Davenport has suggested that this barrier is broken in cases of gastric ulcer, leading to back diffusion of H+ ion into mucosal cells; this would account in part for the apparently reduced secretion of acid in such patients, although the reduced number of parietal cells in such patients may produce hyposecretion. The barrier may be damaged by bile acids refluxed through the pylorus and by drugs such as salicylates and alcohol. Irritation of the gastric mucosa may lead to excess mucus production.

Duodenal Exocrine Secretion

Although the duodenum is a relatively short tube, its surface area is extensive, due to the arrangement of the mucosa in transverse folds, the valvulæ conniventes ('winking' valves). In the first and second part of the duodenum, an alkaline secretion is produced by Brunner's glands into the crypts of Lieberkühn: the volume of secretion is related to the amount of acid delivered through the pylorus. This alkaline secretion is largely responsible for correcting the pH of chyme to neutrality.

Gastric and Duodenal Endocrine Secretion

Both in variety and quantity of secreted polypeptides, the gut (including the stomach) may be justly termed the largest endocrine organ in the body. Although a gastrointestinal hormone, secretin, was the first hormone to be described in physiological terms by Bayliss and Starling, the majority of gastrointestinal polypeptide hormones have been described in the last decade, following advances in immunoassay, cytochemistry and protein chemistry. While the physiology of these substances is still uncertain, there are some facts which are generally agreed.

Structure of the Polypeptides

The majority of the polypeptides may be divided into two groups, on the basis of their structure. *Gastrin* and *cholecystokinin-pancreozymin* (CCK-PZ) have structural and functional affinities, with similar terminal amino-acid chains; both polypeptides occur in man in several variants of different peptide chain lengths. *Secretin*, *enteroglucagon* and *gastric inhibitory peptide* (GIP) have numerous structural affinities. Some polypeptides, such as *motilin*, appear to be unique in structure.

Localisation

The secretory cells of the polypeptide hormones are scattered among the epithelial cells of the gastrointestinal mucosa and are not aggregated in discrete glands. Gastrin is largely confined to the gastric antrum; most of the others are secreted in the small

intestine, and principally in the duodenum. All secretory cells are adjacent to the lumen of the digestive tract, and luminal stimuli provoking polypeptide release (such as peptones releasing gastrin) have been identified in some cases.

Function

Most of the polypeptides seem to be implicated in the control of digestive exocrine secretion, either exciting or inhibiting secretion. Gastrin provokes gastric acid secretion, secretin and CCK-PZ induce pancreatic secretion, while secretin inhibits gastric acid secretion. There is no definite agreement about the physiological role of the remaining polypeptides, but many secretory effects have been induced experimentally.

A second role for the gastrointestinal polypeptides is in the control of gastrointestinal motor activity. CCK-PZ is the agent which mediates gall-bladder contraction, while gastrin stimulates gastric motor activity. Many other motor effects have been described, but, again, no clear picture has yet emerged.

The proximity of some endocrine cells to their exocrine target cells has led to the suggestion that *paracrine* effects (passage of polypeptide from secretory cell to target cell by local spread) may occur, but this is difficult to prove, and proof is as yet lacking.

Gastroduodenal Motor Activity

The complex sequence of digestive and absorptive processes acting on ingested nutrients requires the orderly propulsion of luminal content through different regions at different rates; this is accomplished by neurohumoral regulation of the contractile activity of the smooth muscle which completely invests the digestive tract.

The motor activity of the stomach and duodenum is rhythmic, and is controlled by waves of electrical depolarization, known as *slow waves*. Slow waves are generated at proximal pacemaking sites in the stomach and duodenum, and spread aborally through the longitudinal smooth muscle fibres at speeds of several centimetres per

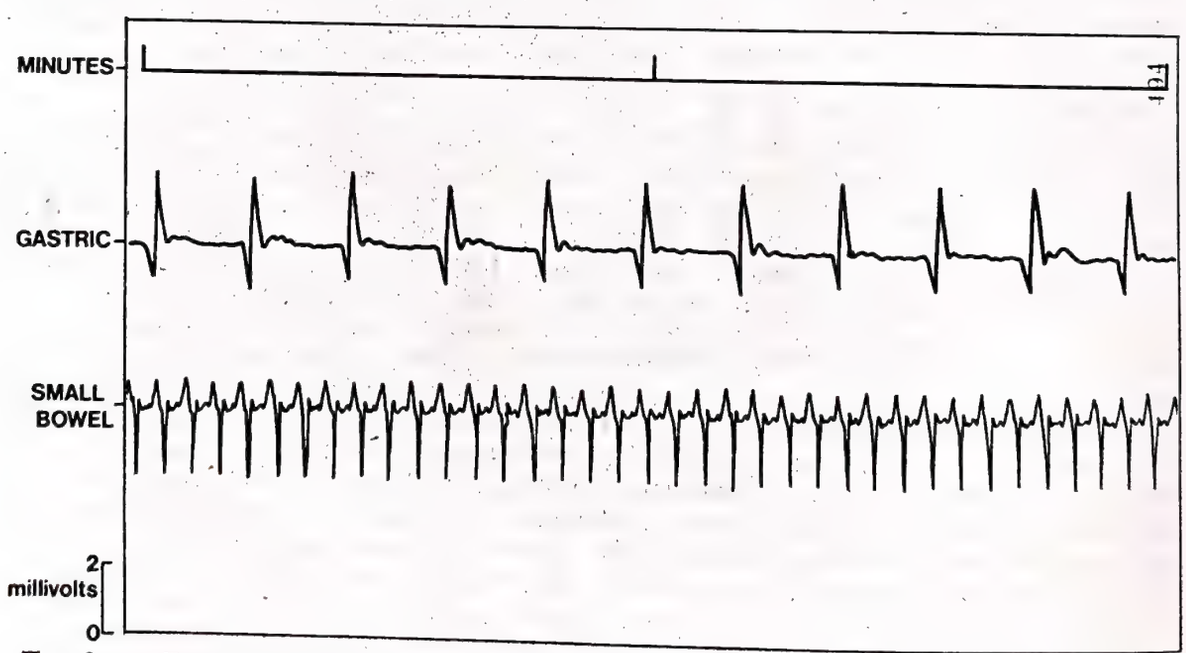

FIG. 857.—Pacemaking activity recorded at a single site in the canine stomach (upper trace) and duodenum (lower trace).

second. The gastric pacemaker, in the gastric fundus, emits three slow waves per minute which descend to, but do not pass, the pylorus. Duodenal slow waves are generated by a pacemaker immediately distal to the pylorus (Hermon-Taylor) at a rate of ten per minute. These rhythmic slow waves, sometimes known as the *basic electrical rhythm*, resemble the electrocardiogram in nature and function: slow wave recording from the serosal surface of stomach and duodenum show rhythmic changes similar to, but slower than the E.C.G. (fig. 857).

Since smooth muscle contraction at any site can occur only during the passage of a slow wave, pacemaker activity controls the *timing* of motor activity, and also the

John Hermon-Taylor, Contemporary. Professor of Surgery, St. George's Hospital, London.

direction, as the slow waves travel caudally. But (unlike the E.C.G.) gastric and duodenal slow waves do *not* invariably initiate contraction during their passage. Simultaneous recording of duodenal electrical activity and intraluminal pressure change (fig. 858) shows regular slow wave activity, but pressure changes only occur with slow waves which show associated action potentials (fig. 858). Intrinsic and

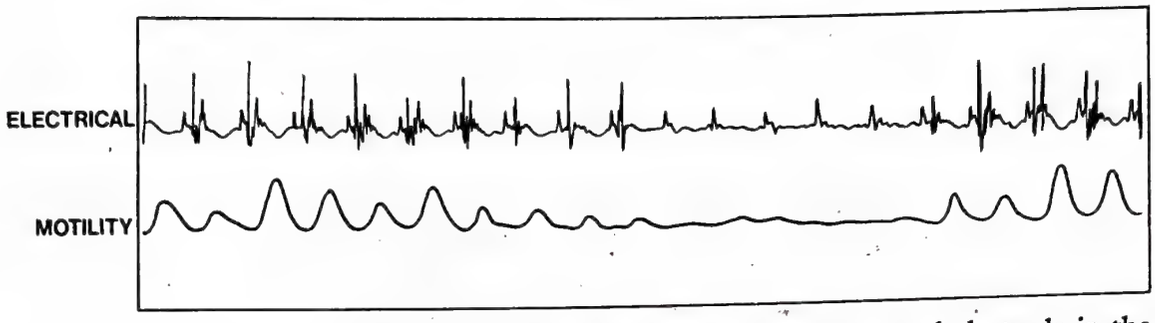

FIG. 858.—Simultaneous recording of myoelectric activity from a serosal electrode in the canine small intestine (upper trace) and intraluminal pressure adjacent to the site of the electrode. Regular pacemaking (small deflections) is visible, but pressure changes only occur when action potentials (large deflections) follow the pacemaking wave.

extrinsic neural and humoral changes, as yet not fully explained, determine whether or not a slow wave will produce contraction; it is these factors, which integrate the motor activity of stomach and small intestine with the processes of digestion and absorption.

Gastric Emptying

The mixing and slow emptying of a mixed meal from the stomach is accomplished by means of the ' antral pump '. Gastrin release stimulates gastric motor activity by a slight increase in slow wave frequency, and a marked increase in the associated

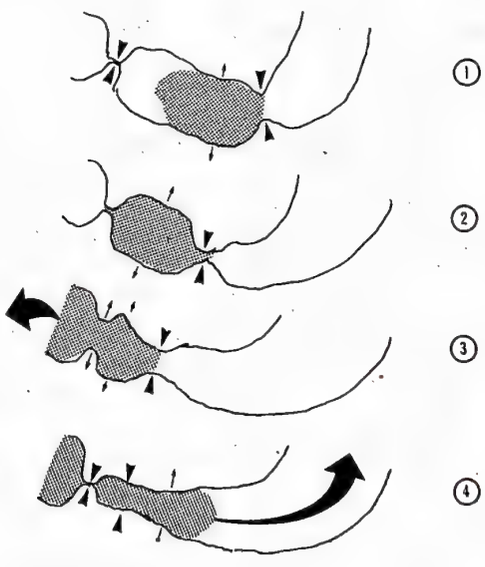

FIG. 859.—Sequential stages of gastric emptying. The pacemaker site and direction of flow wave propagation are shown at the right; the caudal propagation of contraction is shown in sequence from 1 to 4. Gastric contents are propelled into the antrum by the wave of contraction coupled to the slow wave (1, 2); as the antrum contracts some, content is expelled through the lax (3) as antral pressure rises. When the contraction wave reaches the pylorus (4), it closes, and antral pressure leads to retropulsion of gastric contents.

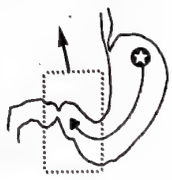
antral pump



contractile activity. Caudal contraction waves propel contents into the gastric antrum (fig. 859): as the antrum fills, the pylorus, which has no resting tone, opens to allow the escape of some chyme. When the contraction wave reaches the pylorus, it closes, and the continuing antral contraction produces retropulsion of antral contents into the

gastric corpus. Thus each contraction wave produces both the escape of a small quantity of chyme and the mixing of the remainder; in this way, the capacity of the duodenum to restore the pH of chyme to neutrality is not overcome. The volume lost through the pylorus with each contraction will depend upon the viscosity and the amount of solid in the gastric contents; fluids are emptied more rapidly.

Fasting *vs.* Feeding

There is a striking difference between the overall pattern of gastroduodenal motor activity during fasting, and following feeding. During fasting, a few minutes of active motor activity is followed by an hour or more of absent motor activity; this cycle of alternating brief activity and prolonged inertia is repeated indefinitely in the absence of food. This pattern is not merely cyclical; it is also migratory. The brief phases of motor activity occur synchronously in stomach and proximal duodenum; as they decline, the activity ' front ' passes caudally to the distal duodenum, and so on

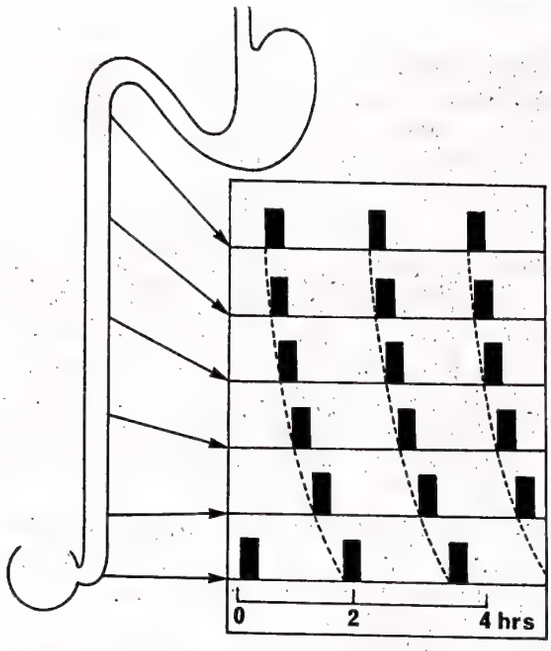


FIG. 860.—The canine ' intestinal housekeeper '; phases of strong motor activity (activity fronts) are shown at six levels in the small intestine, represented by solid bars. Between activity fronts, contractile activity is minimal or absent. Typically, as shown here, the proximal origin of an ' activity front ' coincides with the arrival of the preceding ' front ' at the terminal ileum.

along the length of the small intestine. By contrast with the slow waves, the migration speed of these fronts is slow; passage from the stomach to the terminal ileum takes 1–2 hours, and the appearance of a new gastroduodenal front coincides with arrival of the previous front at the terminal ileum (fig. 860). These migratory complexes have been termed the intestinal ' housekeeper ' (Code) and probably propel fasting secretions and debris. Again in contrast to pacemaking activity, the ' clock ' which controls the migration of fasting fronts lies outside the digestive tract, possibly in the cœliac plexus. The duodenum is important in the intergration of this activity; there is evidence that one of the duodenal hormones, *motilin*, is implicated in this fasting control.

The transit of the ' housekeeping ' front would be too fast to allow digestion and absorption of food to be complete; on feeding, the ' housekeeper ' is immediately abolished, to be replaced at all levels of the intestine by intermittent contractile activity, permitting agitation and mixing of the chyme without rapid passage. When the stomach is empty, the fasting pattern resumes. The effects of feeding on the pattern of motor activity can be simulated by the administration of gastrin (Code); thus it seems that gastrin release has an important motor function. It seems probable that other gastrointestinal polypeptide hormones will be shown to be implicated in the regulation of motor activity, and it may be that further study will lead to clarification of some of the common but ill-defined ' functional bowel syndromes ' as disorders of neurohumoral regulation.

CURRENT TESTS OF GASTRIC SECRETION

(1) Night Fasting Secretion
(2) Maximal Acid Output (Pentagastrin)
(3) Insulin Test (Hollander)

Charles F. Code, Contemporary. Associate Director, Center for Ulcer Research, Los Angeles, California, U.S.A.

(1) Night Fasting Secretion (Dragstedt).—This is a method of assessing the inter-digestive or resting secretion of the stomach. Continuous or intermittent low-pressure gastric suction is carried out through an indwelling gastric tube previously screened into position. Normally about 400 ml. secretion is aspirated in the twelve-hour period from 9 p.m. to 9 a.m. Volumes above this level are suggestive of duodenal ulceration, and in Zollinger-Ellison syndrome cases (Chap. 45), volumes in excess of a litre occur. The estimation of free HCl content is valuable as an index of vagal activity (Table 1). This view has recently been challenged by Baron who found it to give variable results.

TABLE 1

Free HCl in mmol in twelve hours' night secretion

Normal	10– 20
Gastric Ulcer	5– 15
Duodenal Ulcer	40– 80
Duodenal Ulcer with Gastric Ulcer	40– 60
Zollinger-Ellison Syndrome	100–300

TABLE 2

Average HCl response in mmol Free Acid/hr

	Basal	*Maximal*
Gastric Ulcer	2	14·6
Duodenal Ulcer	6	37·5
Anastomotic Ulcer	7·7	31
Zollinger-Ellison Syndrome	22	

(2) Maximal Acid Output (Pentagastrin).—Basal secretion is measured by aspiration of the fasting stomach for 1 control hour. Then the pentagastrin test is performed. Gastric acid secretion may be maximally stimulated using pentagastrin (Peptavlon I.C.I.). Side effects are negligible. 6μg/kg body weight is administered s.c., or i.m. and 15 minute samples are collected during the subsequent hour. (See Table 2.) The total number of mmol/hr secreted is then calculated and is taken to be directly related to the size of the parietal cell mass. Ranges found in different conditions are shown in Table 2.

Only limited reliance may be placed on such tests if they are not carried out by experienced investigators. It can be taken, however, that a patient cannot have *less* acid than is aspirated. He *may* have more. If the technique is faulty this will not be realised.

The tests are of value in the diagnosis of stomal ulcer or the Zollinger-Ellison syndrome (Chap. 45). In duodenal ulcer they may be a useful guide to which operation is more suited to the patient, e.g. where low, vagotomy and drainage—where high, 50 mmol and above—vagotomy and antrectomy or partial gastrectomy.

Achlorhydria, by definition, occurs when a stomach cannot produce juice with a pH of less than 7·1 even after maximal stimulation. It occurs in 18% of patients with gastric carcinoma (Baron).

(3) Insulin Test (Hollander).—Since acid production following hypoglycæmia is attributed to direct vagal action on the parietal cell mass, insulin given to a patient who has had a vagotomy performed should result in no increase in acid production. This test is thus valuable post-operatively to verify the completeness of vagal section. To a fasting patient 2 units/10 kg soluble insulin are given intravenously, and serial quarter-hourly gastric aspirations performed for the next four hours. Blood-sugar levels are also measured at frequent intervals to ensure that the level falls below 35 mg/100 ml (2 mmol/l)—the level necessary to guarantee adequate vagal stimulation.

Early response.—A rise in concentration of 20 mmol per litre above the basal level in the first hour suggests incomplete vagotomy. If the basal samples were anacid, a concentration of 10 mmol per litre is regarded as positive.

Delayed response.—A rise in the concentration of acid secreted may occur between the first and fourth hours. This is thought to be due to vagal gastrin release. It is abolished by antrectomy. It suggests a less than complete vagotomy.

An early negative Hollander test may become positive some years later. The importance of this finding is not yet clear.

In addition, the glucose tolerance curve, an X-ray of the pituitary fossa, the serum calcium and phosphorus levels, and the urinary 17-ketosteroids may help to elucidate the difficult case with an endocrine background (multiple adenoma syndrome).

Estimation of circulating gastrin.—Radio-immunoassay techniques are available.

Lester Reynold Dragstedt, Contemporary. Research Professor of Surgery, University of Florida, Gainsville, U.S.A.
Jeremy Hugh Baron, Contemporary. Consulting Physician, St. Charles Hospital, London.

The principles of assay are:

A specific antigen is raised against gastrin. The biological sample competes with radioactive isotope-labelled hormone for combination with the antigen. The gastrin in the sample quantitatively inhibits the antigen binding with labelled hormone. The degree of inhibition gives a measure of gastrin in the sample. The findings have proved useful in diagnosis of the Zollinger-Ellison syndrome (Chap. 45).

Atrophy of Gastric Mucosa.—Atrophy may be due to duodenal regurgitation or it may be due to antibodies in the blood specific for the cytoplasm of the parietal cells. Such antibodies are found in pernicious anæmia in which there is also an antibody against intrinsic factor.

CURRENT TESTS OF DUODENAL SECRETION

No standard test of duodenal secretion exists, but monitoring of pH in the proximal duodenum may reveal an excessive fall in pH after a meal due to acid hypersecretion associated with duodenal ulcer.

CURRENT TESTS OF GASTRODUODENAL MOTOR ACTIVITY

Gastric emptying of a semi-solid meal can be monitored in a number of ways; the most reliable is the use of a gamma camera to follow the emptying of a meal of scrambled eggs labelled with Technetium. This may be of value in assessing the results of surgery on the gastric outlet.

HYPERTROPHIC PYLORIC STENOSIS OF INFANTS

Ætiology.—The cause of the condition, which occurs 3 or 4 times in every 1,000 births, is unknown. Several theories have been propounded, the most acceptable being that the condition is due to an achalasia (primary failure of the pylorus to relax). In a small proportion (about 7 per cent.) of cases the abnormality appears in certain families with greater frequency than can be accounted for by coincidence. In these families one parent bears the scar of an operation for hypertrophic stenosis in infancy, and in 50 per cent. of cases it is the mother, which, when the much higher incidence in the male is taken into consideration, is remarkable. In these families a brother is affected similarly in 10 per cent. and a sister in 2 per cent. of cases.

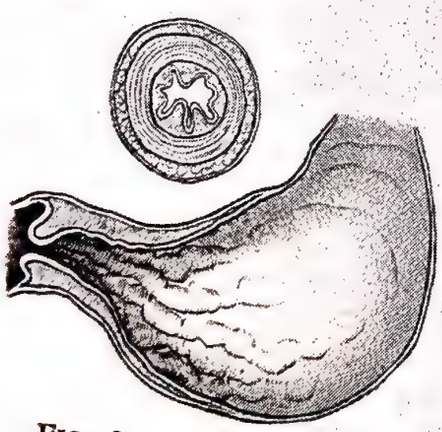

FIG. 861.—Pyloric stenosis of infants. Longitudinal and transverse sections of the stomach to show the enormous muscular hypertrophy. Note the abrupt termination.

Pathology.—The musculature of the pyloric antrum is always hypertrophied. Proceeding distally, the hypertrophy increases, to reach its zenith in the circular fibres of the pylorus. Here the muscle layer is so thick that the mucosa is compressed, and often the lumen admits only a fine probe. As estimated at operation, the size of the pyloric lump is proportional to the duration of the symptoms. The hypertrophy terminates abruptly, the duodenum being normal.

Clinical Features.—Characteristically first-born male infants are most commonly affected.

The peak incidence for the onset of symptoms is between the third and sixth weeks of life; however, the condition can commence before that time, and as late as the seventh week. The pillars upon which the diagnosis rests are:

Vomiting is the presenting symptom in all cases and within two or three

days it becomes forcible and projectile. Bile is not present in the vomit. Immediately after vomiting the baby is often very hungry.

Visible Peristalsis.—After the child has been fed, peristaltic waves may be seen passing from left to right across the upper abdomen (fig. 862). A good light is essential for this; the abdomen should be watched throughout a feed until vomiting occurs.

The Presence of a Lump.—The palpation of the hypertrophied pylorus is the most essential step in reaching a diagnosis. The surgeon should sit on the left side of the child and palpate under the liver with a warm hand. It may be helpful to examine the child more than once. The lump is most easily felt when the child is given a feed.

FIG. 862.—Visible peristalsis in hypertrophic pyloric stenosis: it is unusual for the waves to be so obvious. (*Alan Kark, F.R.C.S., London.*)

Constipation is usually present, and when a stool is passed it is small and dry resembling those of a rabbit. It is important to ask the mother about napkins; if the child is dehydrated, they are not wet and the case is correspondingly more urgent.

Loss of Weight.—One of the most striking signs of infants suffering from hypertrophic pyloric stenosis is loss of weight. Moreover, it is not long before the infant begins to look emaciated and dehydrated.

Often a change from one type of feeding to another brings about a remission. Consequently a series of changes in diet are sometimes made before the diagnosis is established, by which time the infant's condition may be pitiable.

In premature infants, in whom the condition is not uncommon, the symptomatology is often paradoxical. There is anorexia instead of a voracious appetite; the vomiting is regurgitant rather than projectile, and so frequently is peristalsis normally visible in these attenuated subjects that its significance is liable to be disregarded. None the less, amidst this sea of bewilderment one diagnostic rock remains—a hypertrophied pylorus can be felt through the poorly-developed abdominal wall with comparative ease.

Radiography.—The diagnosis should be made on a careful clinical examination and an X-ray is rarely necessary. To be diagnostic, a barium meal should show persistent narrowing and elongation of the pyloric canal.

Differential Diagnosis.—Conditions from which hypertrophic pyloric stenosis must be differentiated are (*a*) intracranial hæmorrhage; (*b*) duodenal atresia; (*c*) high intestinal obstruction, e.g. volvulus neonatorum (Chap. 48). In (*b*) and (*c*) bile will be present in the vomitus.

Treatment.—The majority of pædiatricians believe that surgery is the treatment of choice: the condition is immediately and completely corrected and the child is well within twenty-four hours. Babies who are admitted in a dehydrated condition should receive sufficient half-strength dextrose-saline solution, given subcutaneously with hyaluronidase, to restore the fluid balance. This results in a remarkable improvement in the general condition:

the sunken eyes and cheeks and depressed fontanelle fill out; the dry skin and mucous membrane become moist, and the output of urine increases.

Medical Treatment

In cases complicated by infection, especially of the mouth, medical treatment is advisable because of the increased risk of post-operative gastro-enteritis, even if operation would otherwise be indicated.

In subacute cases the patient often reaches the age of two months before the symptoms become obvious and if, as a result of medical treatment, the gastric residue decreases in amount, a cure by non-operative means can be anticipated.

Eumydrin (atropine methylnitrate) 1:10,000 of water, freshly made, is given half an hour before each feed, beginning with 0·5 to 1 ml. and increasing to 2·5 ml. to control the symptoms. Toxic symptoms (erythema and hyperpyrexia), though less common than when atropine is employed, do occur with Eumydrin[1], and are signs that the dose of the drug should be decreased or its use discontinued. Small, frequent feeds of milk (if possible the mother's milk), diluted with 5% dextrose, are given. Eumydrin must never be given until a firm diagnosis has been made.

Surgical Treatment.—After correction of dehydration, operation is performed without delay. The recovery rate approaches 100 per cent in early cases.

Ramstedt's Operation.—*Preliminary Preparation.*—The stomach is washed out with saline several times; finally, one hour before operation. Immediately before operation gastric aspiration must be performed, and continued throughout the operation. The prevention of chilling is of great importance. To this end the temperature of the operating theatre should be high (27°C) and the infant's body is encased in wool, the upper abdomen alone being accessible.

FIG. 863. — The upper part of the hypertrophied pylorus is comparatively bloodless.

Operation.—Local anæsthesia is advisable unless the child is in good condition and the services of an anæsthetist skilled in anæsthesia of infants are available. The abdomen is opened by a grid-iron[2] incision in the upper right quadrant of the abdomen. The hypertrophied pylorus is delivered and rotated so that its superior surface comes into view; thus the least vascular portion (fig. 863) can be selected for the incision. In order to ascertain the distal limit of the hypertrophied pylorus the surgeon invaginates the duodenum with his index finger. The incision is made through the serosa only from this point along the whole length of the lump (fig. 864). Because the hypertrophied pylorus is the consistency of an

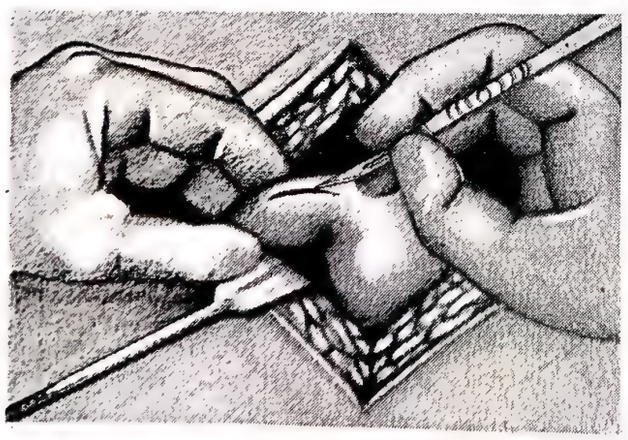

FIG. 864.—Ramstedt's operation.

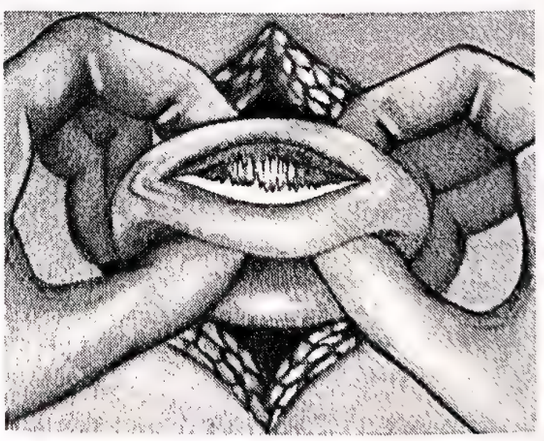

FIG. 865.—Showing the hypertrophied muscle divided and the mucous membrane bulging into the incision.

[1] Eumydrin was introduced as a therapeutic improvement on atropine in the treatment of congenital pyloric stenosis by Svensgaard in 1935.

[2] Transverse through the skin and the anterior rectus sheath, and splitting the rectus muscle vertically.

Elisabeth Svensgaard, 1894–1952. Physician, Rigshospitalet, Copenhagen.
Wilhelm Conrad Ramstedt, 1867–1963. Surgeon, Rafael Clinic, Munster, Germany. Performed his first pyloromyotomy in 1911. He discovered in church records that his grandfather had misspelt the family name with two 'm's, so in 1920 he reverted to the original spelling.

unripe pear, splitting of muscle coats can be accomplished with a blunt dissector. On separating the edges with artery forceps, the pyloric mucosa bulges into the cleft which has been made in the muscle (fig. 865). Great care is taken not to penetrate the mucosa, an accident which is liable to occur while dividing the most distal part of the constricting fibres which are in the vicinity of the duodenal 'fornix' (fig. 861). In order to be sure that there is no perforation, some air is squeezed from the stomach into the duodenum. If a perforation has occurred, it is closed by a wisp of omentum held in place by three or four interrupted sutures of fine silk (fig. 866). The free entry of air into the duodenum indicates adequate division of the muscle. Hæmostasis must be meticulous. The abdominal incision is repaired. It is important to remove the wool from the infant's body as soon as the operation is over, or hyperthermia may occur.

After-treatment.—A small feed of not more than 5 ml should be given one hour after operation, and after that the feeds can be rapidly increased. The child should be feeding normally in forty-eight hours and if there is no vomiting at this time, it is the practice in many hospitals to send the child home and bring it back for removal of stitches. If the mucosa was accidentally opened at operation, it is wise not to feed the child orally for forty-eight hours.

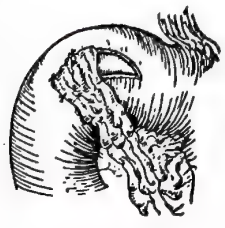

FIG. 866.—Patching a perforation of the mucous membrane. *(After C. E. Welch, Boston, Mass.)*

Complications:

(*a*) *Post-operative pyrexia* is rather common and is not necessarily of serious consequence. If protracted, tepid sponging is advisable.

(*b*) *Gastro-enteritis* is minimised by absolute cleanliness of feeding utensils, segregation and sending the child home as soon as convenient.

(*c*) *Disruption of the wound* is also rare, and is more liable to occur in emaciated subjects. The use of the grid-iron incision in these cases has reduced the incidence of this complication.

Hypertrophic pyloric stenosis of adults is a definite entity and is often mistaken for carcinoma of the pylorus. When a diagnosis can be made with certainty, pyloroplasty or a gastro-jejunostomy (p. 803) gives excellent results; when doubt exists, a Billroth I gastrectomy is done. Microscopical examination of the specimen shows fibrosis of the myenteric plexus (contrary to the corresponding condition in the infant).

CONGENITAL ATRESIA OF THE DUODENUM

There is stenosis, usually complete, across the duodenum (fig. 867). This occurs at the point of fusion of the fore- and mid-gut, and consequently lies in the neighbourhood of the ampulla of Vater. It is frequently accompanied by other congenital

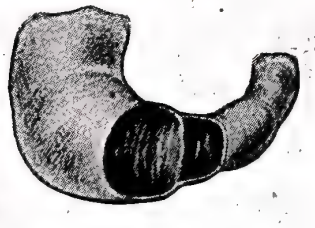

FIG. 867.—Congenital septal duodenal obstruction at the commencement of the third part of the duodenum. The gut above is enormously dilated. *(After W. E. Ladd.)*

defects. The infant vomits *from birth*, and daily rapidly loses weight. In contradistinction to congenital pyloric stenosis *the vomit contains bile.* Laparotomy should be undertaken without delay. Duodeno-jejunostomy is the best procedure when, as is usually the case, the obstruction is in the second or third part of the duodenum (Ladd). In these cases the stoma is difficult to keep open and it is wise to introduce a fine plastic tube through a gastrostomy opening, through the stomach across the stoma and down into the jejunum for a few inches. This should be retained for several days for feeding purposes.

PEPTIC ULCERS

There are two main types—gastric and duodenal. Either may present in an acute or chronic form.

Christian Albert Theodor Billroth, 1829–1894. Professor of Surgery, Vienna.
Abraham Vater, 1684–1751. Professor of Anatomy and Botany, Wittenberg, Germany.
William Edwards Ladd, 1880–1967. Professor of Child Surgery, Harvard University, Boston, Massachusetts, U.S.A.

Acute Peptic Ulcers

Ætiology.—Acute gastric ulcers are thought to be due to disruption of the gastric mucosal barrier. They appear as multiple erosions and the gastric mucus presents as large white globules instead of the usual opalescent fluid. About half the patients give a history of ingestion of aspirin or butazolidine. Classically they present with hæmorrhage.

Pathology.—Acute peptic ulcers are frequently multiple—in 75 per cent. of cases more than three of these lesions are present. They can occur in any part of the stomach, but in the duodenum they are almost confined to the first part. These ulcers are oval or circular in shape, and vary in size from 1 to 2 mm in diameter (when they are called erosions) to 1 or more cm in diameter. They are shallow, punched out, and seldom invade the muscular coats. When healing occurs, acute peptic ulcers are unlikely to leave scars.

Clinical Features.—Acute peptic ulcers probably occur with great frequency. They give rise to short-lived attacks of dyspepsia which are not diagnosed, and the ulcer heals. Usually they are recognised only when they cause hæmatemesis. Occasionally an acute ulcer, particularly when it is situated on the anterior wall of the duodenum, perforates. By gastroscopy, it has been ascertained that acute peptic ulcers can be the cause of hæmatemesis at all ages and in both sexes. Such lesions have been seen to progress to chronic ulceration (Tanner).

Treatment.—If possible, the cause must be removed. Under medical treatment acute peptic ulcers tend to heal rapidly. Blood transfusion may be required for hæmatemesis. Dietetic irregularities must be corrected in order to prevent recurrence or chronicity.

Stress Ulcers.—These constitute a special group of acute ulcers. They occur most frequently in patients in Intensive Therapy Units. There is usually a history of hypotension from hæmorrhage, endotoxin shock or cardiac infarction. Sometimes they are seen after cerebral trauma or neurosurgical operations (Cushing's ulcer) but it has been held that these are not true stress ulcers. After major burns two types of ulcer occur (Curling's ulcer). Within the first 48 hours multiple acute erosions may develop anywhere in the body and fundus of the stomach (14% of cases). The antrum and duodenum are unaffected. These are thought to be true stress ulcers. Later, during convalescence acute duodenal ulcers may occur (9%), which sometimes become chronic. These are probably not stress ulcers.

As to ætiology, there may be mucosal ischæmia due to vascular shunting, as well as reflux of duodenal contents into the stomach. The output of gastric mucosubstances is also increased and there is shedding of the surface epithelial cells all of which predisposes to ulceration. Patients on steroids may develop similar lesions, sometimes referred to as *steroid ulcers*.

CHRONIC PEPTIC ULCER

Ætiology.—We do not know why some acute ulcers become chronic. Many theories have been put forward but none is a satisfactory explanation for all the various forms of the lesion.

Incidence.—Peptic ulcer, rare before the age of sixteen, becomes more frequent as middle age approaches, and in England nearly 10 per cent. of men aged forty-five to fifty-four years are thus afflicted. Occupation has some bearing on the condition; thus significantly high incidences are found among doctors, foremen and business executives, while significantly low incidences occur among agricultural workers and sedentary workers, e.g. clerks, civil servants and draughtsmen (Doll). The popular belief that bus-drivers are especially liable to this condition has not been substantiated. In many parts of the world, e.g. U.S.A., Scandinavia, this disease is as rife as it is in Great Britain. Conversely, the incidence among Africans and Asiatics living in their native lands is comparatively low, except in the newly emerging nations where the local population are assuming increasing responsibility. Duodenal

Norman Cecil Tanner, Contemporary. Formerly Surgeon, St. James's Hospital, Balham, London.
Harvey Cushing, 1869–1939. Professor of Surgery, Harvard University, Boston, Mass., U.S.A.
Thomas Blizard Curling, 1811–1888. Surgeon, The London Hospital. Described this ulcer in 1842.
Sir William Richard Shaboe Doll, Contemporary. Regius Professor of Medicine, Oxford, England.

ulcer is found four times more commonly than gastric ulcer in patients under the age of thirty-five years, but after forty-five years of age it is only one to two times more common. In Scotland the ratio of duodenal to gastric ulcer is higher than in England, while in India the ratio of duodenal to gastric ulcers is 30:1.

All over the world the incidence of peptic ulcer in women is much lower than in men, and in women the two types of ulcer are about equal. Chronic gastric and duodenal ulcers not infrequently co-exist. In such instances the duodenal ulcer appears first.

Gastric Ulcer.—Chronic gastric ulcer is associated with either normal or hyposecretion, atrophic gastritis, and usually occurs in a later age group. It is a disease of the labouring classes rather than those subject to stress and responsibility. Frequently the patient has dental trouble.

Duodenal Ulcer.—Most patients, although by no means all, have gastric hypersecretion of acid. Duodenal ulcer patients tend to have a larger than normal parietal cell mass.

(*a*) *Genetic and Blood Groups.*—There is definite evidence that chronic ulcers occur in families. Moreover, persons of blood group O are about three times more likely to develop a peptic ulcer than are persons of other blood groups. It seems possible that the ABO genes may modify the size of the parietal cell mass.

(*b*) *Neurogenic Theory.*—Stimulation of the vagus results in gastric hypersecretion and hypermotility. Stress and anxiety are undoubtedly a leading cause of duodenal ulcer and these probably exert their effect via the vagus.

(*c*) *Accessory Causes.*—Inadequate mastication, alcohol, irregular meals, excessive smoking, and vitamin deficiency have, at one time or another, been blamed. It has been conclusively shown that smoking delays healing in gastric ulcers.

(*d*) *Endocrine.*—The effects of emotional, as well as physical stress are hormonally transmitted to the stomach via the pituitary-adreno-cortical axis (fig. 684). There are specific endocrine disorders which may be associated with severe or intractable ulceration. These include (i) the Zollinger-Ellison syndrome, where a non-beta cell tumour secreting 'gastrin' occurs in the pancreas (Chap. 45); (ii) the multiple adenoma syndrome, where adenomas occur in the pituitary, adrenal, pancreatic, and parathyroid glands (p. 620); (iii) hyperparathyroidism (p. 620).

Pathology.—Ulcers, whether gastric or duodenal, tend to occur in alkaline mucosa. The ulcer-bearing area is shown (shaded) in fig. 868. This

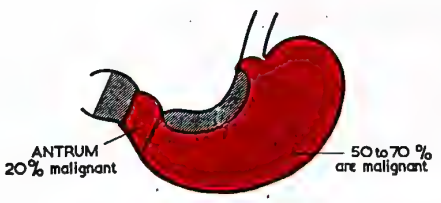

FIG. 868.—*Shaded Area.*—The common area for benign ulcers in stomach and duodenum. *Red Area.*—In this area ulcers carry a high risk of malignancy.

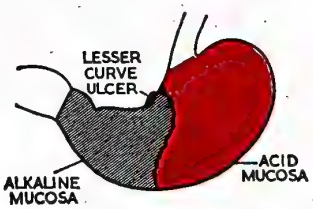

FIG. 869.—Area of gastritis (alkaline) in gastric ulcer. Red area = acid mucosa.

area is much smaller than the area of atrophic gastritis (fig. 869) which is the precursor of gastric ulcer. The ulcer itself occurs in the alkaline mucosa of the atrophic area adjacent to the acid-secreting fundic mucosa. A chronic peptic ulcer invades the muscular coats, which it tends to penetrate. When a

gastric or duodenal ulcer heals, the site is covered by a mucosal scar. Fibrosis, the result of recurrent ulceration, causes deformities, including pyloric stenosis and hour-glass contracture.

Chronic Gastric Ulcer is usually larger than a chronic duodenal ulcer. It varies in size, but in a well-established case it will admit the tip of a finger. The floor of a chronic gastric ulcer is situated in the muscular coats of the stomach, and as time goes on the ulcer occupying the posterior wall becomes adherent to, and later invades (chronic perforation), the pancreas. In the same way a chronic ulcer situated on the antero-superior aspect of the stomach can penetrate the liver, while a saddle-shaped ulcer situated on the lesser curvature can, and often does, penetrate both the liver and the pancreas.

Chronic Duodenal Ulcer.—The ulcer is nearly always situated in the first part of the duodenum, and sometimes two 'kissing' ulcers are present: one on the anterior surface and one on the posterior surface of the first inch of the duodenum. An anterior ulcer may perforate, a posterior one carries the risk of secondary hæmorrhage by erosion of a large vessel.

Microscopical Examination.—There is nearly always greater destruction of the muscular coat than of the mucosa. The base of the ulcer is covered by a thin layer of granulation tissue. The arteries in the neighbourhood show evidence of endarteritis obliterans. Often there are no nerves in the floor of the ulcer but always many in the edge. The terminations of these nerves are bulbous, akin to those in an amputation stump (Kinsella). At the margin of the ulcer there may be epithelial proliferation, and downgrowths of glandular tissue are apt to be found, which are sometimes misinterpreted as indicating a carcinomatous change (Newcomb).

Do Peptic Ulcers become malignant?—A chronic duodenal ulcer never becomes carcinomatous. On the other hand, a chronic gastric ulcer may become malignant, but how frequently this change takes place is a matter of great difference of opinion (see above). It would seem probable that it does not exceed 0·5 per cent. Even **giant ulcers** (those with a crater of more than 2·5 cm. in diameter) are seldom carcinomatous.

Pathology at Operation.—A chronic peptic ulcer may present as a white scar under the peritoneal coat. Delicate vascular adhesions, salmon pink and fluffy in appearance, can often be observed in the immediate neighbourhood of the peritoneal aspect of the ulcer. At other times the ulcer must be sought for by palpation; induration, frequently extensive in the case of a gastric ulcer, is centred over the mucosal lesion. When the ulcer is situated in the duodenum, the surrounding induration is not so evident, but if the ulcer is situated on the posterior wall it may be possible to feel the crater with the tip of the finger. A useful method of confirming the presence of a peptic ulcer, particularly one situated on the anterior wall of the duodenum, is to rub the peritoneal surface gently with a swab; the peritoneum overlying the ulcer becomes speckled, as though sprinkled with cayenne pepper (fig. 870), a characteristic phenomenon due to minute petechial hæmorrhages.

If there is any doubt about the presence of an ulcer, a longitudinal gastrotomy incision should be made and the mucosal area inspected. Ulcers in the pyloric channel (p. 811), and around the cardia, may be missed if this is not done.

Victor John Kinsella, Contemporary. Consulting Surgeon, St. Vincent's Hospital, Sydney, Australia.
Wilfrid Davidson Newcomb, 1889–1971. Professor of Pathology, St. Mary's Hospital, London.

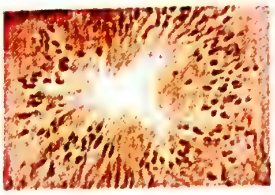

FIG. 870.—Petechial hæmorrhages around the peritoneal aspect of a chronic peptic ulcer. These become more obvious after gently rubbing the surface with gauze.

THE CLINICAL FEATURES OF GASTRIC AND DUODENAL ULCERS CONTRASTED

It is useful to record the patient's history under seven headings.

Chronic Gastric Ulcer.—The patient is usually beyond middle age, and by reason of a restricted diet is often thin. In many instances the patient appears anæmic, and this is often confirmed by a hæmoglobin estimation. On careful enquiry certain features of the dyspepsia become manifest. Typically there is:

1. *Periodicity.*—The attacks last for several weeks, and are followed by intervals of freedom from two to six months. The attacks are more in evidence in the spring and autumn and should be recorded.

2. *Pain* is epigastric, and may occur immediately, or any time up to two hours, after food. Pain may radiate through to the back, is relieved by lying down flat and practically never occurs at night.

3. *Vomiting.*—In over 50 per cent. of cases vomiting is a notable symptom. It relieves the pain, and may be self-induced.

In the 'pyloric channel' ulcer vomiting may be the predominant or only symptom and the barium meal may be negative. Endoscopy is essential in order to make the diagnosis. Pyloric channel deformity may be the precursor of a lesser curve gastric ulcer.

4. *Hæmatemesis and Melæna.*—At some time or other 30 per cent. of patients with gastric ulcers suffer from bleeding from the ulcer. The ratio of hæmatemesis to melæna is about 60:40.

5. *Appetite* is good, but the sufferer is afraid to eat.

6. *Diet.*—The patient learns to avoid fried foods, stews, curries, and twice cooked meat. Milk, eggs, and fish are the staple diet.

7. *Weight.*—Usually by the time the surgeon is consulted there has been some loss of weight.

On examination there is frequently deep tenderness in the mid-line of the epigastrium a few inches above the umbilicus.

Chronic duodenal ulcer can occur at any time during adult life, but is commonest between the ages of twenty-five and fifty. It is more common in men, who appear otherwise healthy.

1. *Periodicity* is usually well marked, and classically the attacks come on in the spring and in the autumn and are precipitated by 'work, worry, or weather'. These attacks usually last from two to six weeks, with intervals of freedom from one to six months.

2. *Pain* is severe, and may double the patient up. It usually occurs two to two and a half hours after food. As it is often relieved by food, the pain is known as 'hunger pain', and, classically, the patient carries biscuits, which he eats at frequent intervals to prevent this gastric torment. The pain, which is also relieved by alkalis, often awakens the patient round about 2 a.m. but is usually absent at the normal hour of rising.

Berkeley George Andrew Moynihan (Lord Moynihan of Leeds), 1865–1936. Professor of Clinical Surgery, Leeds, England, was the first to describe 'hunger pain'.

3. *Vomiting* is rare in duodenal ulceration unless it is self-induced or stenosis has occurred. Regurgitation of burning fluid into the mouth (' water-brash ') together with pain deep to the sternum (' heart-burn ') due to reflux œsophagitis are common complaints (1:10).

4. *Hæmatemesis and melæna*, which occur in the ratio of 40:60, but sometimes together, are rather more frequent than in the case of gastric ulcer.

5. *Appetite* is exceptionally good, but the patient sometimes refrains from eating solid food during the attacks.

6. *Diet.*—In contradistinction to patients with a chronic gastric ulcer, those suffering from duodenal ulcer who have not been ordered a special diet seldom display much dietetic discrimination, although some of the more intelligent find it advisable to avoid fried food.

7. *Weight.*—Usually there is no loss of weight; indeed, the patient often becomes plump (partly because of the ingestion of milk to relieve pain).

On examination it is not unusual to find localised deep tenderness in the right hypochondrium.

After about two years the course of the disease becomes steady. There is 1 per cent. risk of perforation and 3 per cent. risk of massive bleeding—1 in 4 require surgical intervention in four to five years. An ulcer that starts with bleeding or perforation is likely to do it again.

Summary

	Gastric Ulcer	*Duodenal Ulcer*
Periodicity	Present	Well marked
Pain	Soon after eating, but not when lying down	Two hours after food Night pain
Vomiting	Considerable vomiting	No vomiting
Hæmorrhage	Hæmatemesis more frequent than melæna	Melæna more frequent than hæmatemesis
Appetite	Afraid to eat	Good
Diet	Lives on milk and fish	Eats almost anything
Weight	Loses weight	No loss in weight

SPECIAL METHODS OF INVESTIGATION

Barium Meal.—The radiological findings are often conclusive. In a lesser curve *gastric ulcer* a niche will be seen projecting from the usually smooth outline (fig. 871). The stomach is often hypotonic and J-shaped and hangs low in the pelvis. In *antral ulcer* the appearance of the niche is similar (fig. 872). *Anastomotic ulcers* can also be shown (fig. 873) although only about 30% can be demonstrated. In *duodenal ulcers* diagnosis depends on demonstrating an ulcer crater filled with barium—this is positive evidence of an ' active ' ulcer (fig. 875). In longstanding ulcers so much scar tissue is present that it is often impossible to show an ulcer crater with a persistent flake of barium. Where, however, deformity is *constant* the inference is that there has been a chronic cicatricial process due to an ulcer. In such a case the folds of scar tissue converge on the ulcer site, and if this ' *rugal convergence* ' can be shown, there is a very strong suspicion that an ulcer is present. It is important to recognise the shape of the normal duodenal cap when distended with barium (fig. 874). The appearances of pyloric stenosis (fig. 893) and hour-glass deformity (fig. 894) are characteristic.

Blood Studies.—A hæmoglobin estimation may show evidence of chronic blood loss. A raised erythrocyte sedimentation rate in a gastric ulcer suggests malignancy.

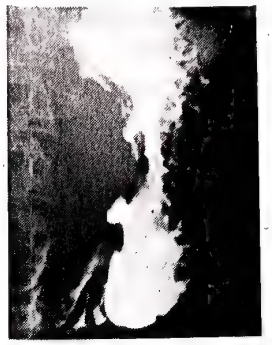

FIG. 871.—Typical gastric ulcer on the lesser curve.

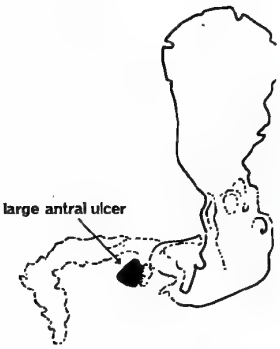

FIG. 872.—Antral ulcer.

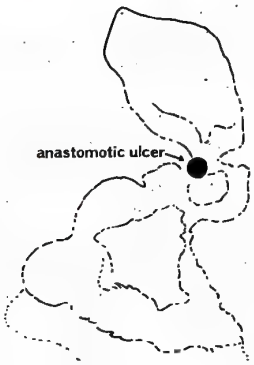
FIG. 873.—Anastomotic ulcer.



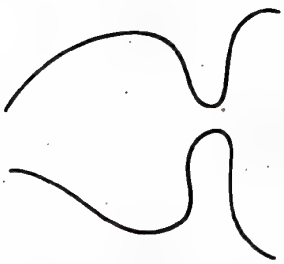


FIG. 874. — Normal duodenal cap filled with barium.

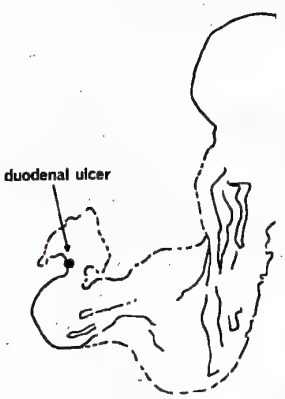

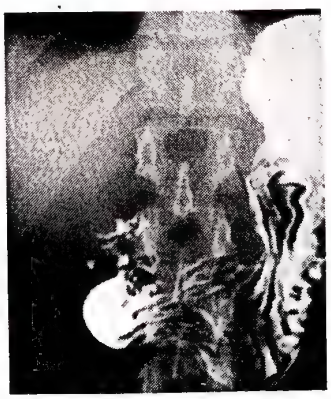

FIG. 875.—Duodenal ulcer.

Stool Studies.—Examination for occult[1] blood is important and should be done routinely in such cases on the specimen of fæces on the finger-stall at rectal examination. If the patient has recently ingested meat or aspirin, or has used a stiff tooth brush, a false positive may be obtained.

Studies of Gastric Function.—These are described in the section on gastric physiology on p. 782.

Gastroduodenoscopy requires special training and considerable experience but affords valuable information. By its employment the whole of the interior of the stomach can be adequately scrutinised by the eye of the gastroscopist (fig. 876).

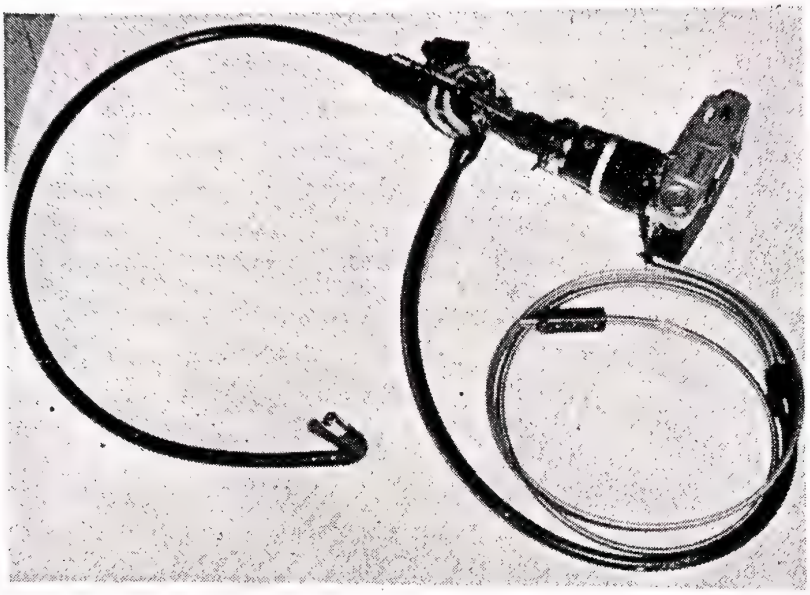

FIG. 876.—Flexible Lo-Presti oesophago-gastric fibrescope with terminal lens, biopsy channel and camera. (*A.M.S.C. and M.S.A. Ltd.*)

The fibrescope is an instrument in which glass fibre provides the lens system. It is thus flexible and the technical difficulties associated with the introduction of earlier gastroscopes are eased. It can be used to inspect the duodenal bulb (Hirschowitz) and to see beyond a gastro-duodenal anastomosis.

Following the development of the gastrocamera in Japan there is now a wide range of endoscopes which allow biopsies to be taken under direct vision. Photographs may be taken by still or cinecamera and television methods.

Indications.—Gastroduodenoscopy is valuable in the diagnosis of shallow gastric ulcers that do not show on radiography, in checking the results of medical treatment in cases of chronic gastric ulcer, in the differential diagnosis between a chronic peptic ulcer (fig. 877) and a carcinoma (fig. 878), in the diagnosis of a small gastric neoplasm,

FIG. 877.—Gastroscopic view of the lesser curvature showing a gastric ulcer above the entrance to the antrum. (*W. W. Davey, F.R.C.S.*)

FIG. 878.—Gastroscopy — early carcinomatous change in a chronic gastric ulcer in a patient undergoing medical treatment. (*Hermon Taylor, F.R.C.S., London.*)

[1] Occult = hidden.

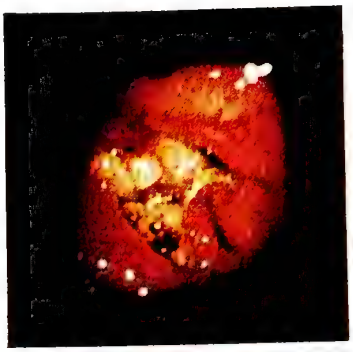

FIG. 880.—Neoplastic ulcer involving the pylorus.

in the detection of certain forms of gastritis, in the examination of the stoma in cases of suspected gastrojejunal ulcer, and in the diagnosis of duodenal ulcer.

TREATMENT OF CHRONIC PEPTIC ULCER

All are agreed that in the absence of complications threatening life, the treatment of a chronic peptic ulcer, chronic duodenal ulcer or proven benign gastric ulcer, should in the first instance be conservative (medical).

CONSERVATIVE (MEDICAL) MANAGEMENT

The same treatment regimen is appropriate for both gastric and duodenal ulcers; management differs only in the criteria of therapeutic success.

Treatment of Chronic Peptic Ulcer.—In recent years, advances in gastroduodenal physiology and pathophysiology have led to important modifications in the treatment of peptic ulcer. The basis of the regimen is the correct timing of meals and supplementary antacids. Three regular meals are essential; the content of the diet is unimportant except that all foods which the patient associates with the aggravation of symptoms must be avoided. Antacids should be given one hour and three hours after meals; combinations of aluminium and magnesium hydroxides usually represent the optimum combination of palatability and efficacy. A further dose of antacids should be taken before sleep at night.

Histamine H_2-receptor antagonists such as Cimetidine, are likely to prove more effective than antacids when administered in a similar schedule.

The value of bed rest probably derives from relief from stress, and greater adherence to the treatment regimen; it is indicated when ambulant treatment is ineffective. If prolonged pain persists in spite of bed rest and antacids, a continuous milk drip through a fine polyethylene nasogastric tube may be required to bring relief.

Provocative agents to be avoided in the treatment of an active ulcer include irritant drugs, such as aspirin, butazolidine and corticosteroids, and alcohol and tobacco. Absolute prohibition of alcohol and tobacco is not justified on scientific grounds, or for the avoidance of stress in a patient addicted to these agents. It is more realistic to limit the use of alcohol and tobacco as far as possible in the acute stage, and to aim for eventual abstinence to minimise relapse, although alcohol taken in moderation with a meal is permissible.

Criteria of Successful Therapy

The aim of therapy is the abolition of symptoms from both gastric and duodenal ulcers. In duodenal ulcer, the correlation of symptoms with radiological change is poor, and X-rays are not helpful in assessing progress. Fibre-endoscopy of the duodenum may be more informative but appearances can be misleading, and symptoms, rather than clinical tests, are the index of successful treatment. Because of the importance of not missing a malignant gastric ulcer, *radiological evidence of healing after six weeks of treatment is mandatory*, even if symptomatic remission has taken

place. If healing is not demonstrated four-quadrant endoscopic biopsy of the lesion is essential. If doubt persists, a Billroth I gastrectomy is indicated.

SURGICAL TREATMENT

Indications for Operation.—This is such an important decision that each patient must be considered individually and judged on his merits. It is wise to let the duodenal ulcer patient 'earn' his operation. If surgery is done early in the disease before he has had much pain or a complication, he will be likely to resent some of the sequelæ of surgery. In general, the following facts suggest the need for surgery:

(*a*) Intractable pain, or recurrence of pain with frequent loss of work, especially after previous perforation or hæmorrhage.

(*b*) Complications, e.g. pyloric stenosis, hour-glass deformity, perforation, or bleeding.

(*c*) In general, ulcers which have been present for five years are unlikely to heal (Watkinson). It has been suggested that the risks of operation approximate to the risks of having a peptic ulcer for five years.

(*d*) Most gastric ulcers occur on the lesser curve above the angulus. When first recognised radiologically these should be submitted to endoscopy and four quadrant biopsy. If this is negative, the patient should undergo a rigorous six-weeks' course of medical treatment. By the end of this time the ulcer should be showing gastroscopic and radiological evidence of healing, if indeed this has not already occurred. Under these circumstances medical supervision may continue. Where healing has not progressed or where there is any doubt about the histology, operation is indicated. Less frequently, the ulcer may be in the antrum or in the prepyloric region. Antral ulcers have a 10% and prepyloric ulcers a 20% chance of being malignant when they are first diagnosed radiologically. These ulcers therefore must be regarded with considerable suspicion, and endoscopy with four quadrant biopsy is mandatory. Biopsy, however, is often difficult to achieve from ulcers in this region and requires the services of a highly skilled endoscopist. Where such a person is not available, it is wise to submit these patients to operation, because of the high risk of malignancy. Medical treatment unless covered by biopsy evidence, is unjustified in such cases.

Assessment for operation.—Since the advisability of operation, the type of operation, and additional operative procedures may be affected by the results of assessing the patient, it is important to note :

1. The age, sex and general condition of the patient, including the cardio-vascular, respiratory and renal systems.

2. The presence of pyloric stenosis, bleeding, combined gastric and duodenal ulcers, hiatus hernia, gallstones and other gastrointestinal disorders.

Aims of operations.—Surgical treatment for peptic ulcers aims to cure the ulcers with the maximum effectiveness, the minimum danger and side effects. The variety of operations performed testifies to the lack of agreement among surgeons. Because duodenal and gastric ulcers are considered to be

Geoffrey Watkinson, Contemporary. Physician, Western Infirmary, Glasgow, Scotland.

different disease entities, the aims of operation differ for each type of ulcer.

Duodenal ulcer.—1. Operation aims to reduce the acid contact with the ulcer by diverting acid through a stoma as in gastroenterostomy, by removing part of the parietal cell mass as in gastrectomy, or by reducing stimuli to acid secretion by vagotomy and by antrectomy.

2. Correction of ill effects of the ulcer, such as pyloric stenosis, hæmorrhage, gastric ulcer.

3. Prevention of complications.

Gastric ulcer.—Gastric ulcer is not associated with high levels of gastric acid secretion.

1. Orthodox surgical treatment aims at excision of the ulcer-bearing area and the stomach distal to the ulcer.

2. Improving the emptying of the stomach.

3. Prevention of complications.

4. To ensure that malignant ulcers are removed and avoid the risk of such a change in benign lesions.

Mortality.—The average national mortality for gastrectomy is 2 per cent., but this figure is greater in the elderly. The mortality after vagotomy with a simple drainage procedure is 0·75 per cent. Gastrectomy is a more difficult operation and usually takes longer.

The sequelæ of gastrectomy, both immediate and remote, are now well established (p. 815). We are less sure of the remote sequelæ of truncal vagotomy.

Operations

For gastric surgery, the upper abdomen may be opened by a right paramedian incision, but if a vagotomy is contemplated, a left paramedian or mid-line approach is preferable. Having verified the diagnosis and ensured the absence of other pathology, the ensuing procedure differs according to the actual operation to be carried out.

Operations for Duodenal Ulcer

Historical

In January 1881, Billroth of Vienna performed the first successful gastrectomy, and in September of the same year Wolfler introduced the operation of gastroenterostomy. The Billroth operations consisted of gastric resection followed by gastro-duodenal anastomosis (Billroth I technique).

Four years later, in 1885, the Billroth II operation was introduced as a two-stage procedure, more by accident than design. A preliminary gastro-enterostomy was done on a gravely ill patient with a pyloric carcinoma. Contrary to expectations, the patient improved, and the stomach was resected, distal to the anastomosis. It soon became evident that the use of a gastro-jejunal anastomosis after gastric resection could be safer and easier than the Billroth I procedure. Now there are some forty modifications in technique of the Billroth II procedure—the main variations involving the use of an antecolic or retrocolic anastomosis, the direction of peristalsis in the jejunal loop, and the use of a full-width stoma or a restricted stoma with a ' valve '.

Anton Wolfler, 1850–1917. Professor of Surgery, Prague, Czechoslovakia.

I. Polya Gastrectomy (Billroth II type)

The lesser sac is opened through the gastro-hepatic omentum and the left hand introduced behind the stomach. Holding the stomach in this manner, the blood vessels and omentum along the greater curvature are divided and ligated. It is safer to do this between the gastro-epiploic artery and the greater curve. It is important at this stage to see that damage is not done to the spleen itself. The dissection is carried on to the first part of the duodenum below, and up to include the lower short gastric vessels above. The right gastric artery is divided. The duodenum is then divided and closed by at least two layers of inverting sutures. Great care is needed to avoid damage to the common bile duct. With the stomach held up, the left gastric artery is now divided. The stomach is turned over to the left and a clamp is applied to permit removal of about 60 per cent. of the stomach. End-to-side gastro-jejunal anastomosis is now made, so that the afferent loop is as short as possible. This is achieved by a retrocolic anastomosis at the duodeno-jejunal flexure. The closure of the mesocolic leaf around the anastomosis is of paramount importance. There are still many surgeons who advocate an antecolic anastomosis. The addition of ' valves ' offers no increased benefit. If the surgeon is not absolutely satisfied with the duodenal closure, a soft drainage tube should be put down to, but not touching, the duodenal stump (see p. 813).

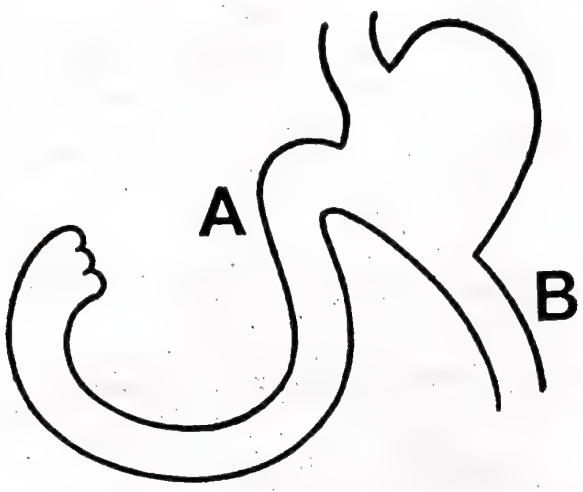

FIG. 881.—Polya type of gastrectomy. The duodenum is closed, and the first piece of jejunum is joined to the stomach remnant. A = afferent 'loop', B = efferent 'loop'.

II. Vagotomy (Vagus Nerve Section) with Gastric Drainage.—Vagotomy has the twofold effect of reducing hypermotility and hypersecretion of the stomach. Unfortunately it also causes gastric retention. It is therefore essential to perform some sort of ' drainage procedure ' such as pyloroplasty or gastro-jejunostomy to correct this. Vagotomy moreover may be followed by severe episodic attacks of diarrhœa. This is less following (1) selective rather than total vagotomy and (2) drainage by pyloroplasty rather than by gastro-jejunostomy; but in any case vagotomy should be avoided in patients who suffer from diarrhœa.

The main varieties of vagotomy are as follows:

(*a*) *Total Abdominal Vagotomy* (fig. 882A).—The abdomen is opened by a left upper paramedian incision, the diagnosis is confirmed, and the other abdominal organs are examined. The left lobe of the liver is mobilised by dividing the left triangular ligament close to its hepatic attachment. The peritoneum to the left of the œsophagus is incised and the right index finger encircles the œsophagus in order (*a*) to pass the soft rubber tube which is used for traction purposes, and (*b*) to identify the position of the posterior vagus trunk, which is thicker than the anterior nerve trunks, and lies almost entirely free from the œsophagus. With the œsophagus taut it is possible to make a thorough search for and divide all the anterior vagal fibres. Two centimetres of the posterior vagus are resected.

(*b*) *Selective* (*Specific Gastric*) *Vagotomy*.—This is best considered in two parts: *Selective Anterior Vagotomy* (fig. 882B). The cardia is exposed as above, but the encircling finger comes out beside the upper part of the lesser curve below the hepatic plexus which can be clearly seen. As the tissues on the front of the œsophagus are ligated and divided, at least 3 cm of the muscle fibres are bared and cleaned of nerves. *Selective Posterior Vagotomy* (fig. 882C). The rubber traction tube is repassed between the œsophagus and the separated posterior nerve, and the stomach is pulled to the left. Another rubber traction tube is passed behind the left gastric vessel pedicle, from below upwards, the posterior nerve being separated from the œsophagus as high as possible. All the gastric branches of the posterior nerve will be severed when all the structures in the pedicle are divided between ligatures, and the traction tube falls out.

Eugen Alexander Polya, 1876–1944. Surgeon, St. Stephen's Hospital, Budapest, Hungary.

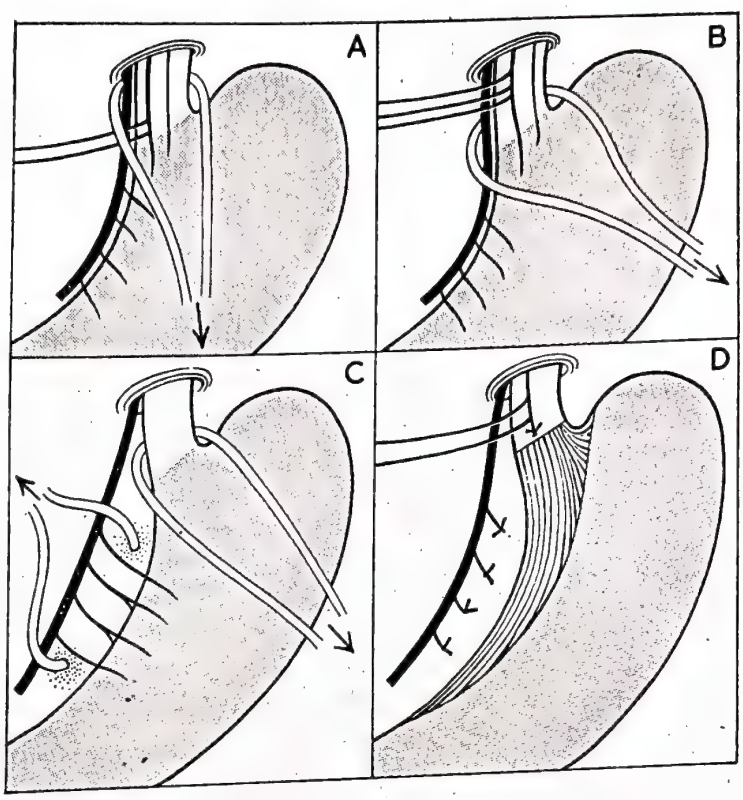

FIG. 882.—(See text.) A—Total vagotomy. B—Anterior selective vagotomy. The rubber sling is sited below the hepatic branches. C—Posterior selective vagotomy (*after Harold Burge, F.R.C.S., London*). The upper sling now excludes the posterior vagus. The lower sling encircles the left gastric pedicle. D—Bilateral selective vagotomy, showing the area cleared of nerve entry and of peritoneum.

All of the above operations are associated with gastric stasis and pylorospasm following the vagal denervation and hence a gastric drainage procedure must be carried out.

(*c*) *Highly selective vagotomy* is now increasing in popularity. This preserves the innervation of the pylorus and hence a drainage procedure is unnecessary. In this the anterior and posterior nerves of Latarjet are identified (fig. 856). Their terminal fibres reach the antral wall about 5–7 cm above the pylorus. They are preserved and with them the innervation of the pylorus. The stomach is now pulled to the left and its lesser curve laid bare from just above this point of entry of these nerves right up to the cardia. The main vagal trunks are now identified, drawn aside and the lower 5 cm of œsophagus is cleared circumferentially of nerve fibrils and vessels. The operation has not yet been widely adopted perhaps because of the anatomical difficulties of identifying these small vagal filaments.

GASTRIC DRAINAGE PROCEDURES

There are three main types:

(1) **Gastro-jejunostomy.**—The essential feature of this procedure is to establish an anastomosis at the most dependent part of the stomach, which is the greater curve on the posterior wall. A short-loop posterior operation with a vertical stoma extending to the greater curvature (fig. 883) is the type of operation that gives the best results. In this operation the stoma should be larger than in gastrectomy. Dragstedt and Tanner advocate an anterior anastomosis made in the pre-pyloric area. The risk of recurrent ulcer is less, and if it does occur, it is easier to deal with.

(2) **Pyloroplasty.**—The aim here is to produce free drainage by division of the pyloric ring. This can be done by two methods, that of Heineke-Mikulicz or that of Finney (figs. 884 and 885).

(3) **Antrectomy.**—In addition to acting as a drainage procedure, antrectomy also abolishes the hormonal phase of gastric secretion. A gastrojejunal anastomosis is

Walther Hermann Heineke, 1834–1901. Surgeon, Erlangen, Germany.
Johann von Mikulicz-Radecki, 1850–1905. Professor of Surgery, Breslau, Germany (now Wroclaw, Poland).
John Miller Turpin Finney, 1863–1942. Surgeon, Johns Hopkins Hospital, Baltimore, Maryland, U.S.A.

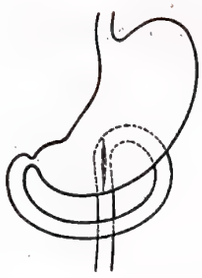

FIG. 883.—The posterior, vertical, short-loop retrocolic gastro-jejunostomy of Mayo.

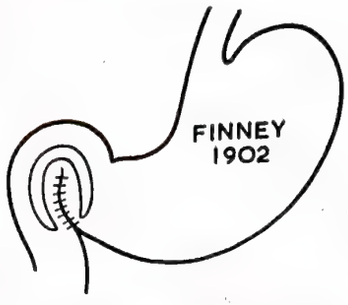

FIG. 884.—Finney pyloroplasty. The adjacent antrum and duodenum is approximated and an inverted U incision is sutured to give a wide gastro-duodenal anastomosis.

FIG. 885.—Heineke-Mikulicz pyloroplasty. A longitudinal incision of 6 cm. is closed transversely by a layer of interrupted silk sutures, reinforced by a large omental patch.

made. The operation is combined with truncal vagotomy. Care must be taken that all of the antral mucosa is removed; hence in practice, a hemigastrectomy is done.

SELECTION OF OPERATIONS FOR DUODENAL ULCER

The mortality rates and recurrent ulcer rates following different operations for duodenal ulcer are set out in fig. 886. Simple operations carry a low mortality, but a high rate of recurrence. More complicated operations carry a higher risk to life

	Mortality	*Recurrence*
Gastrojejunostomy	Less than 1%	40%
Vagotomy + Gastrojejunostomy Vagotomy + Pyloroplasty	Less than 1%	5%
Highly Selective Vagotomy	Less than 1%	?
2/3 Gastrectomy	2%	1–4%
Vagotomy + Antrectomy (hemigastrectomy)	2%	1%

FIG. 886.—Mortality and recurrent ulcer rates following operations for duodenal ulcer.

but are more effective in curing peptic ulceration. The operative risks are increased in elderly patients, in patients with concomitant disease, in those operated upon in emergency conditions because of bleeding. In contrast, all elective operations carry low risks in young, fit patients.

Gastrectomy.—Must be recognised to be an ablative procedure and is not much practised nowadays for chronic duodenal ulcer, the long-term sequelæ being regarded as too heavy a price to pay for a relatively benign condition.

Truncal Vagotomy plus a drainage operation is at present the most widely used procedure, but here the problem of postvagotomy diarrhœa, which is significant in up to 8% of patients and may be present in a lesser form in up to 30%, is a serious drawback (p. 817).

Selective Vagotomy.—These procedures are now used very infrequently.

Highly Selective Vagotomy. Data on the long-term results are not yet available. After it, the Hollander test for incompleteness of vagotomy becomes positive within a year in over half. It must not be carried out if the pylorus is narrowed by scarring. Some advocate simple dilatation for this as part of the procedure. Although tedious to do, the patients seem to tolerate the operation easily and nothing is resected. If its results prove comparable to the more extensive operations described above, it seems likely to prove the operation of choice for chronic duodenal ulcer. There is evidence, however, that the recurrent ulcer rate may be up to 10%.

Vagotomy and Antrectomy.—Is regarded by some as a reasonable alternative and less mutilating than gastrectomy itself, but the mortality rate for this procedure (fig. 886) is the same although the long-term sequelæ are less.

Gastro-jejunostomy.—It would be remiss not to mention the great value of this operation as the *sole* procedure for the treatment of duodenal ulcer. It has been practised for the whole of this century and has given great benefit to hosts of patients. Its mortality is low, but unfortunately the ulcer-recurrence rate following this has steadily increased with time, e.g. it may be as much as 40 per cent. within twenty-five years after operation. It still has a value, however, in the elderly, especially women, with pyloric stenosis in whom the gastric acidity remains low after ten days thorough gastric lavage. Women do not do well after gastrectomy of the Polya type and rarely, if ever, should a woman be submitted to this operation for simple ulceration.

Operations for gastric ulcer.—The classical operation is the Billroth I partial gastrectomy.

The stomach is mobilised by division of the main arteries as shown in fig. 854. The distal part, including the ulcer, is resected. The cut edge of the remnant is partially closed, leaving a stoma at the lower end which matches the lumen of the duodenum. The duodenum may be mobilised by Kocher's method, with division of the peritoneum around its convex border, allowing union of the stomach and duodenum without tension (fig. 887). The stoma should be as large as possible.

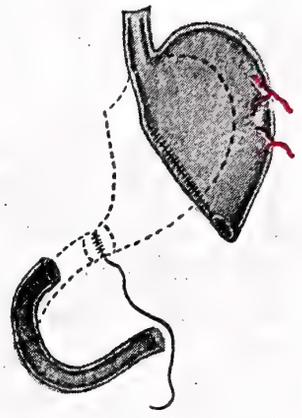

FIG. 887. — Billroth I operation. Dotted lines show rotation of the stomach, mobilisation of the duodenum, and the anastomosis in progress.

Selection of operations for gastric ulcer.

1. Billroth I partial gastrectomy is followed by recurrent ulcer in less than 1%. The resected ulcer is available for histological examination to confirm that it is benign.

2. Polya gastrectomy with resection of the stomach below a high benign gastric ulcer invariably results in healing of the ulcer. The operative difficulty, and consequent risk, is reduced. The post-operative nutritional state of the patient is better following a conservative resection.

3. Vagotomy and pyloroplasty has gained support as a conservative operation for benign gastric ulcer. If necessary, biopsy of the ulcer, with frozen section histology, should confirm the benign nature of the ulcer. The theoretical basis for employing this operation is hotly discussed. In both 2 and 3 an ulcer cancer may be missed.

LOCAL COMPLICATIONS OF CHRONIC PEPTIC ULCER

- **Acute**
  - Perforation
  - Hæmatemesis and/or melæna.
- **Intermediate.**—Residual abscess.
- **Chronic**
  - Stenosis
    - Pyloric stenosis.
    - 'Tea-pot' deformity.
    - Hour-glass contracture.
  - Penetration into neighbouring viscera, notably the pancreas.
  - Carcinoma.

PERFORATED PEPTIC ULCER

Sex.—The ratio is 19 men to 1 woman (Illingworth).

Age.—The highest incidence is between forty-five and fifty-five years.

Most often a peptic ulcer that perforates is situated on the anterior surface

Theoder Kocher, 1841–1917. Professor of Surgery, Berne, Switzerland.
Sir Charles Frederic William Illingworth, Contemporary. Emeritus Regius Professor of Surgery, Glasgow, Scotland.

of the duodenum; much less frequently it is situated on the anterior surface of the stomach, usually near the lesser curvature or the pyloric antrum. Rarely an ulcer on the posterior wall of the stomach perforates into the lesser sac. In 80 per cent. of cases there is a history—often a long history—of peptic ulceration. In 20 per cent. there is no such history; it is a 'silent' chronic ulcer that perforates, especially in those patients who are being treated with cortisone. Usually the symptoms of perforation occur with dramatic suddenness.

The gastric or duodenal contents escape through the perforation into the general peritoneal cavity, resulting in peritoneal irritation (peritonism). At that moment the victim cries out in agony, and, at any rate if the perforation is a large one and the stomach is full, he is riveted temporarily to the spot where the perforation felled him. The peritoneum reacts to this chemical irritation by secreting peritoneal fluid copiously and this gives relief of pain for a short time. This *stage of reaction* lasts from three to six hours, and is followed by diffuse bacterial peritonitis. Following a perforation, gastric secretion is abolished and it is this loss of the acid barrier which permits bacterial invasion to occur.

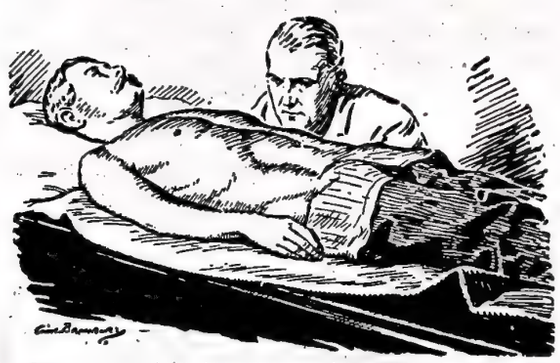

FIG. 888.—A sketch of Mr. Hamilton Bailey watching for abdominal movement on respiration. In cases of perforated peptic ulcer abdominal movement is restricted or absent.

Clinical Features

1. *Massive perforation.*—In the early stage of peritoneal irritation, the patient is pale, anxious, and loath to move. The temperature may be subnormal but the pulse is raised to 80–90. The abdomen is held still, moving little or not at all with respiration (fig. 888). The whole abdomen is tender with board-like rigidity. It is dull to percussion. Sufficient gas may have escaped to reduce liver dullness in the mid-axillary line. Pelvic tenderness may be elicited on rectal examination.

After three to six hours, the pain, tenderness, and rigidity may lessen. The temperature rises to normal or higher. However, the pulse remains high, the bowel sounds are absent. This temporary improvement has rightly been called the 'period of illusion'.

After six hours, the stage of diffuse peritonitis develops, accompanied by silent abdominal distention. Enough free fluid may have collected to be clinically detectable. The rising pulse rate marks the progressive deterioration in the patient's condition with each hour that passes without operative treatment.

2. *Subacute perforation.*—The pain may be less severe, less generalised with definite tenderness but equivocal guarding and rigidity when the perforation is small, and occurs in a robust, phlegmatic patient. Bowel sounds frequently persist. The small amount of fluid may track down the paracolic gutter, producing pain and tenderness in the right iliac fossa, simulating appendicitis. It is important to establish the site of onset of the pain.

Henery Hamilton Bailey, 1894–1961. Surgeon, Royal Northern Hospital, London.

Diagnostic aids.—A plain X-ray of the abdomen with the patient erect reveals a translucent area beneath the right cupola of the diaphragm in 70% of cases (fig. 889). Bile-stained fluid may be aspirated from the peritoneal cavity; it is alkaline to litmus.

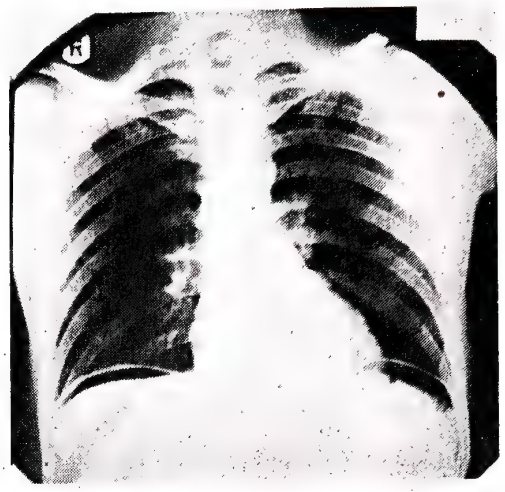

FIG. 889.—Plain X-ray of a perforated duodenal ulcer showing gas beneath the diaphragm. *(Dr. R. Vecht, Bristol.)*

Treatment.—Morphine should not be given until written permission for operation has been obtained. Operation, as soon as the general condition permits, is usually the best course. Laparotomy is performed and the typical œdema with a curious punched-out ulcer of the anterior wall of the pylorus is found. The perforation is closed with interrupted sutures reinforced with an omental patch. In the case of a gastric ulcer a biopsy *must* be taken as there is a risk of malignancy. In large perforations it is advisable to reinforce the suture line with a patch of omentum. *Thorough peritoneal toilet is essential.* With a mechanical sucker fluid and food debris are removed from the peritoneal cavity. Drainage of the peritoneal cavity is employed.

The immediate after-treatment consists of continuous gastric aspiration supplemented by intravenous fluid. Antibiotic therapy and breathing exercises are important in the elderly, and in cases where operation is more than six hours after perforation.

Pyloroplasty with vagotomy may be carried out only if the patient would merit elective surgery for the ulcer before the perforation occurred, if the perforation is recent, if the patient is fit, if the surgeon is experienced and backed by a fully trained supporting team (Kirk).

Follow-up of Patients after Perforation.—As might be expected, there is a transient remission of symptoms due to the rest in bed and the careful dietetic supervision during convalescence. Elderly patients and those of any age with a short dyspeptic history are likely to remain symptom-free after successful treatment of a perforation (Illingworth). Nevertheless, within one year 40 per cent. of patients relapse, and within five years 70 per cent. On this account, those who survive perforation should be followed up as out-patients, so that if symptoms suggesting renewed activity of the ulcer occur, timely treatment can be instituted. Operation is advisable after three months.

Residual Abscess.—This may occur after perforation in any of the subphrenic spaces (Chap. 46) or in the pelvis.

HÆMATEMESIS AND MELÆNA

Ætiology.—Chronic peptic ulcer . . . . 65% of cases.
Acute peptic ulcer (p. 792) } . . . 30% ,, ,,
Multiple erosions }

Raymond Maurice Kirk, Contemporary. Surgeon, Royal Free Hospital, London.

Œsophageal varices (Chap. 43) Carcinoma of the stomach (p. 820) Mallory-Weiss syndrome Peptic ulcer in a Meckel's diverticulum (Chap. 47) Purpura (Chap. 42) Hæmophilia (p. 76) Pernicious and other anæmias	5% of cases.

(Compiled mainly from statistics by Sir Francis Avery Jones, London.)

FIG. 890.—A gastric ulcer with an eroded and aneurysmal artery temporarily sealed by clot. *(Norman C. Tanner, F.R.C.S., London.)*

Special Types.—Chronic Peptic Ulcer.—Slight bleeding due to trauma from solid food occurs frequently from all chronic peptic ulcers; such bleeding is demonstrated by finding traces of blood during gastric analysis and occult blood in the stools. With advancing age and the associated arteriosclerosis there is an increasing risk of severe hæmorrhage due to the erosion of an artery in the base of the ulcer. Occasionally the artery is of considerable size, viz. the splenic or gastro-duodenal artery; more usually it is a branch of one of these vessels. Once a sclerotic artery has been eroded, even if it is sealed by clot, it is liable to bleed again (fig. 890). Even when a large vessel is eroded, death seldom results from the initial hæmorrhage. Far more frequently a large hæmorrhage is heralded by two or three smaller ones on consecutive days, as in other cases of secondary hæmorrhage.

Acute Peptic Ulcer (p. 792).—This may be solitary or present as multiple erosions all over the stomach. The diagnosis is established by gastroscopy. It should be treated conservatively and all drugs withdrawn. If facilities are available, gastric cooling (Wangensteen) may control the bleeding. If all else fails pitressin given intravenously has been found to be effective.

Mallory-Weiss Syndrome. — This condition has specific features—the patient, usually a man over fifty, has a prolonged vomiting bout, often after imbibing alcohol. Having vomited gastric contents, he suddenly starts to vomit blood profusely and persistently, and becomes exsanguinated. As a result of the straining and retching a longitudinal tear of the mucosa just below the cardia occurs and gives rise to the sudden onset of hæmatemesis (fig. 891). The violent vomiting is sometimes due to migraine or vertigo. The diagnosis can be made on the history and is easily confirmed by gastroscopy.

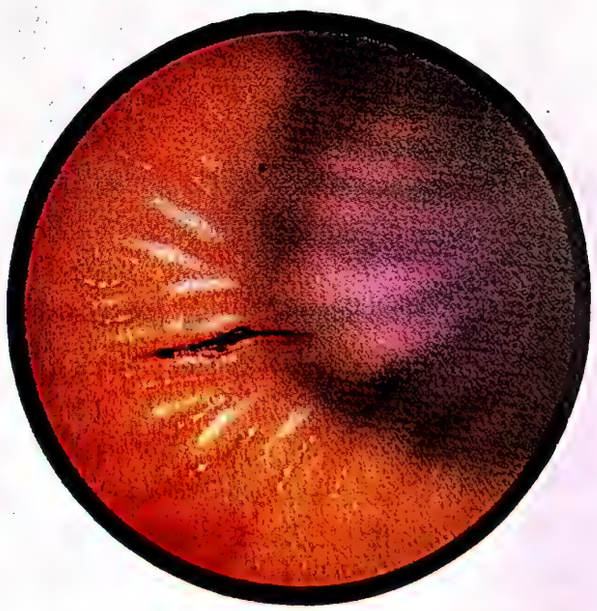

FIG. 891.—A healing mucosal tear extending across the œsophagogastric junction. *(Dr. Michael Atkinson, Worcester, and the Editor and Publishers of 'Gut'.)*

In 90% of cases the condition responds to sedation, blood transfusion and if necessary, pitressin. In the remainder, laparotomy is done and the linear tear exposed through a gastrotomy incision. It can then be sutured.

Sir Francis Avery Jones, Contemporary. Physician, Central Middlesex Hospital, London.
Owen Harding Wangensteen, Contemporary. Emeritus Professor of Surgery, University of Minnesota, Minneapolis, Minn., U.S.A.
George Kenneth Mallory, Contemporary. Professor of Pathology, Boston University, Boston, Mass., U.S.A.
Soma Weiss, 1899–1942. Hersey Professor of Physic, Harvard University, Boston, Mass., U.S.A.

Clinical Features in General.—Initial features are usually faintness, sweating, and pallor; occasionally the patient collapses. Soon afterwards there is hæmatemesis, which is effortless vomiting of coffee-ground material or bright-red blood. Later, black tarry stools (melæna) or red clotted blood may be passed per rectum.

Treatment.—*On admission* the collapsed patient is laid flat, with one pillow under the head, and the foot of the bed is raised. He is accorded the usual number of blankets for the time of year, and not heated artificially in any way. If restlessness is in evidence, morphine 15 mg. is given intravenously and repeated in four hours if necessary. Pending arrangements for blood transfusion, a plasma infusion is given. The important consideration is to replenish the circulation without overloading it, and a drip blood transfusion proportional to the estimated blood loss should be given. A pulse chart, if necessary half-hourly, is compiled, and a careful watch is kept on the blood pressure and central venous pressure (p. 69).

Very soon after a severe hæmorrhage the hæmoglobin concentration is often unchanged, and therefore no reliance should be placed upon it at this critical time. After three hours, estimations, repeated at frequent intervals, provide helpful information.

As a result of replenishing the circulation, improvement often occurs. Conversely, signs that bleeding has very seriously depleted the blood volume and is probably continuing are a cold nose, increasing pallor, increasing pulse-rate, beads of sweat on the forehead, and clammy palms of the hands (p. 66).

Management:

Conservative (Medical) or Surgical Regimen?—This decision should be made by joint consultation and co-operation between the physician and surgeon. They will take into consideration the following factors:

Response to Treatment.—Above all, if there is recurrent or profuse bleeding while the patient is under adequate conservative treatment, the call for surgery is compelling.

Age.—Seventy per cent. of cases of bleeding are over the age of forty-five. After this age operation is increasingly necessary.

Chronicity of Ulcer.—The patient with a short history is more likely to respond to conservative treatment than one whose history suggests a deep penetrating ulcer. Sometimes, on account of cerebral anoxia, the patient's history is unreliable, when it will be necessary to obtain all possible information from the relatives. If he has been treated at another hospital, no time should be lost in contacting that hospital because all-important X-ray evidence may be forthcoming.

Ingestion of Drugs.—The patient must be closely questioned about the ingestion of aspirin, butazolidine, or cortisone. If so, withdrawal of these drugs may suffice.

Condition of Arterial Tree.—The presence of arterio-sclerosis as evidenced

by the radial artery, fundal and electrocardiographic changes suggest the likelihood of recurrent bleeding.

Ancillary Aids.—As far as possible the exact cause of the bleeding should be made before operation.

Œsophagogastroscopy using the fibreoptic-type of endoscope is the ideal means of doing this. The patient's pharynx is sprayed with a local anæsthetic and sedation is achieved with Valium or other appropriate drugs. The instrument is then passed and the œsophagus examined. It is usually possible to exclude bleeding from varices in this way. If these are not seen, the instrument is passed into the stomach and the blood aspirated through its lumen. Should multiple clots be present and the site of bleeding not obvious a plastic nasogastric tube of large diameter should be inserted and the gastric contents aspirated. This is continued until a good view of the stomach can be obtained. Acute ulceration, erosions or the Mallory-Weiss syndrome (p. 808) may be seen. If blood is seen coming back through the pylorus, it is highly likely that a duodenal ulcer is the cause of the bleeding.

Conservative Treatment.—The essentials are:

Blood Transfusion.—When the estimated blood loss has been replenished, a drip transfusion is continued at the rate of 30 drops a minute for as long as is deemed necessary. The aim always is to render and maintain the reading of the hæmoglobin level at least above 75 per cent. of normal. In addition, frequent pulse-rate, C.V.P. and blood-pressure readings are continued for a minimum three days after the apparent cessation of hæmorrhage (p. 69).

Morphine.—Sufficient intramuscular morphine is prescribed to keep the patient just drowsy.

Intragastric milk drip is a valuable adjunct for the first forty-eight hours. It is discontinued when no further bleeding is manifest on gastric aspiration.

Diet.—Two-hourly 200-ml. feeds of milk, egg and milk, alternating with Benger's Food or Ovaltine, are given.[1] After three days milky porridge is allowed. It is essential that an accurate fluid balance-sheet be kept. After a week the patient is given the routine treatment for peptic ulcer (p. 799).

Prevention of Pulmonary Complications.—These patients are prone to develop respiratory infection, and not a few of them have bronchitis, with or without emphysema. Regular chest physiotherapy and prophylactic antibiotics are essential.

Operative Treatment.—A decision should be made within 48 hours of the commencement of bleeding, particularly if the patient rebleeds. Experience has shown that when operation is delayed beyond that time the mortality rises steeply.

Before the patient is anæsthetised it is essential to ascertain that the blood transfusion is capable of rapid acceleration. In this connection, sometimes it is advisable, in order to provide a stream of blood equivalent to that of the splenic or the gastro-duodenal artery, to set up a second transfusion into a second vein. The aim of the operation is to stop the bleeding. *If an ulcer is found*, a partial gastrectomy is performed including removal of the ulcer if gastric. Alternatively, vagotomy and a wide pyloroplasty may be carried out together with direct suture of the bleeding vessel in the ulcer base if it is duodenal.

When no ulcer is found on external examination of the stomach, a wide gastrotomy, extended to gastroduodenotomy, should be made to expose occult ulcers,

[1] Einar Meulengracht, Emeritus Professor of Medicine, Copenhagen, introduced in 1934 early liberal purée feeding in these cases. Before that time absolute starvation by mouth for several days was the unwavering rule.

erosions, vascular 'raspberry' malformations (Gius), and cardiac tears (p. 808). Whenever possible, bleeding should be controlled by suture, diathermy and local excision-biopsy with suture. A 'blind' gastrectomy should be avoided but, if deemed necessary, the Billroth I type is favoured. Should no cause be found, examination of the rest of the gastrointestinal tract, and of structures which may bleed into the gut, must be meticulously performed.

CHRONIC COMPLICATIONS

1. **Pyloric stenosis** is usually the result of cicatrisation from a duodenal or juxta-pyloric ulcer. Not infrequently it is due to a carcinoma situated at or near the pylorus. Classically, pyloric stenosis occurs in women with a slow silent onset, but when there is a long standing history of ulcer the following modifications are evident:

Periodicity is lost.

Pain and *fullness* become more pronounced towards evening. The patients can usually eat breakfast, a very small lunch, and nothing thereafter because they feel full.

Vomiting.—Very large foul and frothy vomits are characteristic. They usually occur once a day, commonly in the evening. Classically, the patient recognises currants or other undigested particulate matter eaten one or more days previously. Vomiting usually gives considerable relief.

FIG. 892.—Pyloric stenosis. Wave of peristalsis passing from left to right. Note that outline of stomach extends well below umbilicus.

On Examination.—In thin subjects the outline of the enlarged stomach can sometimes be observed. Visible peristaltic waves passing from left to right (fig. 892) are characteristic. A succussion splash is heard. These patients may be mentally confused as a result of alkalosis.

Barium Meal.—The stomach is large and low (fig. 893), it is never empty, and the barium is mixed with food residue. There is much delay in its evacuation.

FIG. 893.—Typical X-ray appearance of pyloric stenosis.

Treatment.—Operation in this condition carries a high mortality unless the patient is carefully prepared. Preliminary treatment by gastric lavage with saline through a wide-bore tube for 4–5 days, a high-protein fluid diet, and correction of electrolytes and vitamin deficiencies is necessary. Potassium and chlorides are usually deficient. A normal output of urine indicates adequate hydration (p. 83). Where chronic peptic ulcer is the cause, partial (hemi-)gastrectomy is usually the best procedure. A Polya type operation is preferred. Because of the stenosis, the risk of leakage from the duodenal stump is negligible. In elderly frail patients a gastrojejunostomy will suffice. Should the condition be due to carcinoma, radical gastrectomy will be required (p. 825).

2. **Hour-glass stomach** occurs almost exclusive in women, is usually silent, and is due to cicatricial contracture around a saddle-shaped lesser-curve ulcer. In extreme cases the stomach is divided into two compartments,

John Armes Gius, Contemporary. Professor of Surgery, University of Iowa, Iowa City, Iowa, U.S.A.

FIG. 894.—Hour-glass stomach.

united by a channel which barely admits a pencil (fig. 894). The condition is sometimes associated with pyloric stenosis.

History.—*Periodicity* is lost. The symptoms have become practically constant.

Vomiting is more frequent, and gives no relief to the discomfort.

The *appetite* becomes poor.

Weight.—Loss may be so great that carcinoma is suspected.

Barium meal is often characteristic. We have known of cases of hour-glass stomach being reported as pyloric stenosis, owing to failure of the second pouch to fill. True hour-glass stomach must be distinguished from gastric spasm of the hour-glass type, which is sometimes associated with an uncomplicated ulcer on the lesser curvature.

Gastroscopy.—The gastroscope enters the upper compartment of the stomach, and the narrow, scarred channel leading to the lower compartment is usually seen.

Treatment.—Billroth I gastrectomy, with removal of the second pouch and the isthmus, is the best treatment.

3. **Penetration of pancreas** may occur with posteriorly disposed gastric and duodenal ulcers.

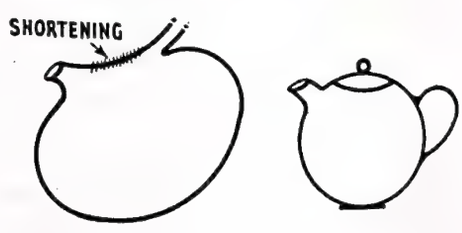
History.—The main change is that pain is referred to the back and may be aggravated by stooping or exercise and *relieved by lying down.* The back pain may be so prominent that the patient is referred in the first instance to an orthopædic surgeon.

Treatment.—Recognition of this feature of the ulcer is an indication for surgery, not only for relief of pain but also because of the possibility of torrential hæmorrhage.

4. **Malignant Change.**—This only occurs in gastric ulcers and is rare in lesser curve ulcers proximal to the angulus (p. 794). Endoscopy and biopsy are essential if surgery is not to be offered.

History and Barium Meal.—This often gives no guide to the seriousness of the condition. The important point is a constant awareness of the possibility of malignancy *de novo* at all times. Over 20 per cent. of all antral ulcers seen on X-ray examination for the first time are malignant, or have been malignant, from the start.

5. **'Tea-pot' Stomach.**—Cicatrisation around a long-standing gastric ulcer often causes shortening of the lesser curvature, thus producing the 'tea-pot' deformity of the stomach, viz.⟶



'Tea-pot' stomach (Davey), called in the U.S.A. 'handbag' stomach, is not uncommon. Unless the deformity is known to the radiologist it is likely to be diagnosed as a congenital abnormality or as the result of a carcinoma. The pylorus being no longer in an advantageous position for complete emptying of the stomach, these patients may present with symptoms and signs of pyloric stenosis.

COMPLICATIONS AFTER GASTRIC OPERATIONS

(1) Complications following any operation (e.g. pulmonary, cardiac, thrombotic).

William Wilkin Davey, Contemporary. Formerly Professor of Surgery, Ibadan, Nigeria.

(2) *Specific* complications of gastric operations.

A. Early	B. Remote
1. Hæmorrhage from anastomotic line.	6. Recurrent ulcer.
2. Paralytic ileus.	7. Gastro-jejuno-colic fistula.
3. Stomal obstruction.	8. Post-gastrectomy syndromes.
4. Duodenal fistula.	9. Intestinal obstruction.
5. Acute post-operative pancreatitis.	10. Pulmonary tuberculosis.
	11. Anaemia.
	12. Decalcifying bone disease.
	13. Carcinoma in remnant.
	14. Gallstones.

1. **Hæmorrhage from Anastomotic Line.**—If it does occur, morphia should be given together with a slow blood transfusion. Adrenaline (1 ml. (1:1000) solution hourly) by mouth may be helpful. If the hæmorrhage is *severe* and *persistent*, the abdomen should be re-opened, continuous gastric lavage started and the anastomosis oversewn with continuous through-and-through catgut. The stomach is not opened. With control of the hæmorrhage, the washouts become clear. If this measure fails, the stomach must be opened and the cause of the bleeding found.

2. **Paralytic Ileus.**—Is treated by 'drip and suction' (Chap. 48.)

3. **Stomal Obstruction.**—This includes two different conditions: (*a*) Due to œdema of the actual stoma or of adjacent small bowel. This occurs more frequently after a gastro-duodenal anastomosis—hence the need for a large stoma in this operation. It is important to persevere with gastric aspiration and intravenous therapy maintaining correct electrolyte balance, especially of potassium. After a Polya gastrectomy, the stoma should be open and the patient absorbing fluids within 3 days. The Billroth I operation stoma often takes 5 days to open.

(*b*) Due to the occurrence of *retrograde jejuno-gastric intussusception* (fig. 895). This, of course, only occurs after a gastro-jejunal anastomosis and may appear immediately or after many weeks or months. The stomach completely fails to empty and a filling defect can be clearly seen on X-ray with a small amount of barium. The intussusception may reduce following the barium or gastric saline lavage or the adoption of the sitting or standing position. If it does not respond to these measures (and it usually does in a few hours), an operation must be done to reduce the intussusception by gentle downward traction. An attempt may be made to anchor the loop by stitching or entero-anastomosis.

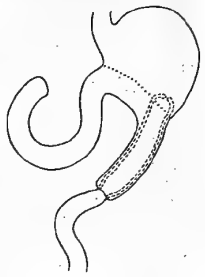


FIG. 895.—Jejuno-gastric intussusception following Polya gastrectomy. (*After P. F. Early, F.R.C.S.*)

4. **Duodenal fistula ('Blow-out')** is an infrequent, but very serious, complication of Polya partial gastrectomy with a maximal incidence about the fourth day. It may occur in cases where there has been difficulty in closing the duodenum so that avascular necrosis occurs. Another cause is increased tension within the afferent jejunal loop. It accounts for 60% of the deaths after gastrectomy.

Prevention.—There are two important points in technique:

(*a*) Careful duodenal closure with meticulous turn-in. A crushing clamp should not be used.

(*b*) Construction of the stoma in such a way that afferent loop contents have free egress. Multi-lumen tubes have been used to drain the afferent loop, but unless they are stitched into position, the tube is usually rejected. A tube drain down or into the duodenal stump is a worthwhile safeguard if trouble is anticipated. When a blow-out occurs the duodenal sutures give way and, if drainage was not provided at the time of the operation, there is intense thoraco-abdominal pain, which is not infrequently mistaken for acute basal pneumonia with pleurisy. Unless prompt action is taken, diffuse peritonitis ensues, and death is the usual sequel.

(*c*) Avoid operating on a hot duodenum, i.e. where the ulcer is active and inflamed. Choose another operation, e.g. vagotomy and gastrojejunostomy.

Treatment consists in providing free drainage down to the duodenum with peritoneal toilet by suction. When drainage of the periduodenal tissues was not provided at the time of the gastrectomy, a small subcostal incision is made down to the duodenum. In either event, sump suction drainage (fig. 1033) is instituted until, and even after, the track of an external duodenal fistula has become defined. Some advise temporary jejunostomy at the same time. The duodenal discharge can be collected and returned into the jejunostomy together with the necessary nutritive fluids (p. 829). The fistula usually closes spontaneously.

FIG. 896.—Jejunal ulcer following gastro-jejunostomy. (*The late Dr. K. J. Yeo, London.*)

5. **Acute post-operative pancreatitis** is rare. The condition carries a high mortality rate. Treatment is along the usual lines (Chap. 45).

6. **Recurrent Ulcer.**—This includes the true anastomotic ulcer (gastro-jejunal, gastro-duodenal or jejunal ulcer) or a gastric ulcer in the remnant. True anastomotic ulceration has an incidence of 3 per cent. after a Polya gastrectomy, 5 to 7 per cent. after vagotomy and gastro-enterostomy, and up to 40 per cent. following gastro-enterostomy (fig. 896). If any part of the antrum is left *in situ* after gastrectomy, the recurrence rate may rise to 30 per cent. The symptoms which appear usually within two years after operation consist of severe persistent pain, 'boring' in type, which is worse within a few minutes of taking food. The pain passes down the left side of the abdomen, sometimes into the perineum, but may be felt in the lower left chest especially following an ante-colic anastomosis. It is not relieved by antacids or milk. Bleeding manifest as haematemesis, melaena, occult blood, or secondary anaemia is common and perforation may occur. Only 30 per cent. are seen by radiology. Gastroscopy tends to be more helpful. A maximal acid output of 25 mEq/l (25 mmol/l) is, however, very suggestive of stomal ulceration. Diagnostic laparotomy may be justified if symptoms are severe.

Management.—Conservative treatment is ineffectual, or of only temporary benefit; re-operation is usually necessary.

(a) **Following Polya gastrectomy.**—An anastomotic ulcer may be obvious or require the opening of the anterior suture line. If the stoma is adequate and acid hypersecretion is present, vagotomy will cure the patient. If low acid secretion is found, revision gastrectomy with a fresh anastomosis to correct stasis, is advisable.

(b) **Following Billroth I gastrectomy.**—Anastomotic ulcers should be treated by vagotomy. Recurrent gastric ulcer should be treated by higher gastrectomy, including the ulcer in the resected specimen. A Polya type operation is preferred.

(c) **Following gastro-enterostomy.**—Provided the stoma has not been narrowed by scarring, vagotomy will effect a cure.

(d) **Following Vagotomy and a drainage operation.**—The Hollander Test (p. 783) should reveal incomplete nerve section. A search must be made for an intact vagal trunk in order to divide it. The drainage operation should not be changed but it must be functioning adequately. If an intact vagus nerve cannot be found, the operation should be converted to Polya gastrectomy. If, however, a gastric ulcer is present, Billroth I conversion should be carried out, resecting the ulcer with the specimen.

(e) In all patients having anastomotic ulcers and gastric hypersecretion, a search must be made for an ulcerogenic pancreatic islet-cell tumour.

7. **Gastro-jejuno-colic fistula**—is a complication of gastro-jejunal ulcer, and more

often follows simple gastro-enterostomy than partial gastrectomy. The ulcer penetrates and erodes the transverse colon. Usually the symptoms of anastomotic ulcer disappear soon after the fistula develops, but in their place the unfortunate patient is troubled with severe diarrhœa after every meal, and eructates foul gas. Exceptionally the patient vomits fragments of formed fæces. Loss of weight and strength, dehydration, and anæmia complete the picture. It is important to stress that this final picture may be of extremely rapid onset so that the patient becomes desperately ill within two to three weeks. Severe malabsorption is shown by the presence of cachexia, hypoproteinæmic œdema, and steatorrhœa. The chief factor producing the rapid deterioration of the patient is the fouling of the jejunum by colonic contents with resulting disturbance of the vital absorptive mechanisms. It is *not* that the gastric contents pass directly into the colon. The diagnosis is established by a barium enema; in more than half the patients a barium meal may fail to reveal a fistula (fig. 897). *The sudden onset of severe diarrhœa in a patient who has a gastro-enterostomy must always raise the serious possibility of this condition.*

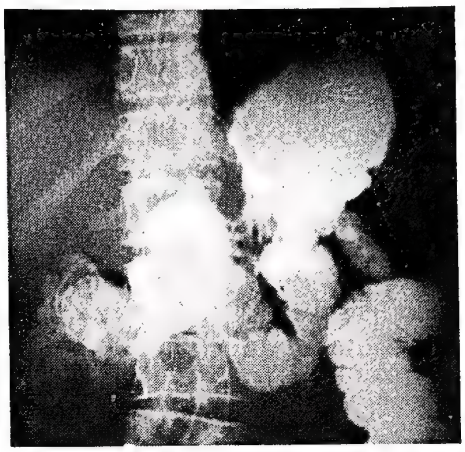

FIG. 897.—Gastrocolic fistula.
(*Courtesy Dr. Vachhani*).

Treatment.—This consists of a resection of the fistula with repair of the colon and jejunum, together with either vagotomy or a high partial gastrectomy. This can be one of the most difficult procedures that any surgeon may be called upon to do.

Some of these patients are extremely ill, and may require resuscitative measures, oral antibiotics and intravenous feeding before operation is attempted.

8. Post-gastrectomy Syndromes

These are special complications directly attributable to altered alimentary function following the operation. The proper understanding of all these syndromes depends on a thorough knowledge of the physiology of gastric function (p. 782) and intestinal absorption.

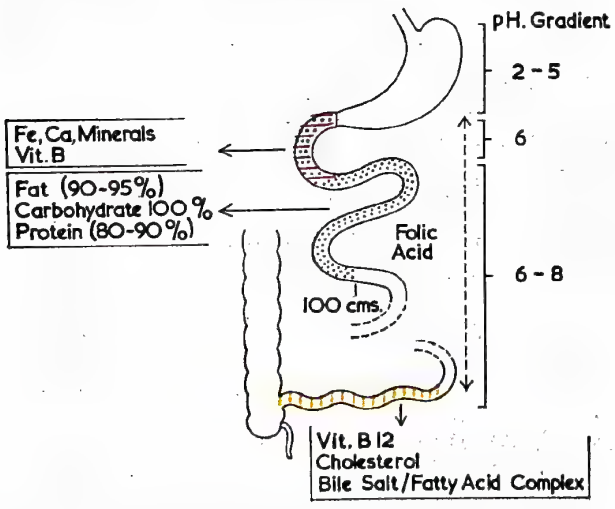

FIG. 898.—Absorption areas of small intestine.
(*After T. J. Butler., F.R.C.S., Bristol.*)

Absorption is the prime function of the **Small Intestine** and it is essential to appreciate that there are *zones of maximal and selective absorption* (fig. 898). The first 100 cm. of small intestine distal to the pylorus are of great importance for in this zone the maximal absorption of carbohydrate, fat and protein occurs. The duodenum is the site of maximal absorption of carbohydrate, soluble vitamins, iron and calcium. Vitamin B_{12} is maximally absorbed in the terminal ileum. Folic acid is absorbed generally all over the small intestine.

The recognition of these essential functions of the small intestine is important for two reasons:

(1) Following gastrectomy food enters the small intestine rapidly without preliminary preparation by the stomach. This may bring out certain latent defects of absorption.

(2) When a gastro-jejunal anastomosis is made after gastrectomy a part of this important proximal 100 cm. is by-passed and in this vital matter of absorption even a few centimetres make a difference.

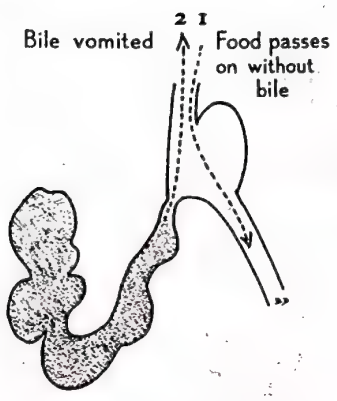

FIG. 899.—The afferent loop syndrome. The food (1) passes out of the gastric remnant before the bile (2) is ejected. (*After Charles Wells, F.R.C.S.*)

Summarising, therefore, gastrectomy may cause reduced secretion of HCl, pepsin, intrinsic factor and pancreatic enzymes, inadequate mixing of food with enzymes and bile, reduced absorption of protein, fat and iron, rapid absorption of glucose, increased intestinal motility, and creation of a blind loop (i.e. the afferent loop, fig. 899).

The effects of some of those changes may appear a few weeks after operation, especially the post-cibal syndromes. It may be several years, however, before the absorption defects produce apparent nutritional disturbances.

The various **Post-gastrectomy Syndromes** therefore may be classified as follows:

A. Post-cibal Syndromes

(i) Early post-cibal syndrome (*syn.* early dumping).

(ii) Late post-cibal syndrome (*syn.* hypoglycæmia or late dumping).

(iii) Bilious vomiting.

B. Nutritional Syndromes

(i) Weight loss.
(ii) Steatorrhœa.
(iii) Diarrhœa.
(iv) Iron-deficiency anæmia.
(v) Megaloblastic anæmia.
(vi) Vitamin B deficiency.
(vii) Calcium deficiency.
(viii) Gross malabsorption states.

By and large the higher the resection, the greater the risk of post gastrectomy troubles. In addition, these syndromes are best prevented if the normal duodenal pathway is maintained—and not by-passed.

Post-cibal Syndromes—Early and Late

In general, these occur more frequently in women than in men, and are seen following the Polya operation rather than the Billroth I. Time relation to meals permits classification into early and late varieties; the main features of these are summarised in the following table:

	Early	*Late*
1. Incidence	5–12 per cent.	5 per cent.
2. Relation to meals	Immediately afterwards	During second hour afterwards
3. Duration of attack	Thirty to forty minutes	Thirty to forty minutes
4. Long-term	Severe cases indefinitely	Two to five years
5. Relief by	Lying down	More food, glucose
6. Aggravated by	More food	Exercise
7. Precipitating factor	Bulk of food, especially if wet	Carbohydrates
8. Chief symptoms	Epigastric fullness Sweating Sensation of warmth Tachycardia Occasionally colic, diarrhœa	Tremor Faintness Epigastric emptiness Nausea
9. Occurrence	Commonest after Polya	After any type of gastrectomy

The Early Post-cibal Syndrome.—This syndrome, consisting of abdominal and vasomotor symptoms, is seen in the majority of patients during convalescence, and persists in 5–12 per cent. A variety of causes may be involved—rapid emptying of the stomach with increased small bowel activity, distension of the afferent loop, and a fall of blood volume (of the order of 7 per cent.), especially in patients susceptible to such changes. According to Le Quesne, there is a primary disorder of carbohydrate metabolism. Following the ingestion of glucose, there is initial transient hyperglycæmia. This suppresses further absorption of glucose, which is retained in the intestine, resulting in fluid shift from the blood to the lumen of the intestine. Both increased intestinal activity and fall of blood volume may occur.

Treatment.—Time must be allowed to elapse for the syndrome to subside naturally. Meals should be small in bulk and dry. Milk and carbohydrate meals should be avoided. Belladonna or codeine may reduce intestinal activity. Insulin or an oral hypoglycæmic agent before food has a beneficial action. It is important to maintain the hæmoglobin level as near 100 per cent. as practicable. When the syndrome persists, especially when associated with nutritional defects, conversion of a Polya anastomosis to a Billroth I is the operation of choice.

Late Post-cibal Syndrome.—This is not a common or a serious cause of symptoms. It is due to a low blood sugar, occurs two hours after meals, and may be seen in some 5 per cent. of patients. After the initial hyperglycæmia there is a rapid fall of blood sugar to 50 mg/100 ml (2·8 mmol/l) or so. This rapid fall is probably due to increased insulin sensitivity. The syndrome is readily corrected by taking food, especially glucose.

Bilious Vomiting.—This symptom is usually an isolated feature but may be associated with dumping. It occurs in 10 to 15 per cent. of patients and consists of vomiting of bile unmixed with food. The vomiting is intermittent rather than after every meal. In the Polya operation the cause is probably transient obstruction of the afferent loop. Following the Billroth operation it is more likely to be due to incompetence of the cardia. This symptom can be eliminated almost entirely by a retrocolic anastomosis with the shortest possible afferent loop, i.e. into the fourth part of the duodenum if this is possible. If surgery is necessary to correct the vomiting, conversion to a Billroth I should be done if there are other post-cibal symptoms.

Nutritional Disturbances

Weight Loss.—This is a well recognised feature, occurring in some 50 per cent. of patients. It is the rule after total gastrectomy, common after the Polya operation, and infrequent after the Billroth I. It is due to reduced intake of food, and diminished absorption, and is particularly liable to occur in patients with postcibal symptoms. It is not necessarily serious, and indeed may have a beneficial effect. There is a reduced incidence of coronary disease following gastrectomy.

It is essential in these patients to exclude reactivation of previous tuberculous disease.

Steatorrhœa.—This has a similar incidence to weight loss, and is due to poor mixing of food and enzymes, reduced pancreatic output, and inactivation of pancreatic enzymes in the afferent loop. If it appears slowly after operation, the cause may be latent intestinal disease such as jejunal atrophy or the development of a cul-de-sac phenomenon (i.e. blind loop, fig. 1089) in the afferent loop.

Diarrhœa.—Most patients say that their bowel habits are much improved after gastrectomy, but some 5 per cent. have diarrhœa, either episodic or persistent. It may be related to intestinal hurry or to steatorrhœa.

Iron-deficiency Anæmia.—This is a progressive condition after gastrectomy, and may be seen in some 40 per cent. of patients, particularly when the duodenum is by-passed. If occult blood loss is excluded, daily supplements of iron are essential.

Megaloblastic Anæmia.—Although invariable several years after total gastrectomy, it is rare following partial gastrectomy. It may occur as an isolated lesion due to gastric mucosal atrophy, or as part of a gross malabsorption defect (*vide infra*). There is evidence of reduced serum vitamin B_{12} levels in some 25 to 50 per cent. of patients five to ten years after partial gastrectomy. Intramuscular vitamin B_{12} (Cyanocobalamin) 100 μg. weekly is given until the blood is normal; thereafter a maintenance dose each month is necessary.

Vitamin B Deficiency.—This occurs in roughly 10 per cent. of patients, and is manifest by angular stomatitis, glossitis, or peripheral neuritis. A regular supplement is the best method of prevention.

Leslie Philip Le Quesne, Contemporary. Professor of Surgery, Middlesex Hospital, London.

Calcium Deficiency.—Reduced acidity in the proximal intestine may interfere with calcium absorption, and some 40 per cent. of patients may become deficient. Bone changes may occur in some 5 per cent. and although such changes are usually seen associated with steatorrhoea, they may occur independently.

Gross Malabsorption States.—Very rarely, in less than 1 per cent. of patients, a severe malabsorption syndrome may develop. Conversion to a Billroth I is usually very effective.

Post-vagotomy Syndromes

Effects of Vagotomy.—In addition to its gastric secretory effects, total abdominal vagotomy may produce undesirable side effects. The loss of gastric motility produces gastric distension, with delayed emptying, resulting in a persistent gastric splash, nausea, loss of appetite, foul eructations, vomiting and abdominal pain. Gastric ulceration may occur. The effect of vagotomy on the rest of the bowel is variable. About 30% of patients have an increase in bowel habits; of these a very small number suffer from variable diarrhœa which at its worst is urgent, episodic, uncontrollable and watery.

Vagotomy and inadequate drainage operation.—When no drainage operation accompanies vagotomy, gastric emptying may be inadequate, partly resulting from duodenal ulcer scarring, partly resulting from the reduced gastric motility following vagotomy. It is not possible to estimate the size of the pyloroduodenal canal by inspection from outside; moreover the site of narrowing is inconstant. Pyloroplasty in which the duodenotomy does not extend beyond any narrowing is similarly inadequate. A small, badly sited gastroenterostomy stoma may not allow the stomach to empty. Symptoms of gastric retention follow, and can be relieved by performing an adequate drainage operation.

Vagotomy and adequate drainage operation.—In spite of apparently adequate complementary surgery following vagotomy, some patients have symptoms of gastric retention after operation. Failure of gastric emptying may continue for up to 3 weeks, even though the stoma is patent and bile can be aspirated from the stomach. This functional disability slowly resolves. However, post-prandial fullness, regurgitation of bitter fluid into the mouth, and abdominal colic are experienced by some patients for longer periods.

The post-operative effects may be linked not to the vagotomy but to the complementary operation. As a result, the merits of each operation are hotly debated.

Because the symptoms tend to improve, conservative treatment usually suffices. The patient is advised to take small dry meals, with fluids taken between meals. Foods which are found to produce symptoms are temporarily discontinued.

Metoclopramide and more recently bethanecol 5 mg q.i.d. before meals (Catchpole) have been used with success.

Diarrhœa may be controlled by codeine phosphate or similar drug. A course of phthalylsulphathiazole or neomycin is often beneficial and the improvement may continue after these drugs are stopped.

Recurrent ulcer after vagotomy.—The insulin test of gastric secretion confirms that vagotomy is incomplete. If the symptoms do not respond to medical treatment, re-operation is performed. If a vagal trunk is found and divided, provided that the existing drainage procedure is adequate, nothing more should be done. If no residual intact vagal fibres are found, gastric resection is necessary. If a gastric ulcer is found, gastrectomy should be performed. The possibility that the Zollinger-Ellison syndrome may be present should be borne in mind.

Intestinal Obstruction

(*a*) **Herniation Obstruction.**—In cases of a Polya gastrectomy with an antecolic anastomosis, small intestine herniates through a gap between the anastomosis and the transverse mesocolon, either from right to left or from left to right. It is easily prevented by a few stitches between the anastomosis and the transverse mesocolon at the time of gastrectomy (Stammers).

Clinical Features.—Usually symptoms of high intestinal obstruction commence between the third and eighteenth post-operative days, but often these symptoms soon become atypical because gastric aspiration is instituted after the first or second vomit. For the same reason colicky pains, so typical of intestinal obstruction, are often lacking; in most cases the pain is continuous, and increases in severity.

Bernard Newman Catchpole, Contemporary. Professor of Surgery, Perth, Western Australia.
Francis Alan Roland Stammers, Contemporary. Emeritus Professor of Surgery, Birmingham, England.

Treatment.—Even if the condition is only suspected, the abdomen should be re-opened. The hernia is usually reducible, but gangrene has occurred from long delay. The gap should be closed as detailed above and gangrenous bowel resected if necessary.

(*b*) **Bolus Obstruction.**—The commonest cause of this is a piece of unmasticated orange pith which, in the absence of the pylorus, is able to pass into the small intestine and lodges about two feet from the ileo-cæcal valve. Clinically, it is not unlike gall-stone obturation (Chap. 48) but occurs in a younger age group. *Every patient who has had the pylorus excised or by-passed must be told not to swallow orange pith or dried fruits.*

Pulmonary Tuberculosis

Gastrectomised persons show a slight but definite increased susceptibility to pulmonary tuberculosis, probably due to reactivation of a latent focus owing to diminished nutrition.

Carcinoma

Following a gastrectomy, especially for a gastric ulcer, the gastric remnant is slightly more prone to develop a carcinoma than is a normal stomach. This risk appears after a latent period of fifteen to twenty years or more. It is because of such a complication following gastrectomy that the recent results of vagotomy plus a drainage procedure must be accepted with some reserve. Carcinoma may follow this operation also.

Gallstones

There is evidence that the incidence increases after all types of gastric surgery.

GASTRIC NEOPLASMS

Benign Tumours.—Although they constitute 3 per cent. of all gastric neoplasms benign tumours of the stomach are so over-shadowed by the frequency and gravity of gastric carcinoma that they tend to be forgotten.

Leiomyoma is the most common benign neoplasm of the stomach. Sometimes it grows mainly towards the serosal coat, in which case it is symptomless, and attracts notice only when it is large enough to constitute a painless, smooth lump in the epigastrium. It may cause a low-grade fever. More usually a leiomyoma protrudes towards the lumen of the stomach, and gives rise to melæna, mild indigestion, and epigastric pain, in that order. Hæmatemesis is, however, the most common symptom, and results from deep central ulceration of the tumour. Radiography after a barium meal reveals a space-filling lesion (fig. 900). Necrobiosis of the tumour has led to perforation of the serosal surface with intraperitoneal bleeding, and even to perforation of the stomach. Local excision is curative.

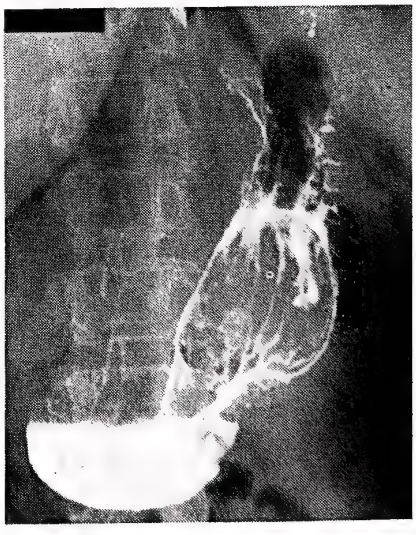

FIG. 900. — Leiomyoma of stomach. A round space filling defect in the mid-stomach with small ulcer cavity at 3 o'clock.

Neurofibroma and Neurilemmoma. — A tumour arising from a nerve sheath gives rise to exactly the same symptoms as a leiomyoma.

Adenomatous polypus, sometimes single, but more often multiple, is, as a rule, situated in the distal half of the stomach. Usually the symptoms are bleeding and abdominal pain. Achlorhydria is present in nearly all cases. Rarely a pedunculated adenomatous polypus of the pyloric antrum is carried into the pyloric canal, there to cause pyloric obstruction. The diagnosis rests on gastroscopy and/or X-ray. It is wise to regard multiple polypi as premalignant, and accordingly perform partial gastrectomy so as to include all the polypi; a single polypus can be excised locally.

Adenomatous Polypi and Pernicious Anaemia.—In pernicious anæmia there is severe atrophy of that portion of the gastric mucosa containing the fundal glands, and this

provides a fertile bed for precarcinomatous adenomatous polypi to flourish. In about one in five cases of pernicious anæmia gastroscopy reveals adenomatous polypi. It is for this reason that patients suffering from pernicious anæmia are recommended to undergo annual gastroscopy and a barium meal.

An aberrant pancreas has been found arising in the wall of the stomach from time to time. Usually partial gastrectomy has been performed by a surgeon mistaking it for a carcinoma.

CARCINOMA OF THE STOMACH

Carcinoma of the stomach is one of the 'captains of the men of death'. In 1959, 14,076 persons died from this cause in England and Wales but, fortunately, it now appears to be decreasing. While from early adult life to senility no age is exempt, the highest incidence is between forty and sixty years of age. Three times as many males as females fall victims to this disease.

Ætiology.—There are a few definite pre-malignant conditions. These are a gastric polypus, pernicious anæmia, and possibly, but only rarely, a gastric ulcer (p. 794). Ingested carcinogens seem to be important:—the hydrocarbons of cooking fat and tobacco juice. Furthermore, substances that cause an irritative gastritis, such as neat spirits as drunk in Scandinavia, Holland, and Czechoslovakia, may increase the incidence of carcinoma. The geographical distribution of this disease is important and may prove a most profitable avenue in the study of ætiology. An interesting example of this is the differing incidence in the North and South of Iceland. Crude smoked salmon was the staple diet of the Northerners who have a much higher incidence than those in the South. Aird found a higher incidence of gastric carcinoma in people with blood group A.

Pathology.—*Macroscopically* five types can be recognised:

Type 1.—A cauliflower-like growth with sharply defined edges. Its surface is indurated. Later it ulcerates.

Type 2.—An ulcer with an irregular indurated edge. Sometimes small superficial ulcers are present in the immediate vicinity.

Type 3.—Colloid carcinoma.

Type 4.—Scirrhous localised or diffuse (leather-bottle, fig. 905).

Type 5.—Carcinoma secondary to a chronic gastric ulcer (p. 794).

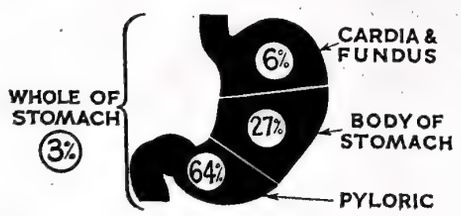

FIG. 901.—Incidence of carcinoma in various portions of the stomach.

Microscopically.—The growth is usually columnar-celled, but cubical, and even squamous-celled neoplasms arise near the œsophageal orifice. The last type probably arises within the œsophagus.

Site:—The most common site for the neoplasm is in the prepyloric region (fig. 901); when carcinoma follows pernicious anæmia however, it is more likely to be fundal and polypoid.

The Spread of Carcinoma of the Stomach.—No better example of the various modes by which carcinoma spreads can be taken than the case of the stomach.

1. *Direct Spread.*—As the growth enlarges, it tends to invade neighbouring structures. The pancreas, transverse colon, mesocolon, œsophagus, or liver may be involved.

2. *Lymphatic Spread* (fig. 907): both by emboli and permeation.

3. *Spread by the Blood-stream.*

Ian Aird, 1905–1962. Professor of Surgery, Royal Postgraduate Medical School, London.

4. *Transperitoneal Implantation.*—Carcinoma cells sometimes pass from the stomach into the peritoneal cavity. They gravitate to the pelvis, where secondary tumours palpable on rectal examination may develop. On occasions, in the female, they alight upon the ovaries, giving rise to **Krukenberg's tumours** (fig. 902), which are liable to cause diagnostic confusion. These tumours are premenopausal, because after the climacteric the ovaries atrophy and thus are unlikely to give sustenance to tumour cells. In some cases Krukenberg's tumours are not the result of transcœlomic implantation, but are due to retrograde lymphatic permeation, especially from a carcinoma of the colon.

FIG. 902.—Krukenberg's tumours from a woman of thirty-seven. Scale in inches.

Clinical Features.—This is a very difficult disease to diagnose early, not only because of the diversity of its presentation but also because of the time-lag between the commencement of the growth and the appearance of symptoms:—

1. Gastric distension: inability to take a normal meal, vomiting.
2. Anorexia leading to loss of weight.
3. Anæmia, tiredness, weakness, pallor.
4. Persistent pain: no response to treatment—no periodicity.

Clinical groups.—i. The '*new dyspepsia*' *after forty*—vague but *persistent* indigestion occurring in a patient who has never previously had 'stomach trouble'.

ii. *Insidious Onset.*—Especially in a man: he feels tired and weak, and the three A's may be in evidence—Anæmia, Anorexia, and Asthenia. Although the majority have an iron-deficiency anæmia, a few may present with a macrocytic anæmia.

iii. The *obstructive* types—carcinoma of the cardia presents with dysphagia; carcinoma of the pylorus with fullness, belching, and then vomiting.

iv. *Lump.*—The incidental discovery of a lump in the epigastrium, no other symptoms being present, is sometimes the cause of the patient seeking advice. In about 30 per cent. of cases a lump can be palpated.

v. *Silent.*—Carcinoma of the body of the stomach may be silent but give rise to features in other organs, such as obstructive jaundice due to secondary deposits in the liver, ascites from carcinomatosis of the peritoneum (Chap. 46.), Krukenberg's tumours (see above), Trousseau's sign (phlebo-thrombosis of superficial veins of leg), or Troisier's sign (fig. 903).

INVESTIGATIONS IN A SUSPECTED CASE

If the diagnosis of this dread condition is to be made earlier, it is essential that attention is paid to the following investigations in *all* cases of indigestion.

Hæmoglobin—anæmia is present in 45 per cent. of cases.

Sedimentation rate—this is raised in 70 per cent. of cases.

Friedrich Ernst Krukenberg, 1870–1946. Ophthalmologist, Halle, Germany, wrote a classic paper on malignant tumours of the ovary in 1896.
Armand Trousseau, 1801–1867. Physician, Hôtel-Dieu, Paris. It was this sign which first caused him to suspect his own gastric carcinoma.
Charles Émile Troisier, 1844–1919. Professor of Pathology, Paris.

FIG. 903.—Troisier's sign found in the course of a routine examination for vague dyspepsia of recent origin. In this case there was a visible as well as a palpable mass of lymph nodes in the left supraclavicular fossa.

Occult blood is present in the stools in 80 per cent. of cases.

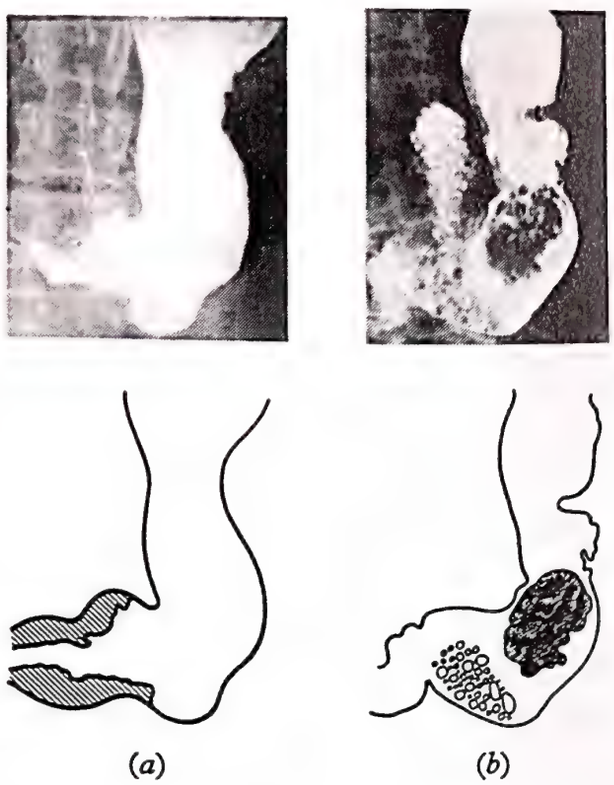
Where necessary, repeated tests should be done. It is important to remember that a negative test does *not* exclude a neoplasm.

Radiology.—While a skilled radiologist attains a high degree of accuracy in the interpretation of a barium meal, small lesions are liable to escape notice, particularly if too much barium is given initially. Irregularities of the cardia or fundus are inclined to be overlooked unless the technique includes an examination in the inverted position. Flat growths may remain undetected in the early stages. Radio-diagnosis is accurate in 90 per cent. for pyloric growths, 75 per cent. for the cardia, and 60 per cent. for neoplasm of the body, but in only 47 per cent. of patients with conclusive radiological findings (filling defects) (fig. 904) is the neoplasm found to be resectable.

Gastric Secretory Studies.—The majority have either achlorhydria (p. 787) or hypochlorhydria, but occasionally some increase of acid is found. If the M.A.O. (p. 787) is more than 20 mEq/l (20 mmol/l) HCl a carcinoma is unlikely.

Gastroscopy.—If the tumour can be visualised, its characteristics are obvious. Its nodularity, the presence of several irregular superficial ulcers, the multi-coloured base, the immotility of the adjacent mucosa, all point to the nature of the lesion. Multiple biopsies are essential.

Exfoliative Cytology.—Examination of cells found in the washings after gastric lavage has proved sufficiently reliable to confirm a diagnosis of carcinoma of the stomach in doubtful cases in about 70 per cent. of cases. Negative results are of no moment. Chymotrypsin lavage to soften the mucous lining has aided this method of investigation.



(*a*) (*b*)

FIG. 904.—Barium-meal X-ray in carcinoma of (*a*) the antrum and (*b*) the body of the stomach.

Laparotomy.—If there is still reasonable doubt after all these tests, it is wise to explore the abdomen.

COLLOID CARCINOMA

The stomach appears infiltrated in all its layers by a kind of areolar tissue, the interspaces of which contain a transparent gelatinous substance. Groups of cancer cells often line the accumulations of colloid. The tubular glands are extremely distended with this substance. Colloid carcinoma represents about 6 per cent. of the total cases of gastric carcinoma. It is this type of carcinoma which classically gives rise to the Krukenberg phenomenon (p. 821).

The treatment is the same as that for leather-bottle stomach and the prognosis is almost equally gloomy.

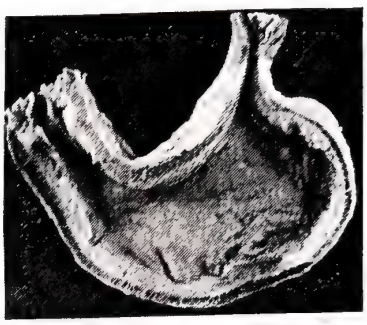


FIG. 905.—Leather-bottle stomach, showing the enormous thickening of the stomach wall.

LEATHER-BOTTLE STOMACH (*syn.* LINITIS PLASTICA)

There is a generalised and a localised form of leather-bottle stomach.

When localised, it is the pyloric antrum that is mainly involved. The stomach wall is enormously thickened (fig. 905), and feels, as its name implies, like leather.

The enormous proliferation of fibrous tissue involves especially the submucosa, which often appears as a dense layer, mother-of-pearl in appearance. Astonishingly, the whole of the mucous membrane looks and feels quite normal.

FIG. 906.—X-ray of a case of leather-bottle stomach.

It is often difficult or impossible to find any evidence of carcinoma, even in serial sections, but metastases are usually found in the regional lymph nodes. When distant metastases occur they are usually found in the liver or the ovary; on rare occasions bones are involved.

The symptoms are those of pyloric obstruction, but the small capacity of the stomach as revealed radiologically by a barium meal (fig. 906) makes the diagnosis tolerably certain.

Treatment.—In the localised variety, partial gastrectomy, and in the diffuse, total gastrectomy, offer hope of prolonging life, but the results, especially in the more common generalised variety, are among the worst, if not *the* worst, of all varieties of carcinoma of the stomach.

Boeck's sarcoid of the stomach occurs occasionally (p. 187), and gives symptoms and X-ray findings identical with those of leather-bottle stomach.

Crohn's Disease (Chap. 47) may affect the stomach.

Carcinoma of the pancreas invading the posterior wall may be misleading.

TREATMENT OF CARCINOMA OF THE STOMACH

No description of the treatment of carcinoma of the stomach is comprehensible without a knowledge of its lymphatic drainage (fig. 907).

The lymphatic vessels of the stomach arise in its submucous and subperitoneal layers, and divide into four main sets that accompany corresponding blood-vessels. Each set drains

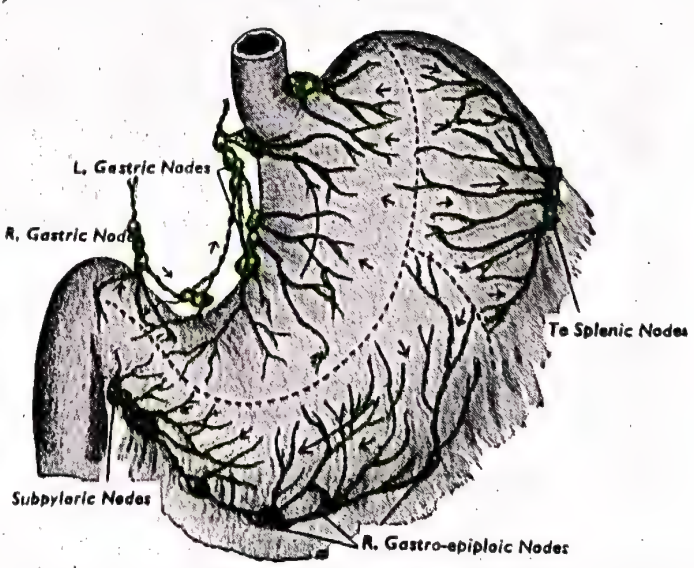

FIG. 907.—The lymphatic drainage of the stomach. (*After Jamieson and Dobson.*)

both the anterior and the posterior surfaces of the stomach, and although they intercommunicate, their valves direct the lymph flow as follows :

The lymphatics of the proximal half of the stomach drain primarily into the left gastric and the splenic lymph nodes, and thence into the left, middle, and right superior pancreatic lymph nodes.

The lymphatics of the antrum drain into the right gastric lymph nodes superiorly and the right gastroepiploic and sub-pyloric lymph nodes inferiorly.

The lymphatics of the pylorus drain into the right gastric (suprapyloric) superiorly and the subpyloric lymph nodes, situated around the gastro-duodenal artery, inferiorly. The efferent lymphatics from the suprapyloric lymph nodes converge on the para-aortic lymph nodes around the cœliac axis, while the efferent lymphatics from the sub-pyloric lymph nodes pass to the main superior mesenteric lymph nodes situated around the origin of the superior mesenteric artery. The lymphatic vessels related to the cardiac orifice of the stomach communicate freely with those of the œsophagus.

Whether or not there is histological evidence of regional lymph node involvement makes a tremendous difference in the prognosis of *completely operable* cases of carcinoma of the stomach. It must be remembered that retrograde (or downward) spread may occur if the upper lymphatics are blocked.

Forty per cent. of patients without regional lymph node involvement survive five years or more, whereas less than 10 per cent. with regional lymph node involvement survive this length of time.

Prognosis.—Of recent years the extent of stomach resected has been on the increase without any coincident benefit. The important fact that has emerged is that, providing a reasonable amount of stomach is resected, it is the histology of the growth which determines the prognosis. The clinical counterpart of this is that the longer the history the better the outlook. Fifty per cent. of cases are inoperable when first seen; in the remainder exploration is worthwhile, resection being possible in half of them. Five per cent. of the initial cases, and ten per cent. of those having resection, survive for more than five years.

Operative Treatment :

Nomenclature.—A ' curative ' resection consists of removing a block of tissue, including the growth, a margin of at least 4 cm beyond its palpable limits with the stomach unstretched, and the related lymph nodes. The term radical gastrectomy should be reserved for a monoblock dissection fulfilling these requirements, thus bringing the term ' radical ' into line with operations for carcinoma in other situations, e.g. the breast. Radical operations upon the stomach are of three varieties —(1) radical total gastrectomy, (2) radical upper gastrectomy, and (3) radical lower gastrectomy.

Incision.—Where possible an abdominal approach is to be preferred to an abdomino-thoracic (fig. 908). The latter carries an increased risk. The deciding factor for the use of an abdomino-thoracic incision is involvement of the gastro-œsophageal junction.

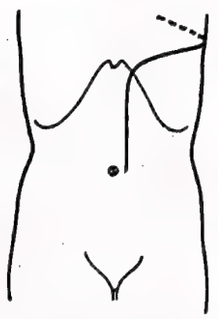

FIG. 908.—Abdomino-thoracic incision started as a left paramedian.

Operability.—As soon as the abdomen is opened, a firm plan, based on the extent of the growth, must be made. This decision is of profound importance and calls for considerable clinical judgement. There are three possibilities—radical surgery, palliative surgery, or the lesion may be inoperable.

Signs of Inoperability.—In general, these depend on the extent of the growth which include (1) fixation to the pancreas or posterior abdominal wall or involvement of the mesentery especially the origin of the superior mesenteric vessels, (2) gross local involvements of lymph nodes leading to fixity and evidence of retrograde spread downwards in the pre-aortic lymph nodes, (3) the presence of secondaries in the liver—an exception may

be made in the case of a solitary resectable nodule, (4) peritoneal seedlings either locally or in the pelvis. A Krukenberg tumour does not of itself make the case inoperable.

Radical Operations

1. **Total gastrectomy.**—Indicated for growth involving the upper or middle two-thirds of the stomach. An upper left paramedian incision is made (fig. 908). The spleen with its hilar lymph nodes, the stomach, the splenic vessels, the tail and body of the pancreas are mobilised from left to right *en bloc*, the operation being essentially retroperitoneal. The left gastric artery and the splenic vessels are ligated retroperitoneally. The lymph nodes around the cœliac axis and cardiac orifice are freed, and the lesser omentum is detached as far from the stomach as possible. Similarly, the subpyloric lymph nodes are mobilised and the greater omentum is detached from the transverse colon. The cut edge of the pancreas is closed with sutures and a soft rubber drain is passed down to this site, to be brought out through a separate stab incision. The stomach having been excised, the continuity of the alimentary canal can be restored in the manner shown in fig. 909; this procedure is valuable because it prevents regurgitation of bile and pancreatic juice into the œsophagus, which is so vulnerable to these digestive ferments. An œsophagoduodenostomy should not be done as an *alkaline* œsophagitis so frequently follows. If a thoraco-abdominal incision has been necessary, the diaphragm must be carefully repaired with non-absorbable sutures. Waterseal drainage of the pleural cavity is instituted.

Post-operative Care of Total Gastrectomy.—Here nutritional disorders, e.g. weight loss, steatorrhœa, and macrocytic anæmia are the rule. The first two appear early but the anæmia takes five or six years to develop. These patients need frequent small meals of high protein, high calorie content, and regular vitamin B_{12} supplements (100 to 200 μg. monthly).

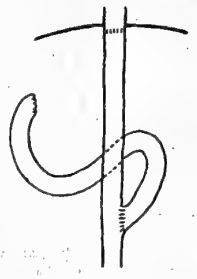

FIG. 909.—Total gastrectomy with œsophago-jejunostomy-en-Y (Roux's method).

2. **Upper Radical Partial Gastrectomy.**—Indicated for growth involving the cardia and upper third of the stomach. The procedure here is as for total gastrectomy, but the pyloric end of the stomach is preserved and anastomosed to the œsophagus. A pyloroplasty is usually done to prevent post-vagotomy retention (p. 818).

3. **Lower Radical Partial Gastrectomy.**—This operation for carcinoma of the pyloric end of the stomach involves separation of the greater omentum from the colon in its entirety, separation of the lesser omentum from the liver, freeing the subpyloric lymph nodes, and removal of the spleen and body and tail of the pancreas. The left gastric vessels and the right gastro-epiploic vessels are divided at their origin, stripping all fatty and lymphatic tissue around them towards the stomach. The operation is then completed by a Billroth I anastomosis.

Palliative Operations.

(1) *Palliative Gastro-jejunostomy.*—For irremovable pyloric carcinoma gastro-jejunostomy should be performed some distance from the tumour, so that the advancing growth will not invade the stoma, at any rate for some time.

(2) *Exclusion Operation.*—Excluding the growth from the pathway of the food is often beneficial, especially where an antral growth is fixed and inoperable and the upper part of the stomach is free. The risk of bleeding is reduced, appetite is increased, and vomiting ceases. The stomach is transected 2·5 cm proximal to the edge of the growth, the distal end is closed with non-absorbable sutures, and a gastro-jejunostomy is done. If the pylorus is completely occluded, this operation is contraindicated.

(3) For *obstruction of the cardia* considerable relief can be obtained by the introduction of a plastic tube (p. 779). This is a most valuable manœuvre in those patients whose days are numbered. It is preferable to a palliative œsophago-jejunostomy which carries a definite operative mortality in these debilitated patients.

SARCOMA OF THE STOMACH

Sarcoma of the stomach accounts for about 1 per cent. of gastric neoplasms.

Lymphosarcoma is the most common variety. In contradistinction to lympho-

César Roux, 1857–1934. Professor of Surgery and Gynæcology, Lausanne, Switzerland. Described this method of forming a jejunal conduit, which has so many uses in modern gastro-intestinal surgery in 1908.

sarcoma of the small bowel which is multiple, this tumour is usually solitary. In all inoperable cases a piece of the growth should be removed for histological examination. Although radio-sensitive, the best treatment, if circumscribed, is gastrectomy. Chemotherapy may be useful.

Leiomyosarcoma.—The first symptom may be a massive hæmatemesis and/or melæna. The presence of a barium-filled sinus extending into the tumour visualised by X-rays is extremely characteristic of leiomyosarcoma. Unlike a carcinoma of similar dimensions, the gastric acidity is unchanged. Usually these tumours metastasise late, and, when they do, secondary growths are often found in the liver. The treatment is partial gastrectomy. The tumour is more vascular than a carcinoma. It is stressed particularly that leiomyosarcomata should be attacked with vigour, regardless of the magnitude of the procedure, as the results are so much more gratifying than those of carcinoma of the stomach. At least 50 per cent. of the patients are alive five years after the operation.

Neurofibrosarcoma behaves precisely as a leiomyosarcoma, from which it is distinguished only by histological examination.

Fibrosarcoma, derived from the subserosa, is the rarest variety and the least malignant; it sometimes gives rise to a tumour of immense size, and in the female such a tumour is liable to be mistaken for an ovarian cyst.

DUODENAL NEOPLASMS

Neoplasms of the duodenum are very rare. Adenomas have been reported as causes of severe melæna. Carcinoma of the first part of the duodenum is so rare that many of great experience have never seen a case. There is an apparent bar to spread of carcinoma of the pyloric end of the stomach into the duodenal mucosa, but there is no such obstacle to the spread in the subserous layer which, indeed, occurs with some frequency—hence the necessity for excising 2·5 cm of the duodenum when performing radical lower partial gastrectomy. Carcinoma of the second and third parts occurs. It may occlude the ampulla of Vater.

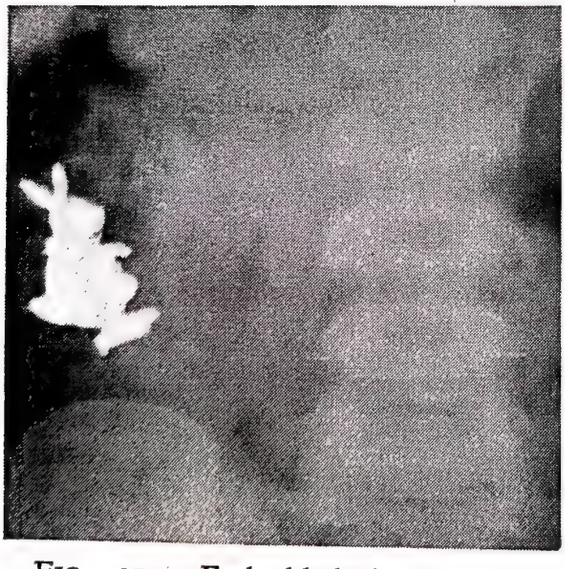

FIG. 910.—Embedded in Normacol, this foreign body was passed naturally in three days.

MISCELLANEOUS CONDITIONS OF THE STOMACH AND DUODENUM

Foreign Bodies in the Stomach

A variety of ingested foreign bodies reach the stomach. Fortunately, for the most part they are opaque to X-rays (fig. 910). Sharply pointed or long objects are best removed promptly by gastrotomy because they have difficulty in negotiating the curves of the duodenum. Rounded, smaller foreign bodies may be left to pass along the natural passages. Suitable doses of Normacol form a gelatinous pabulum, in which the article becomes embedded during its transit along the alimentary tract. X-ray examinations should be undertaken sparingly.

Hair-ball of the Stomach (Trichobezoar).—An example of this rare condition is usually to be found on the shelves of pathological museums. Trichobezoars occur almost exclusively in females, and in 80 per cent. of cases the patient is a psychiatric case. Trichobezoars can give rise to gastro-duodenal ulceration leading to hæmatemesis, perforation, peritonitis, or obstruction. A trichobezoar shows well on radiography. The treatment is removal by gastrotomy.

Acute Dilatation of the Stomach

This dangerous complication can occur after any operation or even after such trauma as a fractured femur or the application of a plaster-of-Paris jacket.

Clinical features. Muffled hiccoughs, rising pulse rate, and shock, may occur up to three days after operation or accident. Vomiting starts, and unless prompt treatment is given, characteristic effortless vomits of dark, watery fluid occur. Inhalation of vomitus may cause cardiac arrest.

Treatment.—1. The stomach is emptied and kept empty by aspiration through a nasogastric tube.

2. Fluid balance is restored by intravenous infusion. After replacing lost chloride with normal saline, dextrose-saline is given. Hypo-potassæmia must be avoided (p. 87).

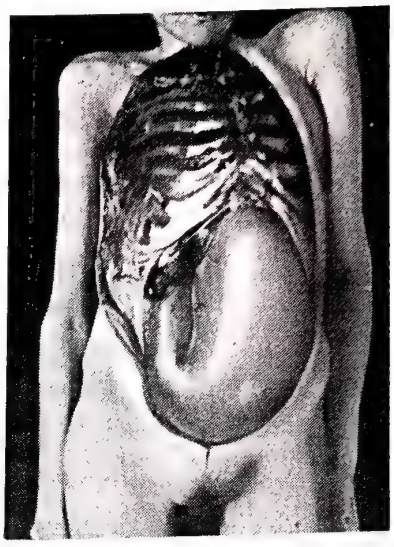

FIG. 911.—Acute dilatation of the stomach seen at necropsy.

Volvulus of the Stomach

Rotation of the stomach usually occurs around the axis made by its two fixed points, i.e. the cardia and the pylorus (fig. 912). Although the rotation can occur in a horizontal or vertical direction, in its common form the greater curve with the colon moves upwards to lie under the cupola of the left diaphragm (fig. 913). An important predisposing cause of this event is eventration of the diaphragm from whatever cause. It is probable that the colon moves up first and takes the stomach with it. The condition is usually intermittent, but it may present in an acute form. The patient takes a small amount of food and he feels full; there is slight epigastric pain and retching. He has to wait awhile, and he may find that if he lies flat he can then eat some more. The diagnosis is established by a barium meal (fig. 914). It is often impossible to pass a stomach tube.

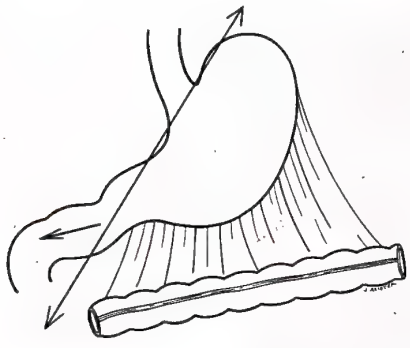

FIG. 912.—Volvulus of stomach —common axis of rotation.

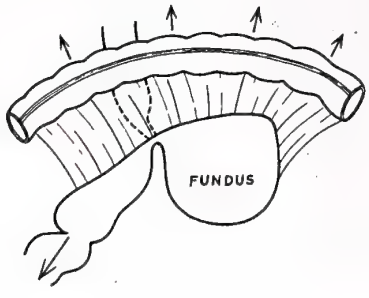

FIG. 913.—Volvulus of stomach—colon passes upwards and greater curve of stomach is inverted.

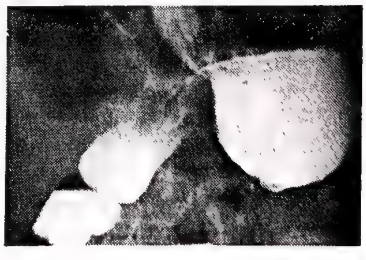

FIG. 914.—Volvulus of stomach—barium meal findings.

Treatment.—Operation is the only satisfactory form of treatment. The greater curvature of the stomach must be completely freed from the colon by division of the gastro-colic omentum. It is probable that this of itself is adequate. A further safeguard, however, consists of fixing the greater curve to the duodeno-jejunal flexure (or better, the fourth part of the duodenum), as in a posterior gastro-enterostomy but without a stoma.

Where the rotation occurs as the result of and into a large hiatal defect, the essential treatment consists of closure of the hiatus around the œsophagus.

Gastric Tetany

Tetany due to alkalosis may occur where there is long-continued vomiting, gastric aspiration, or excessive ingestion of alkali. The extracellular alkalosis is always accompanied by cellular acidosis, potassium depletion, and a fall in the blood calcium (parathyroid tetany, p. 619). Clinically there are muscle spasms in the extremities, shallow respiration, and cyanosis. The stomach must be kept empty by a tube and the blood electrolytes estimated so that the specific deficiencies may be rapidly corrected. Whilst these are being done, continuous intravenous dextrose saline with calcium gluconate should be given. Even when the chloride deficit is corrected, the alkalosis may persist and this is indicative of the need for potassium (p. 87).

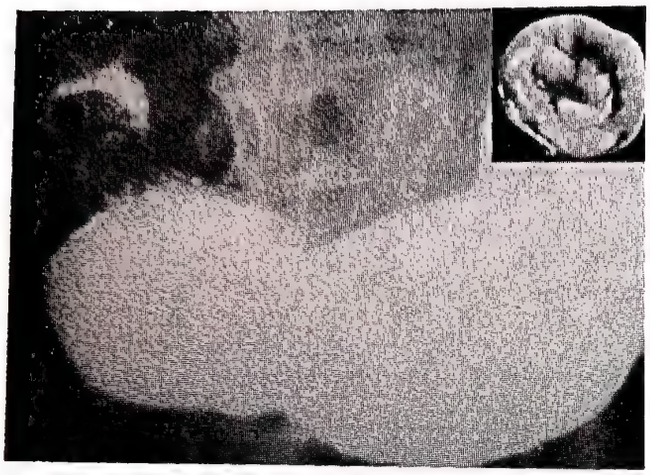

FIG. 915.—Prolapsing gastric mucosa. Inset. —The prolapse viewed from the duodenal aspect of the pylorus. (*L. H. Appleby, F.R.C.S., Vancouver*).

Prolapsing Gastric Mucosa.—This is an X-ray finding. Hypertrophied gastric mucosa prolapses through the pylorus (fig. 915 (inset)). Pyloric obstruction has been attributed to this phenomenon.

Giant rugal hypertrophy of the stomach is a descriptive name given to a condition which may manifest itself clinically as a protein-losing gastro-enteropathy. Recognition of this feature may necessitate gastrectomy. The thick folds can be demonstrated radiologically, seen at gastroscopy, and palpated at laparotomy. There is not the slightest evidence that this condition is premalignant, nor is it inflammatory. The ætiology is unknown (Johnson).

Duodenal Diverticulum

There are two varieties:

1. **Primary diverticulum** of the second and third parts of the duodenum. They occur on the concave border, are usually single but may be multiple, and commonly arise at the portal of entry of the blood-vessels into the duodenal wall. In 90 per cent. of cases they are an incidental finding during the course of a barium meal. It is wise not to incriminate them as a cause of symptoms (fig. 916) but to make a thorough search for pathology elsewhere. Rarely, a large diverticulum near the ampulla of Vater may cause jaundice. In addition, if a diverticulum is persistently tender when visualised during screening or if it retains barium for days, then it may be justifiable to operate. The duodenum is mobilised, turned medially, and the diverticulum dissected free. The duodenum is then opened opposite the diverticulum which is seized, inverted into the lumen, and is ligated. The duodenum is then closed and the fascia over the site of the diverticulum oversewn. The duodenum is deficient of peritoneum in this area and the operation may be complicated by a fistula.

FIG. 916. — Duodenal diverticulum arising from the third part of the duodenum.

2. **Secondary Diverticula.**—These occur in the first part of the duodenum and are the result of scarring following duodenal ulceration. They are responsible for the trifoliate duodenum seen on X-ray (fig. 917).

Chronic duodenal ileus is a rare condition which may mimic pyloric stenosis. The duodenum is dilated up to the superior mesenteric vessels. The dilated segment has a characteristically smooth outline (fig. 918). It is a radiological diagnosis rather than a clinical one. Some advocate duodeno-jejunostomy for this condition, but the results are disappointing.

H. Daintree Johnson, Contemporary. Surgeon, Royal Free Hospital, London.

Duodenal Fistula

The most usual causes are as follows:

1. As a complication of gastrectomy (p. 813).
2. An abscess connected with a perforated duodenal ulcer.
3. Traumatic rupture of the duodenum (see below).
4. As a complication of transduodenal sphincterotomy, right nephrectomy, or right colectomy.

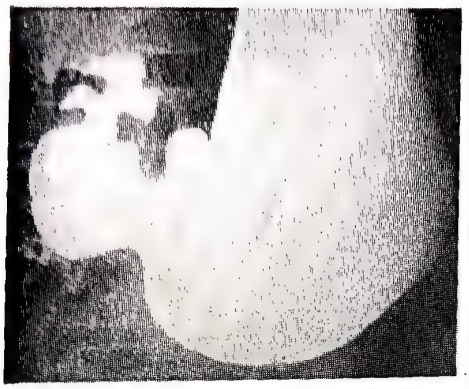

FIG. 917.—Duodenal ulcer showing typical trefoil or shamrock deformity. (*Dr. G. Stachurko, London.*)

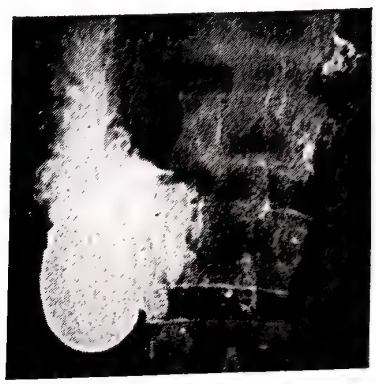

FIG. 918.—Duodenal ileus. Note the abrupt obstruction to the third part of the duodenum.

The fistula discharges bile and pancreatic juice which cause excoriation of the skin. Excessive discharge may quickly lead to dehydration, electrolyte imbalance, and hypoproteinæmia. The management consists essentially of three procedures:

1. Protection of the skin by 1 per cent. HCl in zinc oxide cream.
2. Continuous and efficient suction drainage of the fistula (fig. 1033) which may be facilitated by gravity—the patient lying prone.
3. Replacement therapy—when the fistula drainage is small, closure may be confidently expected within a few days using simple intravenous therapy. If the discharge is profuse, a severe illness can be prevented by a simple feeding jejunostomy on the left side of the abdomen. The valuable pancreatic and biliary juices may be returned to the jejunum by this route.

Traumatic Rupture of the Duodenum.—This is an increasingly common problem in hospitals near a fast main road (see seat belt syndrome, Chap. 46). If the rupture is extraperitoneal the initial symptoms are often slight and the condition is overlooked until an abscess forms. When the abscess is opened a fistula develops. With intraperitoneal rupture the clinical features resemble a perforated duodenal ulcer. Laparotomy is performed and the tear can usually be sutured.

Traumatic fistulæ of the first part usually close spontaneously—those of the second and third part are formidable indeed. They present such a grave problem that it is worth considering a duodeno-jejunal anastomosis to overlie the defect if this cannot be closed easily at the primary operation.

CHAPTER 42

THE SPLEEN

Surgical Physiology.—The functions of the spleen are not wholly understood.[1] In general they may be considered as:

1. **Destruction of effete and misshapen erythrocytes** and possibly of platelets. It is believed that during their sojourn in the spleen the lipoid coverings of ageing erythrocytes are rendered less strong. If red blood cells from a patient with hereditary spherocytosis are transfused into a normal person, they are destroyed in fifteen days. When transfused into a splenectomised person, they have a normal life span. After splenectomy the liver, bone marrow, and lymph nodes deal with effete red cells.
2. **Formation of erythrocytes and lymphocytes** during fœtal life, infancy, and childhood. In case of need, this function may be resumed during adult life.
3. **Maintenance of a reserve of erythrocytes.**—Anoxia, caused by high altitudes, hæmorrhage, carbon monoxide poisoning, or prolonged exercise, stimulates the spleen to contract, thereby causing reserve red cells idling in its mesh-work to be conscripted into circulation as oxygen-carriers. This reaction may be useful in some animals like dogs, but the spleen is relatively too small to be of much use in man (containing about 1 per cent. of the blood volume).
4. **Regulation of iron metabolism and iron storage.**
5. **Phagocytosis of foreign substances** by the reticulo-endothelial cells of the spleen is well illustrated by the high concentration of opaque substance in the spleen in patients who have received an injection of thorium. This function is also evident in the lipoid dystrophies, when phagocytosis of abnormal lipoids is the main cause of splenic enlargement.
6. **Protection against certain toxins.**—It would appear that the spleen plays a part in the formation of antibodies. There is increasing evidence that splenectomised children are less able to combat severe infection than those with a normal spleen, and they require close observation so that immediate and energetic steps can be taken in cases of pyogenic infection.
7. **Hormone regulation of the marrow.**—There is some evidence that the spleen secretes a hormone that inhibits the production of thrombocytes and leucocytes by the bone marrow. Dameshek considers excess of this hormone to be the cause of thrombocytopænic purpura and splenic neutropænia.

PHYSIOLOGICAL EFFECTS OF SPLENECTOMY

1. **Splenunculi** (accessory spleens), if present, **hypertrophy.**
2. **Bone marrow changes its character.**—Within six months red marrow replaces yellow marrow in many of the long bones (Short). This accounts for fleeting bone pains ' like rheumatism ' that are sometimes a matter of serious concern to the patient.
3. **Changes in the blood.**—*Initial changes:*

(*a*) Leucocytosis
(*b*) Erythropenia
(*c*) Diminution in hæmoglobin
} These changes reach their zenith between the second week and the second month after splenectomy.
(*d*) Increased platelet count.
(*e*) Increased coagulability.

A characteristic morphological change occurs in some of the erythrocytes, viz. the presence within them of Howell-Jolly bodies. These are rounded structures usually occurring singly, and placed eccentrically, that stain in the same way as nuclei. They are thought to be fragmented nuclei.

---

[1] Organum plenum mysterium (*Latin*) = Organ full of mystery (*Galen*).

Galen, 130–200. First experimental physiologist and personal physician to the Roman emperors Marcus Aurelius, Commodus and Septimus Severus.

After two months lymphocytosis is present invariably. *After many months* there is moderate eosinophilia, and the mast cells increase in number.

4. **Undue excretion of iron by the kidneys.**—Therefore the patient should take a preparation of iron.

SPLENUNCULI (*syn.* ACCESSORY SPLEENS)

Instead of a spleen, some fishes are provided with islets of splenic tissue scattered through the cœlom. In man, accessory spleens, in common with the main organ, are derived from the dorsal mesogastrium. One or more are present in 25 per cent. of children (Jolly), but they are to be found in only 11 per cent. of adults (Adami). Obviously then, as maturity is reached accessory spleens tend to disappear. Their usual locations are as follows:

1. In contact with the spleen (fig. 919), usually near the hilum; more than 50 per cent. are found in this situation.

2. Related to the splenic vessels and behind the tail and body of the pancreas—about 30 per cent.

3. The remainder are found in the splenic ligaments, the greater omentum, mesentery, mesocolon, and abutting on the left ovary or testis (carried thither during descent of the gonad).

When splenectomy has been performed for conditions that are known to be cured by removal of the spleen, return of symptoms after an interval of freedom is the result of hypertrophy of (usually) one accessory spleen. Occasionally a morsel of the spleen left attached to the pedicle during splenectomy continues to grow, and may be said to form a new spleen. Therefore not only must the whole of the enlarged spleen be removed, but, except in cases of rupture, the sites of an accessory spleen should be examined meticulously and any splenunculi present excised.

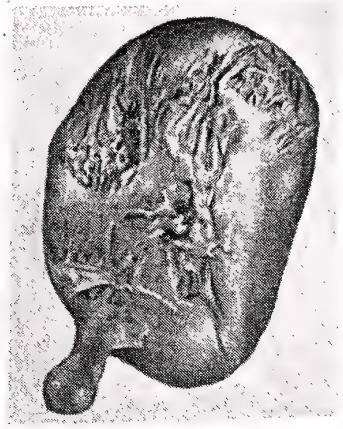

FIG. 919.—Spleen with a splenunculus.

Splenosis is a rare condition, and nothing to do with splenunculi. Fragments of splenic tissue, spilled at the time of bygone rupture of the spleen, are found disseminated widely over the peritoneum, having thrived in situations other than those to be expected on developmental grounds. Sometimes there are scores of them. Splenosis does not give rise to symptoms, and is found only at laparotomy or necropsy. It is liable to be confused with endometriosis of the peritoneum, carcinomatosis or multiple angiomata.

SPECIAL METHODS OF INVESTIGATING THE SPLEEN

1. **Radiography.**—In plain films of the upper abdomen the spleen is visible in whole or part, especially when the stomach and the splenic flexure contain gas, and the patient is not obese. These findings, repeated at intervals, are good evidence that the spleen is unruptured (p. 832).

2. **Splenic Puncture.**—Provided the following stipulations are adhered to rigorously, splenic puncture can prove a valuable diagnostic aid in hæmatology.

(*a*) Only definitely palpable spleens should be punctured.

(*b*) No patient with a hæmorrhagic tendency should undergo splenic puncture.

(*c*) The puncture should not be performed in the presence of infective splenomegaly, or of a tender spleen.

(*d*) Unconscious patients and children must never undergo splenic puncture.

Technique.—An ordinary lumbar puncture needle equipped with a guard to regulate the depth of the thrust should be employed. With the patient lying on his back, the site puncture (fig. 920) is infiltrated with local anæsthetic. The puncture must be performed during full inspiration, with the guard set to the required depth. Strong aspiration with the syringe is performed for several seconds. Before the needle is withdrawn the negative pressure must be released. After splenic puncture the patient is kept in bed for six hours, as a precaution against hæmorrhage.

3. **Splenoportography** can be carried out under general anæsthesia prior to laparotomy, or under local anæsthesia. The needle is inserted as above. After withdrawal of the stilette of the lumbar puncture needle, blood drips from the lumen;

Hugh Reginald Jolly, Contemporary. Pædiatrician, Charing Cross Hospital, London.
John George Adami, 1862–1926. Strathcona Professor of Pathology, McGill University, Montreal, Canada.

only after this has been demonstrated is the dye-filled syringe connected, and 30–50 ml of Hypaque injected *rapidly*. Apnœa, voluntary or controlled, must be maintained during insertion of the needle and throughout the injection of the dye. If this stipulation is not adhered to rigorously, a laceration of the spleen as the spleen moves with the diaphragm, and possibly serious hæmorrhage, may result. Splenoportography permits visualisation of the spleen and the portal venous system (p. 871). The first exposure is made towards the end of the injection, and three or four exposures follow subsequently.

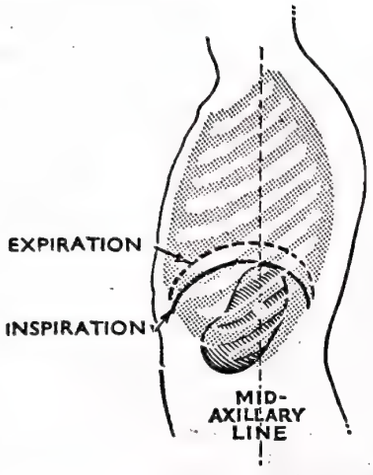

FIG. 920.—The puncture is made in the 9th intercostal space in the mid-axillary line during full inspiration.

CONGENITAL ABNORMALITIES OF THE SPLEEN

Congenital absence of the spleen is exceedingly rare, and when it occurs it is nearly always associated with a gross congenital cardiac abnormality (usually a septal defect) and also the presence of accessory lobes to the lungs, and sometimes lobulation of the liver.

Movable Spleen (*syn.* Wandering Spleen).—The spleen, well supported by its two ligaments (the gastrosplenic and lieno-renal), and resting on a third (the costocolic), which acts as a shelf, is the one abdominal organ that maintains its correct anatomical position in general visceroptosis. Movable spleen is a congenital abnormality that occurs more often in women. The condition is of great rarity, and the diagnosis is seldom made correctly.

Torsion of the splenic pedicle sometimes complicates the wandering organ. The torsion may be acute or chronic, acute cases presenting the symptoms of an intra-abdominal catastrophe. Chronic torsion may result in atrophy of the spleen, and after a period of indefinite abdominal discomfort all symptoms abate.

RUPTURE OF THE SPLEEN

Usually a ruptured spleen occurs as the result of an industrial or traffic accident of the crushing or run-over type. Blows on the abdomen or the left lower thorax and falls on to a projecting object are other causes of rupture. When rupture of the spleen occurs as a result of a traffic accident, associated injuries are commonly present. A number of cases of spontaneous rupture of a normal spleen have been reported, but in all probability in some of these there has been an accident that has been forgotten or suppressed by the patient. The spleen in infectious mononucleosis ruptures easily.

Cases of ruptured spleen may be divided into three groups:

1. **The Patient Succumbs Rapidly, Never Rallying from the Initial Shock.**—This type is comparatively rare in temperate climates; tearing of the splenic vessels and complete avulsion of the spleen from its pedicle[1] give rise to the symptoms which characterise this group. In countries where malaria is rife, splenic rupture is often rapidly fatal, and advantage was once taken of this knowledge by murderers in the Orient, who achieved their end by digging the victim beneath the left ribs with an implement known as a larang (fig. 921).

FIG. 921. — A larang, which, being interpreted, means 'forbidden'. (*After J. Johnston Abraham.*)

2. **Initial shock; recovery from shock; signs of a ruptured spleen** is the usual type seen in surgical practice. After the initial shock has passed off, there are

[1] Favoured by adhesion of the spleen to the diaphragm.

signs which point to an intra-abdominal disaster, and by correlating these signs it is often possible to arrive at a correct preoperative diagnosis.

General signs of internal hæmorrhage are inconstant. Perhaps the most helpful are increasing pallor, a rising pulse-rate, sighing respiration, and restlessness.

Local Signs.—(*a*) Abdominal rigidity is present in more than 50% of cases; it is most pronounced in the left upper quadrant.

(*b*) Local tenderness is found constantly.

(*c*) Shifting dullness in the flanks is often present.

Ballance's sign is positive in about 25% of cases. There is a dull note in both flanks, but on the right side it can be made to shift, whereas on the left it is constant. The interpretation is that there is blood in the peritoneal cavity, but the blood in the neighbourhood of the lacerated spleen has coagulated.

(*d*) Abdominal distension commences about three hours after the accident, and is due to intestinal paresis, an early stage of paralytic ileus.

(*e*) Kehr's sign is pain referred to the left shoulder. There may be hyperæsthesia in this area. This sign is present very often, especially if sought a quarter of an hour after elevation of the foot of the bed, and is due to blood in contact with the under-surface of the diaphragm, the pain being mediated through afferent fibres in the phrenic nerve.

(*f*) Rectal examination frequently reveals tenderness and sometimes a soft swelling, due to blood or clot in the rectovesical pouch.

3. **The Delayed Type of Case.**—After the initial shock has passed off, the symptoms of a *serious* intra-abdominal catastrophe are postponed for a variable period up to fifteen days, or even more. As a rule it is only a matter of minutes to an hour or so, during which time the patient often appears to have recovered from the blow. Thus a Rugby footballer may continue to play after a short rest, only to collapse later from internal hæmorrhage.

Considerable delay of serious intraperitoneal bleeding is explained in one of the following ways:

(*a*) The greater omentum, performing its well-known constabulary duties, shuts off that portion of the general peritoneal cavity in the immediate vicinity of the bleeding (fig. 1066 (*c*), p. 951).

(*b*) A subcapsular hæmatoma forms and later bursts.

(*c*) Blood-clot temporarily sealing the rent becomes digested by escaping ferments from the lacerated tail of the pancreas. What may happen is that a patient with a suspected rupture of the spleen is taken into hospital; the symptoms abate, and in due course he is allowed up. Suddenly he collapses, perhaps in the lavatory while straining at stool. At other times fresh hæmorrhage is heralded by a rising pulse-rate, increasing pallor, advancing to air-hunger and collapse. Such disasters can, and should, be prevented by careful re-examination and radiography.

Radiography.—A normal, well-outlined spleen is a reliable negative sign, but radiographs should be repeated if the decision not to operate *pro tem.* is taken. Indeed, every patient with a left-sided thoracic injury, especially where a lower rib is fractured, should be kept under radiological observation. When there is delayed rupture, or when the symptoms and signs are atypical, radiography often can help considerably in diagnosis. In decreasing frequency, the radiological signs of ruptured spleen are: (1) Obliteration of the splenic outline; (2) Obliteration of the psoas shadow; (3) Indentation of the left side of the stomach air-bubble; (4) Fracture of one or more lower ribs

Sir Charles Alfred Ballance, 1856–1936. Surgeon, St. Thomas's Hospital, London.
Hans Kehr, 1862–1916. Surgeon, Halberstädt, later Berlin. He died of septicæmia contracted during his work.

on the left side (present in 27% of cases); (5) Elevation of the left side of the diaphragm; (6) The presence of free fluid between gas-filled intestinal coils.

Treatment of Rupture of the Spleen.—Immediate laparotomy and splenectomy is the only reliable course. Blood is evacuated and, after injury to other viscera has been excluded, the abdomen closed completely. When the organ is damaged by a stab wound or missile penetrating the left pleural cavity, access to the spleen is best obtained by excising the thoracic and diaphragmatic wounds, and enlarging the opening in the diaphragm.

When circumstances permit, blood transfusions should be given as required. In the absence of stored blood, auto-transfusion is indicated.

Auto-transfusion.—Extravasated blood is collected from the peritoneal cavity by means of a sterile suction apparatus. After mixing it with 3·8% sodium citrate solution, 60 ml. in 568 ml. of blood, it is strained through several layers of sterile gauze and gravitated into a vein. We have carried out the procedure on numerous occasions, and never with regret.

Post-operative Complications

Acute Dilatation of the Stomach.—This preventable complication should not be allowed to occur. Routine gastric aspiration for at least 24 hours post-operatively has banished it.

Hæmatemesis occasionally occurs, possibly due to transient congestion of the gastric mucosa following ligation of the vasa brevia veins.

Left basal atelectasis, sometimes accompanied by left pleural effusion, is particularly common, and is due to bruising of the diaphragm at the time of the accident, or to trauma during splenectomy. Breathing exercises and forced coughing go a long way in preventing atelectasis.

Paralytic ileus (p. 1022) is rather common.

Peritoneal effusion or wound disruption may be secondary to concomitant injury of the tail of the pancreas. If there is any question of damage to the tail of the pancreas at operation, the area must be drained.

'*Rheumatism*' due to bone marrow activity (p. 830).

Persistent hiccough is the result of irritation of the undersurface of the left side of the diaphragm. It may indicate a collection of blood there.

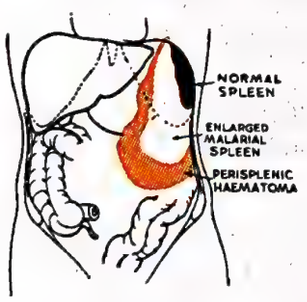

FIG. 922.—Normal spleen, malarial spleen, perisplenic hæmatoma. Note that the splenic contour is lost when the capsule has ruptured.

RUPTURE OF A MALARIAL SPLEEN

As has been mentioned, in tropical countries this is a frequent catastrophe. The delayed type of rupture (following a trivial injury) is also very common, and the patient is admitted with a perisplenic hæmatoma (fig. 922). If splenectomy can be performed before the hæmatoma bursts into the general peritoneal cavity, the prognosis is less grave.

The operation is considerably more difficult than in the case of a ruptured normal spleen. Surgeons with tropical experience have surmounted these difficulties by ligating the splenic vessels as they run along the superior border of the body of the pancreas (fig. 923), before disturbing the hæmatoma (Andreasen).

ANEURYSM OF THE SPLENIC ARTERY

Perhaps due to its tortuosity or to its liability to become arteriosclerotic (sometimes arteriosclerosis affects the splenic artery and no other), the splenic artery is more frequently the site of an aneurysm (fig. 923) than any other artery in the abdomen, the abdominal aorta excepted.

Anthony Turner Andreasen, Contemporary. Surgeon, Kampala, Uganda.

As a rule the aneurysm is symptomless unless it ruptures. It is discovered accidentally, on X-raying the upper abdomen, as a ring of calcification in the line of the artery. Exceptionally it gives rise to upper abdominal pain, in which event the condition has been diagnosed pre-operatively: (*a*) By a bruit over the left hypochondrium; (*b*) By radiography. An unruptured splenic aneurysm may be discovered at operation.

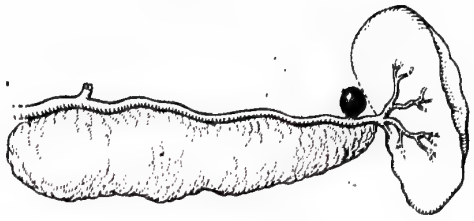

FIG. 923.—Usual position of a splenic aneurysm. (*After O. E. Owen, Caernarvon, Wales*)

Rupture of the aneurysm occurs somewhat more often in women than in men, and it is noteworthy that approximately 25 per cent. of the female patients are pregnant, and usually the pregnancy is advanced (six to eight months). In most instances rupture occurs into the peritoneal cavity, and the symptoms are precisely those of delayed rupture of the spleen (p. 833). During the stage of perisplenic hæmatoma (as in spontaneous rupture of the spleen), bursting often occurs in two stages and either or both the diagnostic signs set out above are frequently present. Hæmorrhage into the stomach or the retroperitoneum has been recorded.

Treatment.—So dangerous is an aneurysm of the splenic artery that unless the patient is very old or infirm, excision of the sac should be advised in all cases. Rupture of the aneurysm demands urgent laparotomy and blood transfusion. The lesser sac must be opened and both the proximal and distal portions of the splenic artery are ligated. Proximal ligation alone is useless, for the distal end bleeds furiously. Splenectomy, although often performed, is not obligatory unless it is obvious that the arterial ligation has deprived the spleen of all its blood supply. Rupture of an aneurysm of the splenic artery carries a high mortality.

FIG. 924.—Infarct of the spleen.

INFARCTION OF THE SPLEEN (Fig. 924)

The patient, who is often suffering from subacute infective endocarditis or auricular fibrillation, is seized with agonising pain in the left hypochondrium. Symptoms usually mimic those of a perforated gastric ulcer, but the heart lesion helps the clinician to elucidate the diagnosis. When the embolus is aseptic the symptoms pass off in a few days. Infarct of the spleen has become a problem of air travel. At a height of over 10,000 feet patients with sickle-cell anæmia (a disease confined to Negroes) frequently sustain a splenic infarct.

In bacterial endocarditis, the infection may be maintained by an infected infarct of the spleen. In a few instances splenectomy has proved to be the deciding factor in curing the patient of this serious condition.

ENLARGEMENT OF THE SPLEEN

The spleen is a meeting-place of medicine and surgery. The following is a useful table of the many causes of enlargement of the organ:

1. Infective	*Bacterial*—	Typhoid and Paratyphoid.
		Typhus.
		Anthrax.
		Tuberculosis.†
		Septicæmia.
		Abscess of the spleen.‡
	Spirochætal—	Weil's disease.
		Syphilis.
	Viral—	Infectious mononucleosis
		Psittacosis.
	Protozoal—	Malaria.
		Egyptian splenomegaly.†
		Kala-azar.
	Parasitic—	Hydatid cyst.*

Adolph Weil, 1848–1916. Physician, Dorpat (Tartu), Estonia.

2. Blood diseases	Myeloid leukæmia. Myelosclerosis. Lymphatic leukæmia. Pernicious anæmia. Polycythæmia vera. Erythroblastosis fœtalis et infantium. Spherocytosis (acholuric familial jaundice).* Acquired hæmolytic anæmia.† Thrombocytopaenic purpura.* Mediterranean anæmia.‡ Hypersplenism.†
3. Metabolic	Rickets. Amyloid. Porphyria. Gaucher's disease‡ (p. 846).
4. Circulatory	Infarct— Portal hypertension (p. 867). Infective endocarditis.‡ Mitral stenosis. Occlusion of the portal vein— Thrombophlebitis.† Neoplastic, e.g. carcinoma of tail of pancreas.‡
5. Collagen Diseases	Still's disease (p. 225). Felty's syndrome.† (p. 845).
6. Non-parasitic cysts	Congenital.* Acquired.*
7. Neoplastic	Angioma.* Primary fibrosarcoma.* Hodgkin's disease.‡ (p. 180). Lymphosarcoma.‡

* Benefited by splenectomy. † Often benefited by splenectomy.
‡ Splenectomy sometimes indicated.

In connection with the above Table, the following points should be noted. In thrombocytopænic purpura the spleen, although somewhat enlarged, is seldom palpable. In psittacosis the enlarged spleen can be palpated regularly after the first few days of the illness; this enlargement is helpful in differentiating the condition from other varieties of pneumonia. In portal hypertension the spleen is enlarged secondary to hepatic cirrhosis or portal vein thrombosis (p. 867).

PERISPLENITIS

Thickening of the splenic capsule has been noted at necropsy, usually in subjects with advanced hepatic cirrhosis. The best example of perisplenitis occurs in association with multiple serositis (Pick's disease). In this obscure malady the spleen appears as though covered with sugar icing. The covering is hard, structureless, and gives staining reactions similar to those of hyaline cartilage.

FIG. 925.—Splenic cyst, about the size of a grapefruit. (*Professor Carl Krebs, Aarhus, Denmark.*)

CYSTS OF THE SPLEEN

Non-parasitic cysts of the spleen are of two varieties: (*a*) *True cysts*, comprise 10 per cent. of the total, and are dermoids. It is difficult to understand how the spleen, which is mesochymal in origin, should contain epithelium. (*b*) *False cysts*, which often reach a large size and are more common than true cysts (fig. 925). They have no lining membrane, and usually are due to past hæmorrhage, and contain blood-stained fluid and cholesterol crystals. Their origin is likely

Friedel Pick, 1876–1926. Professor of Laryngology, Prague, Czechoslovakia. (*See footnote p. 741.*)

to be an ancient subcapsular hæmorrhage or degeneration of an infarcted area. In a number of cases there is a history of malaria. On very rare occasions cysts may be multiple.

3. *Hydatid Cyst of the Spleen.*—Cases of hydatid cyst have been reported. A cyst of the spleen should be treated by splenectomy.

HÆMOLYTIC ANÆMIA

This disorder presents in two forms: (1) congenital (hereditary spherocytosis) and (2) acquired.

1. **Hereditary Spherocytosis** (*syn.* Congenital Hæmolytic Anæmia; Acholuric Familial Jaundice).—The essential lesion is a congenital increased permeability of the red cell membrane to sodium. As the sodium leaks into the cell its osmotic pressure rises, it swells and becomes more spherical and in consequence more fragile. The mechanism by which the cell rids itself of sodium—the sodium pump—has to work harder. This has two consequences (*a*) there is greater loss of membrane phospholipid and so a weakening of the membrane which thus becomes more fragile and (*b*) the energy and the oxygen requirements increase. These requirements are particularly difficult to satisfy in the spleen where there is a deficiency of both glucose and oxygen in the pulp. Thus it is here that a large number of red cells are destroyed and therefore splenectomy helps the patient by reducing red cell destruction.[1] Splenectomy does not, of course, cure the congenital red cell membrane defect but it lessens the anæmia and makes the red cell survival time normal. The defect is transmitted by either parent as a Mendelian autosomal dominant.[2] Males and females are equally affected.

The circulating bilirubin is unconjugated with glycuronic acid, is attached to albumin and is not excreted in the urine (acholuric jaundice).[3]

The spleen enlarges in the disease because of increased work.

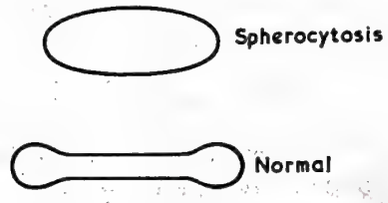

FIG. 926. — Diagrammatic representation of normal (biconcave) and biconvex red cells of spherocytosis.

Clinical Features.—Once the disease manifests itself, spontaneous remissions are almost unknown. As a rule the patient is pale and has jaundice, which varies in intensity and at its height is of a pale daffodil hue. Careful enquiry must be made into similar disease in other members of the family. In established cases lassitude and undue fatigue are seldom absent, but they vary with the amount of hæmolysis that is proceeding.

Sometimes the patient is born jaundiced, or becomes so early in life. In certain families the disease is characterised by severe crises of red-blood-cell destruction; thus, with the onset of a crisis, an erythrocyte count may fall from $4\frac{1}{2}$ millions to $1\frac{1}{2}$ millions in less than a week. Such crises are characterised by the sudden onset of pyrexia, abdominal pain, nausea, vomiting,

---

[1] 'The spleen dislikes, distrusts, and devours spheroidal red cells' (A. Rendle Short).

[2] In 1865 Mendel described 'dominant' and 'recessive' traits in hybrids. His work passed unnoticed for thirty-five years.

[3] Although there is excessive breakdown of red cells with transformation of liberated hæmoglobin to bilirubin, the bilirubin compound so produced is excreted by the liver and not by the kidneys, thus favouring the formation of pigment gall-stones.

Gregor Johann Mendel, 1822–1884. Augustinian Monk and Naturalist, who later became Abbot of Brunn, Austria, (now Brno, Czechoslovakia). His work on inheritance was published in 1866 but passed almost unnoticed during his lifetime.

and extreme pallor, followed by increased jaundice. These crises may be so severe as to cause death in infancy or childhood. They may be precipitated by acute infections. More usually the jaundice, although variable, is very mild, and may not appear until adolescent or even adult life. In adult cases there is often a history of attacks of gall-stone colic; indeed, 68% of untreated patients over the age of ten years have pigment stones in the gall-bladder. Every child with gall-stones should be investigated for evidence of hereditary spherocytosis.

On examination the spleen is large, and in thin subjects it can be palpated easily. Sometimes the liver is also palpable. Chronic ulcers of the legs are a common occurrence in adult sufferers.

Hæmatological Investigations

The Fragility Test.—Increased fragility of erythrocytes characterises this disease. Normally, erythrocytes begin to hæmolyse in 0·47%. saline solution. In this condition hæmolysis occurs in 0·6%., or even in stronger solutions.

The Reticulocyte Count.—To compensate for the loss of erythrocytes by hæmolysis, the bone marrow discharges into the circulation immature red cells, which differ from the adult cells by possessing a reticulum. This cannot be seen in the usual blood films, but can be demonstrated readily by vital stains. Crises are associated with reticulocytopenia, and hypoplasia of the erythroid element of the bone marrow. After a crisis the reticulocyte count is greatly increased.

Fæcal urobilinogen is increased, as most of the urobilinogen is excreted by this route. Although technically difficult, this measurement is the best means of determining the extent of hæmolysis in cases of hereditary spherocytosis.

Use of Radioactive Chromium.—Labelling of the patient's own red cells with ^{51}Cr followed by daily scanning over the spleen will show the degree of red cell sequestration by the spleen. If splenic radioactivity is high, splenectomy will be of value.

Treatment.—All patients who have hereditary spherocytosis should be treated by splenectomy. Not, of course, that the spleen is at fault. The trouble lies with the red cells, but it is the spleen which will not let them survive sufficiently long to be of much service. After splenectomy, the spheroidal cells have a normal life span.

In the great majority of cases splenectomy can be undertaken as an elective operation during a remission. In juvenile cases the age at which operation is recommended has been decreasing. If it is not imperative before, between the third and fourth years seems the optimum time, i.e. before gall-stones have had time to form.

At operation (splenectomy) the gall-bladder should be palpated for gall-stones, and if they are present cholecystectomy can be undertaken then or at a later date, depending on the patient's fitness.

Following splenectomy, the patient soon recovers from the anæmia, which does not return. The jaundice disappears, but the tendency to hæmolysis persists; it has been demonstrated twenty-five years after removal of the spleen. Ulcers of the leg due to this disease heal rapidly. In short (ruptured spleen excepted), in no other condition is splenectomy more triumphant. Owing to the absence of adhesions, the operation can be undertaken easily and expeditiously, which in part accounts for the very low operative mortality.

When a patient is so anæmic as to render blood transfusion advisable, more than ordinary precautions are required. Coombs' test must always be performed

Robert Royston Amos Coombs, Contemporary. Quick Professor of Biology, Cambridge, England.

—in *hereditary* spherocytosis it is negative (cf. *acquired* hæmolytic anæmia). While correctly-matched blood is usually well tolerated and the transfused red cells survive in patients whose disease is in remission, transfusion increases the amount of hæmolysis during a crisis. In such circumstances whole blood should be avoided and a cautious transfusion of packed red cells substituted. As a rule packed red cells are accepted. Should a reaction occur, however, the risk of splenectomy is probably less than risking a severe hæmolytic reaction induced by unacceptable red cells.

Acquired Hæmolytic Anæmia

Whereas hereditary spherocytosis is characterised by an abnormality inherent in the erythrocytes, the acquired form is held to be due to abnormal immunological responses. Erythrocytes of the correct ABO group from normal donors are hæmolysed quickly by patients suffering from hæmolytic anæmia. Thus it has been postulated that the disease is acquired by the production of auto-antibodies that attach themselves to normal circulating erythrocytes and bring about their early dissolution. This phenomenon serves as a basis for the Coombs' test which is usually, but not uniformly, positive.

Clinical Features.—An onset commencing in middle or late life is suggestive that the disease is acquired; the absence of a family history makes it almost certain. The spleen is palpable in 50 per cent. of cases, and in many of the patients with an enlarged spleen, the liver is palpable also. Sometimes there is a generalised enlargement of lymph nodes.

Laboratory Tests.—Anæmia is present. Spherocytosis may or may not be present. A positive Coombs' test helps to establish the diagnosis.

Treatment.—As in this form of the disease spontaneous remissions are not uncommon, a trial of ACTH or cortisone is warranted. If a sufficiently good response is obtained, splenectomy can be postponed in the hope that the remission will be sustained. An additional advantage of taking this course is that there is some evidence that severe transfusion reactions—always a concern in this disorder—are reduced in number and severity in those who receive steroid therapy (Coller).

Splenectomy may be of value in those cases where there is (1) a failure to respond to safe doses of steroids and (2) the ^{51}Cr studies[1] show (*a*) an abnormally great sequestration of red cells in the spleen and (*b*) a high proportional count over the spleen as compared with the liver (high spleen/liver ratio).

PURPURA

Purpura is a condition of great importance to the surgeon. It forcibly intrudes into his diagnostic arena; on rare occasions it is the cause of an intussusception, but more frequently subserosal hæmorrhages produce signs similar to those of acute intestinal obstruction; it may give rise to profound hæmaturia or alarming hæmorrhage from a mucous lining of the body, e.g. epistaxis, hæmatemesis, melæna or, in the case of young females (in whom the condition is particularly common), menorrhagia so severe as to render the patient in danger of exsanguination. The condition frequently calls for blood transfusion, and certain cases are benefited by splenectomy.

FIG. 927.—Purpura. The patient presented with symptoms of acute intestinal obstruction due to submucosal hæmorrhage of the small intestine.

[1] A solution of radioactive chromium salt is mixed with the patient's own blood and becomes attached to the red cells. When these are re-injected into the circulation the concentration of red cells in such organs as the spleen and liver can be counted by an external counter.

Professor of Surgery, University of Michigan, Ann Arbor Michigan, U.S.A.

The hæmorrhages themselves vary from tiny spots easily mistaken for a flea bite to the large bruised areas seen in very old, thin people with senile purpura, in whom there may be dramatically severe bruising after minor injuries. In some forms of purpura, like the allergic anomaly of Henoch-Schönlein purpura, the distribution may be prominently on the extensor surfaces (fig. 927).

In doubtful cases the fragility of cutaneous capillaries may be rendered apparent by:

The Tourniquet Test.—The cuff of a sphygmomanometer is applied to the upper arm, and inflated to just below the systolic blood pressure for ten minutes, thus causing venous congestion. Within five minutes petechial hæmorrhages occur in the skin both under and distal to the constricting agent.

Purpura is of two varieties:

1. **Primary.**—Idiopathic Thrombocytopenic purpura—acute or chronic.

2. **Secondary Purpura.**—(*a*) Thrombocytopenic—secondary to certain infections such as acute septicæmias, tuberculosis and brucellosis; to Boeck's sarcoid (p. 187); as an idiosyncrasy to certain drugs, particularly arsenicals, quinine, alkylating agents and gold salts; to X-ray therapy; to extensive burns; to aplastic anæmia, leukæmia or carcinomatosis of bone; and possibly to food allergy.

(*b*) Symptomatic—as in Senile purpura, Henoch-Schönlein purpura and Ehlers-Danlos disease of the skin.

IDIOPATHIC THROMBOCYTOPÆNIC[1] PURPURA

This is a relatively frequent hæmatological disorder that manifests itself by hæmorrhages of all grades of severity. At one end of the scale there is merely a tendency to bruise easily; at the other the disease is fulminating in its onset, and disastrous in its consequences. It occurs in an acute and a chronic form. The former is a disease chiefly of children; it is self-limiting and affects both sexes equally. The latter chiefly affects females.

Ætio-pathology.—The number of platelets falls to fewer than 60,000 per mm^3 ($60 \times 10^9/l$) of blood.[2] There is increased capillary fragility, increased bleeding time, normal clotting and prothrombin time, and a non-retractile clot—a most significant finding.

Clinical Features.—Its various manifestations are as follows:

1. Ecchymoses (fig. 927) or purpuric patches in the skin and mucous membrane. There is a tendency for these lesions to appear in the more dependent areas, because of the higher intravascular pressure.

2. Sustained bleeding from wounds, which in themselves are often trivial.

3. Bleeding, frequently serious, from mucous membranes, epistaxis, bleeding from the gums and, in women during the period of reproductive life, menorrhagia, are of frequent occurrence. Urinary and gastro-intestinal hæmorrhages are less common.

---

[1] Thrombocytopænia = poverty of thrombocytes (blood-platelets).

[2] The normal blood-platelet count is 250,000 to 400,000 per mm^3 (250 to 400 $\times$ $10^9/l$).

Eduard Heinrich Henoch, 1820–1910. Physician, Berlin.
Johannes Lucas Schönlein, 1793–1864. Physician, Berlin.
Eduard Lauritz Ehlers, 1863–1937. German Dermatologist.
Henri Alexandre Danlos, 1844–1912. Dermatologist, Paris.

4. Intracranial hæmorrhage occurs rarely, and not until other sites of hæmorrhage have given ample warning of the existence of thrombocytopænic purpura. Nevertheless, intracranial hæmorrhage is the most frequent cause of death in idiopathic thrombocytopænic purpura occurring in adults. This tragic complication can be averted by timely splenectomy.

5. Hæmarthrosis is rare (cf. Hæmophilia, p. 76).

Cerebral Purpura.—Usually the onset is sudden, often with pyrexia. The leading features are thrombocytopænia with cutaneous hæmorrhages and neurological lesions attributable to involvement of cortical cerebral vessels. As a rule the patient lingers for a few weeks; in a few instances partial or complete recovery has occurred.

On Examination.—Except for cutaneous ecchymoses or a positive tourniquet test, physical examination is usually unrevealing. In only a quarter of the cases is the spleen palpable, and in these it extends but little below the costal margin. Pronounced splenic enlargement makes the diagnosis of thrombocytopænic purpura highly improbable.

Sternal Puncture.—The bone marrow shows megalokaryocytosis[1] with absent platelet budding.

The behaviour of the disease in adults is dissimilar from that in children.

In Children.—After one acute episode consisting of cutaneous purpura, often accompanied by epistaxis and bleeding from the oral mucous membrane, the disease undergoes a spontaneous cure in 75% of cases.

In Adults.—Although the initial attack is seldom as severe as in children, the disease tends to become cyclic, and often the relapses are of increasing severity, uterine or gastro-intestinal hæmorrhages being much in evidence. This difference has an important bearing on treatment.

Treatment:

In Children.—As intracranial hæmorrhage is exceptional, and for reasons given above, a conservative policy can be followed and, if necessary, continued for three months. No active treatment is given if the symptoms are mild, but should the bleeding be severe or persistent, in addition to maintaining a safe hæmoglobin level, a course of ACTH or cortisone often effectively controls the hæmorrhagic manifestations. Such a course lasts two or three weeks. Splenectomy is advised in (1) severe cases; (2) when relapses occur; (3) especially in girls approaching the menarche. At least two days' steroid therapy should be given prior to operation. The results of splenectomy are usually satisfactory, in spite of the fact that after an initial rise, the low platelet count persists. If, after splenectomy, relapses occur, an overlooked accessory spleen should be suspected.

In Adults.—Steroid therapy, if necessary combined with blood transfusion, should be employed in preparation for splenectomy.

Blood transfusion improves the hæmostatic state for a few hours without necessarily increasing the platelet count. The volume of any one transfusion

[1] Megalokaryocytes (*syn.* megakaryocytes), the giant cells of bone marrow, give origin to blood-platelets.

should not exceed 1 litre, because massive and rapid transfusions often aggravate the thrombocytopænia and the bleeding tendency. For the same reasons repeated transfusions are also contraindicated. Fresh blood is essential. Anything older than 6 hours is virtually useless.

Cortisone Therapy.—Unless the patient has already lost much blood, cortisone therapy frequently controls the hæmorrhage and renders blood transfusion unnecessary. Its mode of action appears to be that of making the capillaries less permeable, it also results in a reduction of the time of clot retraction, but without a change in the platelet count.

Initially 300 mg. of cortisone is given by mouth in divided doses during the first twenty-four hours, 200 mg. during the second twenty-four hours and 100 to 150 mg. daily thereafter for two or three weeks. In preparing the patient for operation the dose of cortisone is decreased in the immediate five days prior to the operation, substituting an equivalent amount of ACTH. No cortisone is given two days preoperatively, but it is given immediately post-operatively, and continued for about a week in decreasing doses.

Splenectomy.—In slightly more than half the cases the bleeding tendency is controlled by the above measures, the operation can be converted from an emergency procedure to one of election which, being unhurried, permits a thorough search for accessory spleens.

In the remainder, operation must be undertaken with as little delay as possible. Following incision into and through the parieties there is profuse and sometimes frightening bleeding. This must be ignored until the splenic artery is reached and clamped. After waiting for twenty minutes or more, clotting will proceed more or less normally and the operation can be completed.

Splenectomy in primary thrombocytopænic purpura is followed by good results in over 60% of cases, in spite of little change in the platelet count after an initial rise lasting about a week.

Treatment of Secondary Purpura.—Obviously, if the cause is known and can be removed, considerable faith can be placed in conservative measures. Cortisone and ACTH are effective in producing a remission in most instances. Up to a few years ago it was thought that splenectomy was contraindicated in secondary purpura, but a number of cases of cure by splenectomy have been reported. Particularly encouraging have been cases where the purpura is due to splenic tuberculosis and in rare examples of Boeck's sarcoid. If the bleeding is so profuse or prolonged as to tax the resources of the blood bank, splenectomy should not be delayed (Lowdon). In most instances, however, with steroid therapy it is safe to wait for a remission. Half of the cases are benefited by splenectomy.

MEDITERRANEAN ANÆMIA (*syn.* COOLEY'S ANÆMIA; THALASSÆMIA[1])

Cooley's anæmia is a hereditary disease due to faulty synthesis of hæmoglobin.

Originally thought to be confined to those who dwelt near the Mediterranean Sea, or who had a Mediterranean heritage, it is now known that this is only partially true, for scattered reports from various parts of the world show that the disease occurs from time to time in families who have no such heritage; for instance, a number of cases

[1] Thalassæmia = Greek, Thalassa — Sea. (Because it occurs in persons of Mediterranean stock.)

Andrew Gilchrist Ross Lowdon, 1911–1965. Professor of Surgery, Newcastle-upon-Tyne, England.
Thomas Benton Cooley, 1871–1945. Professor of Pædiatrics, Wayne University, Detroit, U.S.A.

have been reported in natives of Thailand. The condition is inherited. In a severely affected infant both parents show characteristic blood changes. While the mild form is asymptomatic and can be detected only by an examination of blood, severe forms should be suspected by the following characteristics:

Clinical Features.—The patient is of short stature and the facies are reminiscent of a congenital syphilitic; the skull is large and bossed, and the bridge of the nose is depressed (fig. 43, p. 43). In addition the maxillæ are prominent, also the upper front teeth. There is a mongoloid slant of the eyes. The complexion is muddy; the scleræ have an icteric tinge. Especially in a young child, the abdomen is prominent because of an enlarged spleen and liver. In patients with moderate anæmia these signs are correspondingly less, and in mild cases all are absent.

Blood Examination.—Increased resistance of red cells to hæmolysis in hypotonic saline solution is *the* characteristic finding. It is always present in Mediterranean anæmia, irrespective of the severity or mildness of the disease. In the more severe forms, not only is there a diminished number of erythrocytes and a low hæmoglobin level, but nucleated red cells and other immature blood cells abound.

Radiography of the skeleton shows early rarefaction of all bones and sclerosis of tubular bones.

Treatment.—In selected cases splenectomy reduces the number of transfusions required.

PORPHYRIA, WITH SPECIAL REFERENCE TO THE ABDOMINAL CRISES OF THE DISEASE

Porphyria is an hereditary error of katabolism of hæmoglobin in which porphyrinuria occurs. The abdominal crises, which are characterised by violent intestinal colic with constipation, are liable to be precipitated by the administration of barbiturates, to which these patients have an idiosyncrasy. The patient is anæmic, frequently suffers from photosensitivity, and in advanced stages of the disease neurological or mental symptoms (from damage to the brain) are often present.[1] On examination the spleen will be found to be enlarged. On a number of occasions the splenic enlargement, which is usually well marked, has been overlooked and *the abdomen has been opened on the diagnosis of intestinal or appendicular colic*, with negative findings. Another manifestation of acute porphyria is spasmodic abdominal pain followed by jaundice. This may be due to spasm of Oddi's sphincter.

Two methods of establishing the diagnosis are available:

The urine is sometimes normal in colour. Usually it is orange (which is often dismissed as ' concentrated '). If the specimen is left exposed to daylight for a few hours it develops a port-wine colour, particularly near the surface, where it is exposed to the air. There are several conclusive laboratory tests for porphyrinuria.

Radiography of the abdomen. Serial X-ray films show areas of intestinal spasm causing short segments of gaseous dilatation of the small and large intestine, especially of the cæcum.

Treatment.—Often there is a striking decrease in the serum sodium level and the patient is improved considerably by infusion of normal saline solution with careful control of electrolytic balance. To relieve the abdominal pain methadone is the best drug. If a sedative is required, one of the phenothiazines (e.g. chlorpromazine) should be given. Splenectomy is not of value except in the uncommon erythropoietic type with splenomegaly.

ENDEMIC HEPATO-SPLENOMEGALY (*syn.* EGYPTIAN SPLENOMEGALY)

Although especially common among the fellaheen (peasants) who dwell in the delta of the Nile, this disease is by no means confined to Egypt. It is prevalent in many parts of Africa, and is met with in Asia and South America, particularly Venezuela.

Ætiology.—The consensus of opinion is that in 75% of cases the disease is due to infestation by the *Schistosoma mansoni*, and the remainder by

[1] King George III is believed to have suffered from this malady (a Royal malady).

Ruggery Oddi 1845–1906. Physiologist, Perugia, Italy.
Sir Patrick Manson, 1844–1922. Practised in Formosa and Hong Kong. Later Physician, Dreadnought Hospital, Greenwich, London. He is regarded as the ' Father of Tropical Medicine '.

Schistosoma hæmatobium. In some parts of the world chronic malaria appears to be the cause, e.g. Bengal Splenomegaly (Basu).

Pathology.—A diffuse periportal fibrosis of the liver (fig. 928) is the first manifestation. Bilharzia ova in various stages of degeneration can be found in the portal vein and its tributaries. Next, enlargement of the spleen occurs, due, it is believed, (1) to bilharzial toxins and the products of disintegrated worms and ova, all of which are filtered by the spleen, causing active hyperæmia and hyperplasia of its reticulo-

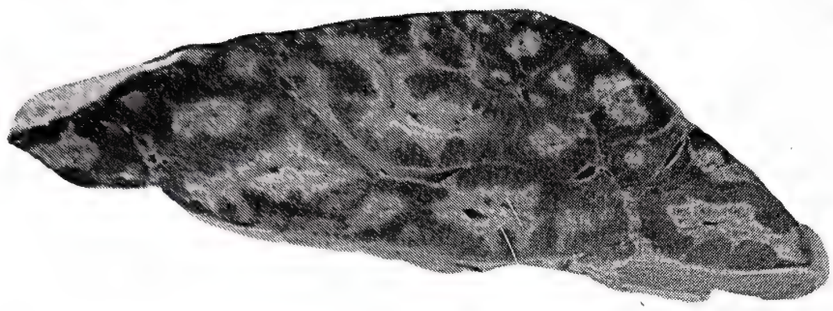

FIG. 928.—Periportal fibrosis of the liver in Egyptian splenomegaly. (*Dr. Halawani, Cairo.*)

endothelial elements. (2) to the portal hypertension caused by the hepatic fibrosis. The splenic capsule becomes thickened, due to perisplenitis, and the splenic vessels are often tortuous and sclerotic. Diminished splenic contractility causes stagnation of blood in the spleen, and results in its further enlargement. About this time the enlarged liver commences to contract, and the degree of enlargement of the spleen is roughly proportional to the degree of fibrosis of the liver (Halawani). Advanced cases are accompanied by ascites.

Clinical Features.—Egyptian splenomegaly is encountered at all ages from ten to seventy years, frequently reaching its zenith in the fourth decade. Ninety per cent. of the patients are males.

1st Stage.—There is gradual enlargement of the spleen, hypochromic anæmia, eosinophilia, leucopenia and a relative lymphocytosis. The liver becomes moderately enlarged and is tender in 70% of cases. During this stage there is little or no disturbance of general health.

2nd Stage.—The spleen becomes further enlarged, extending to the pelvic brim (fig. 929). The liver gradually shrinks. The major symptoms at this time are:

Splenic pain or 'heaviness'	90%
Weakness	78%
Spasmodic abdominal pain	75%
Diarrhœa (often blood-stained	60%
Hæmaturia	38%
Hæmatemesis	4%

The patient suffers from lassitude and may fall a victim to intercurrent infection.

FIG. 929.—Egyptian splenomegaly. Splenectomy was successful. (*Owen Richards, F.R.C.S.*)

3rd Stage.—The liver atrophies more and more. Ascites supervenes. The superficial abdominal veins sometimes become dilated and tortuous. The general health deteriorates, and usually the patient dies in six to twelve months from the appearance of ascites. As a rule it takes eight to twelve years to pass from the first to the final stage.

Ajit Kumar Basu, Contemporary. Director-Professor, Department of Surgery, Institute of Post-Graduate Medical Education and Research, Calcutta, India.
Theodor Maximilian Bilharz, 1825–1862. Professor of Zoology, Cairo.
Ahmed Halawani, Contemporary. Director of the Institute of Tropical Medicine, Cairo.

Laboratory Findings

The urine and the fæces are examined for ova.

Liver function tests reveal a varying degree of hepatic impairment. A hypochronic anæmia is always present.

Treatment.—Many early cases respond to the general treatment of bilharzia mansoni detailed in p. 1074. In more established cases no substantial reduction in the size of the spleen results from a six-weeks' course of this treatment. It is in the latter class that, after careful pre-operative preparation, splenectomy with pre- and post-operative blood transfusions is undertaken under penicillin cover, and is often curative. The consensus of opinion in Egypt is that splenectomy should be performed in cases where there is no evidence of ascites, liver damage or severe renal insufficiency. Following splenectomy, over 70% of the patients are able to return to full work. When ascites has supervened, portacaval or splenorenal anastomosis (p. 873) is the only form of treatment that can slow the course of the disease.

FELTY'S SYNDROME

A moderate number of patients with chronic rheumatoid arthritis develop mild leucopænia; in a few of these the leucopænia becomes extreme and usually is associated with enlargement of the spleen. This combination is referred to as Felty's syndrome. A remarkable characteristic of this syndrome is that the leukopænia and splenic enlargement are apparently unrelated to the severity of the arthritic changes; indeed, in some instances the arthritis has commenced to improve or has become quiescent by the time the low white-cell count and the splenomegaly become unmistakable. In those cases in which the arthritis is slight but the splenic enlargement and the blood changes are much in evidence, a diagnosis of primary splenic neutropænia is sometimes made.

Clinical Features.—Sufferers from Felty's syndrome are very prone to pyogenic infections of all varieties, infected ulcers around the ankles being particularly frequent. They are fatigued easily, lean, and unable to gain weight. It is impossible to say whether these symptoms should be attributed to the arthritic process or to the leukopænia and splenomegaly. As a rule the degree of splenic enlargement is not great. Enlargement of lymph nodes and generalised brown pigmentation of the skin are sometimes present.

Blood Examination.—The white-cell count shows persistent leucopænia varying between 1,000 and 2,000 per mm^3 ($1{\cdot}0–2{\cdot}0 \times 10^9/l$) with less than 20% of neutrophils. The greatest reduction is in the granulocytes. Neutrophils range from slightly below normal to virtually absent. There is almost always an associated anæmia of moderate severity. Achlorhydria is often present.

Sternal Puncture.—The bone marrow shows increased cellularity but a deficiency of mature granulocytes.

Treatment.—The results of splenectomy are variable. Usually there is an improvement in the blood picture with increased neutrophils, but this improvement is not maintained. However, the liability to infections seems to be decreased in many cases and rheumatoid arthritis that had become resistant to cortisone therapy reacts favourably to steroid therapy once more.

OCCLUSION OF THE SPLENIC VEIN

The splenic vein is most often found to be obliterated in young children, probably following umbilical sepsis in the neonatal period and here the portal vein may also be affected giving rise to portal hypertension. In such cases splenectomy with lieno-renal or lieno-caval anastomosis may be indicated. Where portal hypertension does not exist splenectomy will suffice. In adults the vein may become blocked by local infection or by neoplastic infiltration as in carcinoma of the body or tail of the pancreas. Here, again, splenectomy may be worth while if the neoplasm is deemed to be removable.

Augustus Roi Felty, 1895–1964. Physician, Hartford Hospital, Hartford, Connecticut, U.S.A.

GAUCHER'S DISEASE

As mentioned on p. 830, the spleen may take an active part in the storage of abnormal lipoids, as does the remainder of the reticulo-endothelial system. In the case of Gaucher's disease the lipoid in question is a cerebroside, kerasin. Gaucher's disease, which is rare, is characterised by enormous enlargement of the spleen, which may weigh 8 or 9 lb (3·6 or 4·1 kg.). In the majority of cases the splenic enlargement begins in early childhood, often before the age of twelve, although the patient rarely seeks advice before adult life. Until the splenic enlargement becomes massive the symptoms are few. There is anæmia, a yellowish-brown discoloration of the skin of the hands and face due to a deposit of hæmosiderin, and a curious conjunctival thickening that helps to clinch the clinical diagnosis. Slavonic and Jewish races appear to be more prone to this disease than the rest of humanity. The diagnosis is confirmed by finding Gaucher's cells in the bone marrow (fig. 930).

Treatment.—Splenectomy rids the patient of a large abdominal swelling, but the operation is difficult because of perisplenitis and friability of the splenic pulp. It does not greatly influence the course of the disease but because it reduces the hypersplenism (anæmia, leucopenia and thrombopenia) and makes the patient more comfortable it is worth doing.

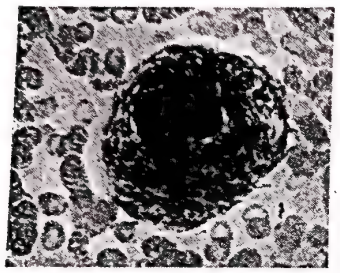

FIG. 930. — Typical Gaucher's cell from bone marrow obtained by sternal puncture. (*Dr. M. L. Thomson, Manchester.*)

LEUKÆMIA

This is of surgical importance in the differential diagnosis of enlarged lymph nodes and splenic enlargement. The diagnosis is made by an examination of the blood. The main treatment (and this is palliative) is deep X-ray therapy and chemotherapy. In the past, splenectomy was tried for this condition, and was found to be useless. In myeloid leukæmia both the liver and the spleen are greatly enlarged.

TUBERCULOSIS OF THE SPLEEN

Tuberculosis of the spleen is not so uncommon as is sometimes believed. It occurs chiefly in adults between twenty and forty years of age. When a patient has splenomegaly with asthenia, loss of weight and an evening temperature, it is well to bear in mind the possibility of the enlargement of the spleen being due to tuberculosis. Too often these signs lead to the erroneous diagnosis of leukæmia or some other disorder for which splenectomy is not indicated. Occasionally tuberculosis of the spleen produces portal hypertension. Another form is cold abscess, which is very rare. Splenic puncture, followed by culture, or guinea-pig inoculation, will yield positive results. A therapeutic test with P.A.S. and streptomycin usually brings about some improvement, and there is less danger of dissemination of tubercle bacilli if splenectomy is undertaken. The operation, which usually is rendered difficult because of adhesions, is contraindicated only if other active tuberculous lesions are present. Otherwise the results of splenectomy in tuberculosis of the spleen are excellent (Patel).

ABSCESS OF THE SPLEEN

If a splenic embolus is infected, and the primary condition does not prove fatal, a splenic abscess may be expected to follow. Other sources of metastatic abscesses of the spleen are typhoid and paratyphoid fever, osteomyelitis, otitis media and puerperal sepsis. An abscess in the upper pole of the spleen may rupture and form a left subdiaphragmatic abscess. If the abscess is in the lower pole, rupture results in diffuse peritonitis. Primary splenic abscess of uncertain origin, containing foul gas and chocolate-coloured pus, occurs rather frequently in Africans in Rhodesia.

Treatment.—As a rule, owing to dense adhesions, drainage of the abscess is the only course. Very rarely, splenectomy may be possible with the abscess *in situ*.

NEOPLASMS

New-growths of the spleen are strikingly uncommon. Of the benign tumours, cavernous hæmangiomas and lymphangiomas have been encountered. Of the malignant, a few examples of primary fibrosarcoma have been described. Lym-

Philippe Charles Ernest Gaucher, 1854–1918. Physician, Hospital St. Louis, Paris.
Jean Patel, Contemporary. Professor of Clinical Surgery, Paris, France.

phosarcoma is somewhat more common. Metastases of carcinoma in the spleen are rare. The primary tumour is usually of lung or breast or melanoma. If it is conceded that Hodgkin's disease is a neoplasm, then this is the commonest cause of neoplastic enlargement; indeed, it is sometimes the leading sign of Hodgkin's disease. In primary neoplasms the treatment is splenectomy.

HYPERSPLENISM

Various conditions involving the spleen, e.g. Hodgkin's disease, leukæmia, portal hypertension, may on occasion cause anæmia, neutropenia, thrombocytopænia or any combination of these. This is probably due to destruction of the relevant cells in the spleen and, if symptoms warrant it, splenectomy is indicated.

SPLENECTOMY

The common indications for splenectomy in this country are trauma, either following an accident or at operation (e.g. gastrectomy), thrombocytopenic purpura, acholuric jaundice, or preparatory to spleno-renal anastomosis.

Other indications for splenectomy are tabulated on pp. 835 and 836.

Technique of Splenectomy.—Most surgeons use a left paramedian or left subcostal incision. For large spleens adherent to the diaphragm a thoraco-abdominal incision may be necessary. Before operation, however, the passage of a naso-gastric tube enables the stomach to be emptied. This facilitates the operation and prevents the post-operative complications of dilatation of the stomach and paralytic ileus.

If the operation is for *traumatic rupture*, a quick mobilisation is necessary. The hand is passed round the outer surface of the spleen, the posterior layer of lieno-renal ligament (fig. 931) divided largely by blunt dissection, and the spleen rotated medially

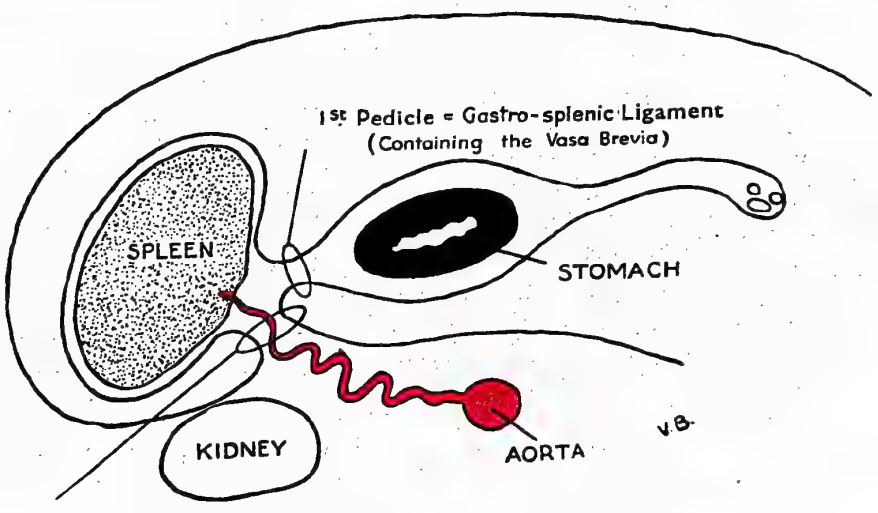

FIG. 931. — From the surgical standpoint the spleen may be said to have two pedicles—the gastro-splenic ligament and the lieno-renal ligament. The splenic artery and vein lie in the latter.

into the incision. A large pack is inserted and the short gastric vessels and those in the pedicle are ligated and divided. It is important to separate the tail of the pancreas from the vessels in the hilum before ligation.

For *hypersplenism and other conditions* requiring splenectomy.—The first step is to open the gastro-splenic ligament and divide the short gastric vessels (fig. 931). The splenic vessels at the superior border of the pancreas are under-run with silk and ligated. The posterior surface of the spleen is exposed, the posterior leaf of the lieno-renal ligament divided by long curved scissors, and the spleen rotated medially, together with the tail and body of the pancreas. The pancreas is separated from the hilum and the vessels dissected out, ligated, and divided. Careful search must be made for accessory spleens. It is wise to drain the wound in case damage to the pancreatic tail has occurred.

Unexplained abdominal pain and fever in the post-operative period may herald thrombosis of the portal vein, when anticoagulants and antibiotics must be given.

CHAPTER 43

THE LIVER

Surgical Anatomy and Physiology.—The dual afferent blood supply, consisting of the hepatic artery and the portal vein, singles out the liver from all other organs. That the portal vein has no valves is basic to the understanding of portal hypertension. Both the portal and the hepatic veins have well-defined coats of unstriated muscle which together with the hepatic artery control the blood flow through the liver.

The blood in the sinusoids is derived from two sources:

1. The portal system conveys between 60 and 80 per cent. of the afferent blood to the liver, together with the products of digestion from the alimentary canal and the internal secretions, insulin and glucagon, from the pancreas. No less than one-fifth of the portal blood comes from the spleen.

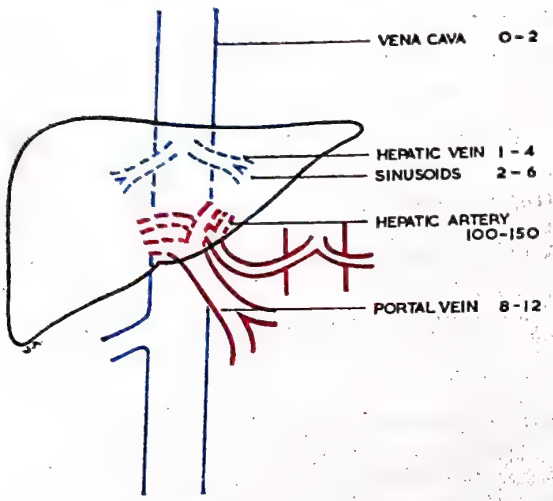

FIG. 932.—Pressure (in mmHg) in various components of the hepatic circulation.

2. The hepatic artery transmits oxygen to the liver and, by a delicate pressure arrangement with the portal venules determines the blood flow through the liver lobules. The pressure relationships of the hepatic artery, the portal vein and the hepatic vein testify further as to the unique nature of the circulation through the liver (fig. 932). During exercise the blood flow through the liver, normally about 40 per cent. of the cardiac output, falls sharply in favour of the heart, brain and muscles.

Surgical Lobes of the Liver:

The right and left branches of the hepatic artery do not supply the two main anatomical lobes as such. Their territory has a boundary running along the gall-bladder bed and thence upwards over the anterior surface to the inferior vena cava, down this vessel to return to the porta hepatis. The biliary ducts and branches of the portal vein follow the hepatic arterial branches. In this way the liver is divided into two surgical lobes, right and left, by a major avascular fissure. The blood from the liver is drained by three major hepatic veins, the middle one of which is located in the major fissure. Knowledge of the anatomy of the surgical lobes is particularly important in planning hepatic resections for injury or tumours.

Functions of the Liver:

1. The secretion of bile.
2. The formation of albumin, fibrinogen, and prothrombin.
3. Storage and metabolism of carbohydrates, including the conversion of monosaccharides (e.g. dextrose) into glycogen, and vice versa.
4. Formation of phospholipids and cholesterol, synthesis of fatty acids from carbohydrate, and other steps in fat metabolism.
5. Deamination of amino-acids with formation of urea. Removal of ammonia from portal blood.
6. Heat production.
7. Reticulo-endothelial activities.
8. Storage of vitamin B12 (cyanocobalamin) and vitamin A.
9. Iron and copper storage.
10. Destruction of bacteria. Bacteria, especially Gram-positive cocci, have been found repeatedly in samples of portal blood taken at laparotomy for non-infected conditions. It is therefore believed that the liver destroys many bacteria that gain entrance to the body through the portal tributaries.

Hans Christian Joachim Gram, 1853–1938. Professor of Medicine, Copenhagen.

11. Detoxication of drugs and hormones, e.g. short-acting barbiturates; œstrogens.

Unlike other organs, the liver possesses a remarkable ability to replace lost tissue rapidly and completely by compensatory cellular hypertrophy and hyperplasia. This permits wide resection for a localised hepatic neoplasm, and removal of large portions of doubtfully viable liver tissue in cases of severe trauma.

HEPATOCELLULAR FAILURE

Hepatocellular failure can complicate almost all forms of liver disease and may be precipitated by intercurrent infection, a surgical operation, administration of a general anæsthetic, bleeding or even narcotics.

Clinical Features.—The most marked features are weakness and general failure in health. Jaundice is usually present. The hyperdynamic circulation is manifested by flushed extremities and bounding pulse. The patient may be cyanosed. Fever is common and septicæmia is found terminally. Fœtor hepaticus, a sweetish, musty odour, is frequently noticeable. Spider angiomas are found in the vascular territory of the superior vena cava. Appearance of fresh crops of spiders suggest progressive liver disease and their disappearance accompanies improving hepatic function. Palmar erythema (liver palms) affects mainly the thenar and hypothenar eminencies.

Other skin changes include loss of axillary and pubic hair, and white nails. In the male, gynæcomastia and testicular atrophy may be found in chronic hepatic failure of the cirrhotic.

In acute hepatocellular failure, personality changes occur early proceeding to delirium, nightmares and unco-operative behaviour.

Treatment.—Precipitating factors must be looked for and treated. Gastrointestinal hæmorrhage may require blood transfusion; an acute infection may be dealt with by antibiotics. Electrolyte abnormalities, especially hypokalæmia, should be corrected.

If the patient can eat, a high carbohydrate diet should be given. Nutrition and fluid intake have to be maintained in the unconscious patient by the use of a nasogastric tube or intravenous infusion. Diuretics, morphine and paraldehyde should be avoided because they may precipitate or potentiate coma.

In acute failure with coma, very skilled and intensive treatment is required. Hypoglycæmia and electrolyte abnormalities will require particular attention. For renal failure with hypokalæmia, peritoneal- or hæmodialysis should be performed. Bleeding due to abnormalities in clotting mechanisms and infection will require skilled hæmatological and bacteriological treatment.

For patients whose condition is not responding, but who are thought to have potentially reversible failure, temporary hepatic support should be considered. These measures include exchange blood transfusion, cross circulation between donor and patient, extracorporeal perfusion of patient's blood through a pig's liver and, recently, perfusion of patient's blood through columns of activated charcoal. The results of these various treatments are uncontrolled and their long-term benefit remains doubtful.

PORTA-SYSTEMIC ENCEPHALOPATHY

This syndrome occurs when much blood is by-passing the liver, as in cirrhosis or if a porta-systemic venous shunt has been created (p. 872). Toxic products of bacterial degradation of nitrogenous material within the bowel are normally absorbed and are removed by the liver. In chronic liver disease—and also because of direct access to the systemic circulation via collateral vessels, surgical shunts or intra-hepatic communications—these toxic products may reach the brain where they exert a deleterious effect. Ammonia is probably one of the toxic products responsible for hepatic encephalopathy but methionine and short-chain fatty acids have also been incriminated. These products are normally metabolised in the liver, and the syndrome rarely occurs unless the liver function is impaired. It thus tends to be precipitated by a large protein meal or an upper gastro-intestinal hæmorrhage. Other precipitating factors include potassium depletion, frequently accompanying drug-induced diuresis, uræmia and narcotics. In individual patients it is often difficult to determine to what extent the symptoms are due to this cause or to liver-cell damage. In patients who have had symptoms for some years, organic changes have been found in the cerebral cortex or in the spinal cord.

Clinical Features.—It is characterised by disorientation and a flapping tremor of the outstretched hands. Cogwheel rigidity of the limbs may be elicited, and the patient may pass rapidly into deep coma. Intellectual deterioration and changes in personality, slurring of speech, can be observed frequently. On the electroencephalogram there is marked slowing of the frequency down to the delta range. Sometimes he may recover equally rapidly when the source of the toxic products is removed from the alimentary canal.

Treatment.—Measures to reduce the amount of nitrogenous material in the bowel, its breakdown by bacteria and its absorbtion are effective, viz:

1. Restriction of dietary protein.
2. Removal of blood from bowel by purgatives and enemas.
3. Administration of antibiotics orally or rectally, especially non-absorbed antibiotics such as neomycin.
4. Oral lactulose (a disaccharide), whose mode of action is still unclear.
5. Colectomy, or colonic bypass, which can reduce the contact of nitrogenous residue with colonic bacteria. The value of these operations is, however, still unestablished.

Other measures include the avoidance of sedatives and the correction of electrolyte deficiencies.

SPECIAL METHODS OF INVESTIGATING THE LIVER

Liver Function Tests.—Owing to its manifold functions, there is no single test by which the liver can be stated to be functioning normally. Therefore several tests are usually undertaken in each patient, and in some instances the individual test must be repeated. No less than 80 per cent. of the liver can be out of action without affecting individual tests, and in

patients with cirrhosis they may all be within normal limits. Among a large number of tests available the following are the most useful:

1. **Serum Bilirubin Estimation.**—A value of conjugated bilirubin exceeding 7 μmol/l (0·4 mg/100 ml) is one of the most valuable indices of either stasis within the biliary tree or hepato-cellular damage, but it is of no value in distinguishing the one from the other.

2. **Serum alkaline phosphatase** (normal value 3 to 13 King–Armstrong (K–A) or 1·5–4 Bodansky units). Values below 30 K–A favour hepatogenous jaundice; those above 30, obstructive jaundice.

3. **Estimation of serum albumin** is a good general test of liver function, as it is the only site of production. A level below 20 g/l (2·0 g/100 ml) indicates that liver function is greatly impaired and, if an operation is essential, only the minimum should be done. Above 30 g/l (3·0 g/100 ml) is satisfactory.

4. **Serum Transaminases (aminotransferases).**—These are enzymes present in liver cells and heart muscle. Increased values (over 100 units) are found in hepatocellular disease but only in prolonged obstructive jaundice when liver damage occurs.

5. **Plasma prothrombin index,** if *low*, is an indication for pre-operative vitamin K therapy. Where there is little or no response to vitamin K, extensive hepatocellular damage is almost certain. Owing to large reserves a satisfactory response does not exclude considerable liver damage.

6. **Bromsulphalein Test.**—The dye bromsulphalein (B.S.P.) is rapidly removed by the liver and excreted in the bile. In the absence of jaundice, it is a sensitive test of derangement of hepatic function. After an intravenous injection of 5 mg/kg of the dye, not more than 5% of it should be present in the serum at the end of 45 minutes.

7. **Scanning of Radioactive Isotopes.**—A gamma emitting isotope such as ^{198}colloidal gold and ^{69}Technetium^{m} is taken up by the reticulo-endothelial system and can be useful in localising lesions in the liver. Rose-bengal labelled with ^{131}I is taken up by the liver parenchyma but unfortunately its concentration in the gall-bladder interferes with delineation of the liver edge.

The normal liver presents an even distribution of activity and lesions which do not take up isotopes, e.g. abscesses, cysts and tumours, appear as defects in the scan. Also extrinsic lesions such as subphrenic abscesses can also be detected. Lesions greater than 2 cm can be detected readily, but false positive scans are a problem.

Generalised decrease in uptake suggests a diffuse hepatocellular disorder such as cirrhosis.

Liver biopsy has a limited field of usefulness. It should never be attempted until the presence or absence of a bleeding tendency on the part of the patient has been ascertained by all accepted tests, and if present, remedied. The puncture is carried out on the right side or in the epigastrium. The Menghini needle (fig. 933) is the best. Sections are cut from the cylindrical specimen obtained. Hæmorrhage or biliary peritonitis are complications. Liver biopsy is of particular value in generalised liver disease, e.g. cirrhosis, reticulosis and hepatitis. Local disease such as tumours, focal granulomas, etc., may be missed. A combination of peritoneoscopy with needle liver biopsy enables a tissue sample to be taken directly from a focal abnormality.

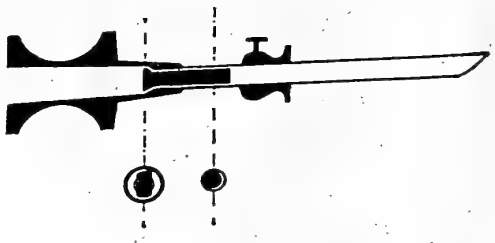

FIG. 933.—Menghini 'one-second' liver biopsy needle. The nail in the cannula allows fluid to pass but prevents the biopsy specimen from being fragmented by violent aspiration into the syringe. (*From* Gastroenterology.)

Angiography by means of cœliac axis or superior mesenteric arteriograms is occasionally valuable in detecting changes in the vascularity of the liver, either due to vascular obstruction or to an avascular lesion such as a cyst or abscess, or to a vascular tumour. In cases of portal hypertension films in the venous phase of superior mesenteric angiography are useful if the spleen has been removed and splenic injection is thus impossible.

Arthur Riley Armstrong, Contemporary. Director of Department of Laboratories, Hamilton Health Association, Hamilton, Ontario, Canada.
Aaron Bodansky, 1887–1961. Biochemist, Hospital for Joint Diseases, New York City, U.S.A.
Georgio Menghini, Contemporary. Physician, Perugia, Italy.

Ultrasonic scanning.—With improved technique, ultrasonic scanning is becoming recognised as a valuable, non-invasive method of diagnosing hepatic enlargements and intra-hepatic masses. It is of especial value in diagnosing fluid-filled lesions, e.g. hydatid cysts, subphrenic abscesses, etc. **EMI computer X-ray scanning** is becoming valuable (page 408).

INJURIES

Rupture of the liver, is an extremely grave accident, and in a considerable proportion of cases it is associated with other serious injuries. Consequently the mortality is high. The violence that produces this injury is usually of a crushing type or from the steering wheel of a car in collision. Rupture of the right lobe is much more common than of the left, because it is larger and less mobile; usually the tear is on the anterior or the superior surface of the organ. Often a rib, or ribs, on the right side are fractured.

Most of the problems of injury of the liver are caused by hæmorrhage, leakage of bile and devitalisation of liver tissue. Hæmorrhage may be free into the peritoneal cavity and the patient presents with the clinical picture of massive intra-abdominal hæmorrhage, perhaps indistinguishable from rupture of the spleen but suggested by localising signs of pain, tenderness and rigidity in the right upper quadrant of the abdomen. Bleeding within the liver may form a large hæmatoma, which may later become infected to form an abscess, or it can rupture into the bile duct giving rise to hæmobilia. Biliary leakage can lead to biliary peritonitis with subsequent abscess or cyst formation. Infarction of liver tissue due to occlusion of blood supply can be complicated by an abscess within the liver or immediately above or below that organ.

Treatment.—In the first three types a blood transfusion is of cardinal importance, and in all cases laparotomy must be undertaken.

Operation.—The abdomen is opened through a right paramedian incision with the patient in a position so that the incision may be extended into the right thorax, an extension which may be required when major hepatic lobectomy is essential. Bleeding vessels in the wall and depths of fissures and tears should be ligated, but it is important that all pulped liver and portions of doubtful viability should be removed. Failure to debride non-viable liver tissue favours infection and secondary hæmorrhage.

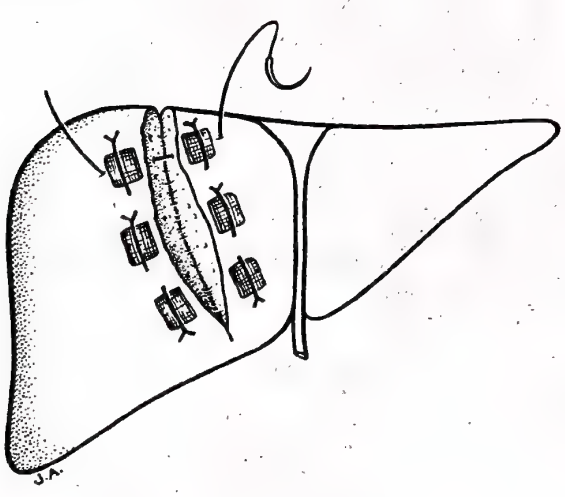

FIG. 934. — Repair of liver tear. Mattress sutures parallel to the tear are then under-run with coapting stitches.

Simple tears may be opposed by inserting sutures parallel to the wound, and then coapting stitches are placed so that they under-run the mattress sutures (fig. 934).

Packing should be avoided because of the danger of infection. With extensive hæmatoma formation and rupture of liver tissue, a major hepatic resection may be required, frequently a right hepatic lobectomy, i.e. removal of the right anatomical lobe and medial segment of left lobe, along with quadrate and caudate lobes. Following such major operations the abdominal cavity must be drained because leakage of bile occurs from torn ducts. It is still a matter of discussion whether the bile ducts should be drained after resection. Following operations such as hepatic resections, complications such as abscess formation, hæmobilia,

hypoalbuminæmia and coagulation defects may occur. The mortality for hepatic injury is about 10%.

Penetrating Wounds of the liver occur as a result of gunshot injuries (page 11) and stab wounds. When, as is commonly the case, the wound of entrance is in the right lower thorax, the thoraco-abdominal approach, excising the wound of entrance, is advisable. In some cases the wound of the liver is comparatively small, and no serious bleeding occurs; but in all cases, laparotomy must be performed to exclude damage to other organs. If the wound is a large one, the principles of arresting hæmorrhage given above are employed.

ENLARGEMENTS OF THE LIVER

- *General enlargement*
  - With jaundice
    - Regular
      - Virus hepatitis.
      - Cholangitis.[1]
      - Pylephlebitis.[1]
      - Carcinoma of head of pancreas.
      - Carcinoma of the common bile duct.
    - Irregular
      - Hepatic cirrhosis.
      - Late secondary tumours.
  - Without jaundice
    - Regular
      - Hepatic cirrhosis.
      - Budd–Chiari's syndrome (p. 863).
      - Failing heart.
      - Leukæmia.
      - Rickets.
      - Amyloid.
    - Irregular
      - Secondary tumours.
      - Gummas.
- *Localised swelling*
  - Riedel's lobe.
  - Hydatid cyst.
  - Amœbic abscess.[1]
  - Hepatoma.
- *Massive irregular enlargement*
  - Polycystic disease.
  - Cholangio-hepato-adenoma.
  - Secondary tumours.

VIRUS HEPATITIS

Two types of disease are described. 'Virus A' hepatitis is used for short-incubation disease, formerly called 'Infective Hepatitis'; 'Virus B' hepatitis is used for long-incubation disease, hitherto called 'Serum Hepatitis'. Our knowledge of the latter type of disease has been advanced by the discovery of hepatitis B (Australia) antigen.[2]

Virus A hepatitis occurs in sporadic and epidemic forms. The virus (type A) is excreted in the fæces and this is probably the method of spread. It is the commonest form of jaundice in children and young adults, and there is no evidence that one attack confers immunity. The incubation period is from three to five weeks.

The condition commences with anorexia, nausea and perhaps vomiting, with malaise and fever, and jaundice appears after about three days. The liver may be palpable and tender, and occasionally there is transient ascites. The fever subsides shortly after the jaundice appears. Usually the jaundice disappears after two or three weeks, but it may persist very much longer. In such cases, the diagnosis from extrahepatic biliary obstruction may be difficult, and liver function tests may not give a clear distinction.

[1] Intermittent pyrexia, sometimes rigors, occur.

[2] So-called, because it was discovered in an Australian Aboriginal.

Bernhard Riedel, 1846–1916. Professor of Surgery, Jeno, Germany.

Sometimes infective hepatitis is followed months or years later by portal cirrhosis, but the factors which cause this are unknown, as most patients recover completely. However, a few develop acute or subacute hepatic necrosis which accounts for the mortality of 3%.

Immune serum globulin is effective in preventing or modifying Type A virus hepatitis and is usually given to household contacts who have not already had the disease. Antibiotics are of no value. Steroids may be given to those with prolonged cholestasis to lower the serum bilirubin. It is regarded as important that the patient should avoid alcohol or strenuous exercise for some months after all symptoms and signs have subsided. A small proportion of patients have recurrent attacks of mild symptoms persisting for a year or more.

Virus B hepatitis.—This may follow blood transfusion, plasma infusion, and, rarely, the administration of sera, and resembles infective hepatitis except that the incubation period is about twelve weeks. Transmission by plasma has been reduced by avoiding the pooling of plasma from a large number of donors. Transmission by syringes is prevented if all syringes are disposable or are sterilised freshly for each patient.

Hepatitis B antigen (HBAg) is found in 80% of sera of those who develop Virus B hepatitis. Under electron microscopy, particles can be seen in the sera of these patients and are associated with the virus. These particles are antigenic. Such patients usually suffer the severest form of hepatitis. The antigen is the scourge of renal dialysis and transplantation units.

CHOLANGITIS (*syn.* INTERMITTENT HEPATIC FEVER OF CHARCOT)

By cholangitis is meant a state of inflammation of the bile ducts, but it is the radicles of the biliary tree within the liver that are the main site of the infection. Cholangitis can occur as the result of obstruction of the common bile duct by a gall-stone (p. 898) or a stricture, or in mucoviscidosis (p. 910). Suppurative cholangitis (p. 900), like pylephlebitis, may be followed by the formation of multiple liver abscesses. There is often septicæmia with a positive blood culture for *E. coli* and other intestinal organisms. Gram-negative shock may develop.

PYLEPHLEBITIS (*syn.* PORTAL PYÆMIA)

Pathology.—Pylephlebitis can follow a suppurative disease in any part drained by the portal system, but usually arises as a complication of appendicitis or diverticulitis. The process commences as a thrombophlebitis of a small vein draining the infected lesion. The thrombus spreads to a larger collecting vessel, and pieces of infected thrombus break off and are swept into the liver, where they lodge and form abscesses. Abscesses so formed are usually small and multiple, in which case they are connected together, forming a 'canal and cavity' system (Turnbull). Cultures show a mixed infection in which *Esch. coli* is prominently represented. In rare instances there is localisation of the infection.

Clinical Features.—Pylephlebitis is characterised by a hectic temperature and the occurrence of repeated rigors. In relevant cases the rigors serve to differentiate the condition from a sub-diaphragmatic abscess, but do not entirely exclude it. If tested for, urobilinogen will be found in the urine in every case. Diarrhœa is a frequent accompaniment. Moderate ascites is sometimes present. The patient soon becomes slightly jaundiced,

Jean-Martin Charcot, 1825–1893. Physician La Salpêtrière, Paris.
Hubert Maitland Turnbull, 1875–1955. Professor of Pathology, The London Hospital.

the liver is somewhat enlarged and tender and the serum bilirubin is raised.

Blood culture is positive in 50% of cases if blood is withdrawn during or immediately after a rigor. Sensitivity tests must be done on the organism so that the correct antibiotic can be given.

Prophylaxis.—The most important means of preventing pylephlebitis is to administer a broad spectrum antibiotic in cases of fulminating appendicitis or diverticulitis.

Treatment.—As the organisms responsible are mixed, initial chemotherapy should include broad-spectrum antibiotics such as amoxycillin and gentamycin administered parenterally. If bacteroides are identified, clindamycin or metronidazole should be given. Cloxacillin should be administered if staphylococci are identified. Blood transfusion is often required. If, in a protracted case, it is considered that there is a sizeable abscess within the liver, laparotomy should be performed with a view to draining the abscess.

Prognosis.—When pylephlebitis is fully established the outlook was formerly almost hopeless, but with the use of antibiotics many cases recover. Extrahepatic portal venous obstruction is likely to develop later.

IDIOPATHIC PYOGENIC LIVER ABSCESS

Acute abscesses are usually multiple and may be associated with biliary or abdominal disease, but often, especially in elderly patients suffering from malnutrition, no cause can be found. The clinical features and treatment are similar to those described for pylephlebitis (see above).

Chronic abscesses usually are single and occur mainly in elderly females. The onset is often insidious, or even silent (cryptogenic abscess). A cause for the infection may be found in the biliary passage or intestinal tract, but in half the cases no source can be discovered. The patient presents with pyrexia, abdominal discomfort, an enlarged liver, and, in advanced cases, hepatic coma. Leucocytosis is absent, but the serum albumin level rapidly falls, while the level of Vitamin B12 rises (Butler). Hepatic scintiscanning and ultrasonic scanning have proved most helpful not only in permitting earlier diagnosis of fluid-filled hepatic masses but also in aiding the localisation of the abscess before exploration and drainage.

The condition is fatal unless, after excluding an amœbic abscess, the abscess is drained, when the mortality is reduced to 30%. Laparotomy is performed, and the abscess is discovered by aspiration. Dependent drainage is effected, after loculi have been broken down by digital manipulation. Examination of the pus will indicate a suitable antibiotic.

In most instances the cause of a liver abscess is apparent, or can be ascertained, infection reaching the liver in one of several ways, viz:

CAUSES OF ABSCESSES OF THE LIVER

Via the Portal Vein

- Suppurative appendicitis.
- Diverticulitis.
- Amœbiasis.
- Infected carcinoma of the colon (especially after resection).
- Ulcerative colitis (rare).
- Actinomycosis of the right iliac fossa.
- Inflamed hæmorrhoids (rare).
- Typhoid and paratyphoid (rare).

Thomas Joseph Butler. Formerly Surgeon, Frenchay and Cossham Hospitals, Bristol, England.

Along the Bile Ducts ← Stone impacted in common bile duct. / Stricture of common bile duct.

Via the Hepatic Artery ← Septicæmia and pyæmia. / Facio-cervical actinomycosis. / Infection of a hydatid cyst.

From the Umbilicus ← Along the umbilical vein of the new-born. / Along the para-umbilical veins.

By Direct Extension ← From a subdiaphragmatic abscess. / From an empyema thoracis (rare). / From a penetrating wound.

AMOEBIC LIVER ABSCESS (*syn.* TROPICAL ABSCESS, DYSENTERIC ABSCESS)

Amœbic abscess of the liver is one of the terminations of amœbic hepatitis, which in turn is a complication of amœbic dysentery—not so very uncommon.

Pathology.—*Entamœbæ histolyticæ* (fig. 935) pass from a focal lesion in the colonic wall into a radicle of the inferior mesenteric vein and via the portal vein they enter the liver to take up residence there, usually in the upper and posterior portion of the right lobe. In the liver the entamœbæ colonise and live at the expense of the liver cells, causing localised liquefaction necrosis. The amount of liver destruction is proportional to the size of the colony, the resistance of the host and the extent of secondary infection. In 70% of cases, the abscess is solitary; in 30% more than one abscess is present. Characteristic pus from an amœbic liver abscess is chocolate-coloured, or like anchovy sauce, and consists of broken-down liver cells, leucocytes, and red blood cells; nevertheless, in an appreciable number of instances the pus is green, from being admixed with bile. In about half the cases the pus contains staphylococci, streptococci, and *Esch. coli*, as well as *E. histolytica*. In the remainder the pus is sterile, but except in long-standing cases, motile entamœbæ can be demonstrated in the last few drops of pus to be withdrawn, or from a scraping of the abscess wall at operation. Commonly perihepatitis causes the liver to become fixed to the diaphragm or the abdominal wall.

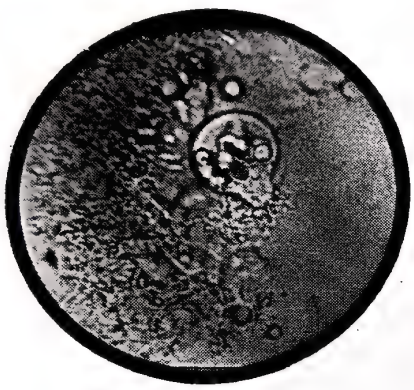

FIG. 935.—Entamœba histolytica.

Course.—An amœbic abscess of the liver runs a variable course:

1. In early stages of amœbic hepatitis with abscess threatening, resolution may occur under emetine treatment, but some authorities doubt whether there is really a stage of hepatitis without abscess formation; it is more probable that treatment results in cure of a small abscess or abscesses (Milroy Paul).

2. When an abscess forms the liver enlarges, most often in an upward direction. It is at this stage that surgical intervention is called for.

3. It may become encapsulated and remain dormant for long periods.

4. Unrecognised and untreated, it may burst into (*a*) the right lung, (*b*)

Milroy Paul, Contemporary. Formerly Professor of Surgery, University of Ceylon.

the peritoneal cavity, (*c*) the right pleural cavity, in that order, or, more rarely, into a hollow viscus (fig. 936). Exceptionally the abscess points subcutaneously. Erosion into the lung and the expectoration of a quantity of chocolate-coloured sputum sometimes results in a natural cure.

Bacterial infection is a rather frequent and serious complication of amœbic abscess. While a solitary amœbic abscess is usually amenable to combined specific drug and surgical treatment, the prognosis in cases of multiple amœbic liver abscesses is extremely poor.

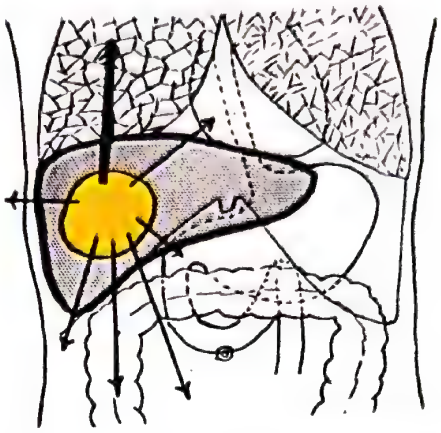

FIG. 936.—Directions in which a tropical liver abscess may burst. (*After Sir Zachary Cope, F.R.C.S.*)

Clinical Features.—As a rule, the condition develops soon after an attack of amœbic dysentery while the patient is resident in a tropical or sub-tropical country. Less frequently its appearance is delayed, sometimes for many months; exceptionally it has occurred more than thirty years after returning home from the tropics. Occasionally an amœbic abscess develops in a carrier who has not had overt dysentery; indeed, it sometimes appears in persons who have had mild diarrhœa not diagnosed as dysentery, and consequently have not had treatment for that condition. There is a striking predominance in young males.

Early Symptoms.—Anæmia, loss of weight, and an earthy complexion are often the first symptoms.

Pyrexia rising to 38°C. or more, at night, with profuse sweating, is usually present. Rigors occur, especially in the early stages.

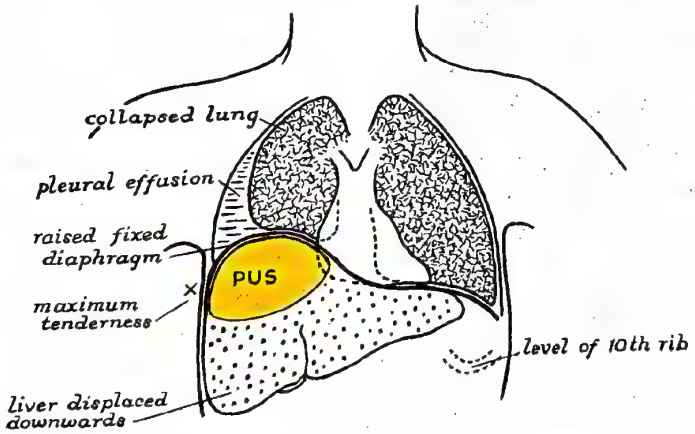

FIG. 937.—The physical signs of a tropical liver abscess (commonest site). (*After A. T. Andreasen.*)

Pain is constantly present in the liver area, and is occasionally referred to the right shoulder. Jarring increases the pain so that the patient learns to try to support his enlarged liver with his hands when he walks.

Tenderness and *rigidity* in acute cases are comparable to that of acute cholecystitis. In chronic cases tenderness may be absent.

Enlargement of the liver may be demonstrated (fig. 937), but it is not unusual for an abscess to be present in a liver which is fixed by perihepatitis, and therefore the liver cannot enlarge in a downward direction.

Scanning of the liver, using Rose Bengal, Indium, Technetium, radioactive

colloid gold, or by employing *ultra-sound* techniques, may help to localise the abscess.

Basal lung signs on the corresponding side.

Leucocytosis is present in nearly all cases. Polymorphonuclear cells constitute, at the most, only 75% of the total count. Anæmia, if present at all, is not marked.

Examination of warm stools for amœbæ should be undertaken, but their absence does not exclude the diagnosis.

Sigmoidoscopy sometimes reveals the characteristic ulcers (p. 974).

Radiography (antero-posterior and lateral positions) often reveals an elevation and fixation of the right cupola of the diaphragm.

Often an absolute diagnosis is possible only on finding typical pus by exploratory aspiration.

Occasionally an amœbic liver abscess does not give rise to symptoms; healed lesions have been found at necropsy and calcified lesions (that may have been abscesses) have been revealed radiologically.

Serological Tests.—The indirect hæmagglutination test, which is sensitive and reliable, is positive in most affected patients.

Treatment.—The treatment of choice is metronidazole (Flagyl) 800 mg three times daily for 7–10 days. Failures are few and side effects much less than with the more toxic emetine and chloroquine.

Aspiration.—Small abscesses respond without aspiration. Needle aspiration should be used if there is a lack of response to five days of metronidazole treatment. A secondarily infected abscess should be treated similarly in the first instance; indeed, such infection can be discovered only by bacteriological examination of the pus.

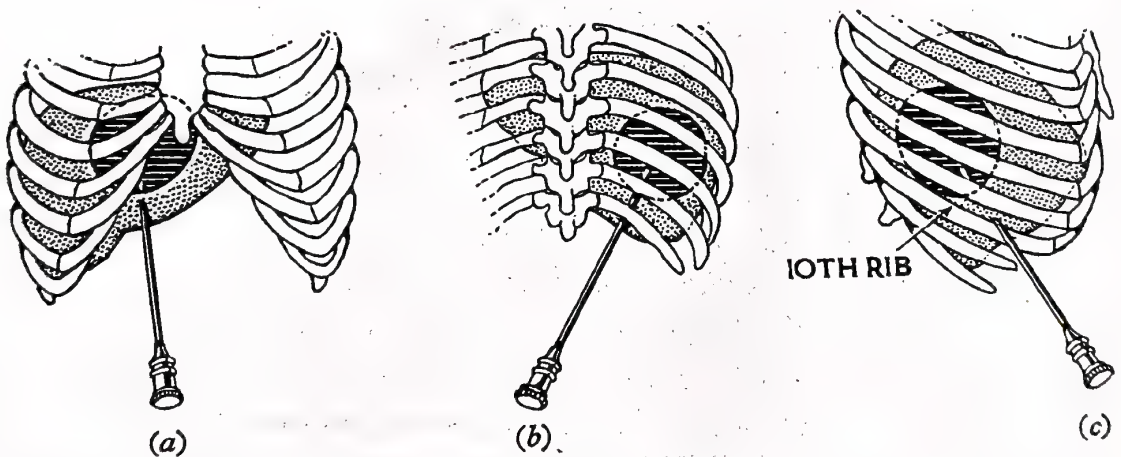

FIG. 938.—Aspiration of an amœbic hepatic abscess: (*a*) in the anterior part of the liver; (*b*) in the posterior part of the liver; (*c*) located near the dome of the diaphragm.

Technique.—Aspiration must be conducted in the operating theatre. A long needle is necessary, and its bore should be wide (1–2 mm), as the pus is usually thick in consistency. The important technique of percutaneous introduction of the hollow needle (under local anæsthesia) into the abscess cavity in various locations is shown in fig. 938. In some cases the abscess eludes the aspirating needle, in which event laparotomy must be performed, thus allowing the liver to be explored by the aspirating needle more thoroughly. At the same time laparotomy permits the exclusion of a primary carcinoma of the liver which, in coloured races, sometimes closely resembles an amœbic liver abscess in its onset and physical signs, and at times is even accompanied by a low pyrexia. When the abdomen is open, packs, impregnated with

a solution of erythromycin 1:1000, are so arranged as to isolate the liver. On aspiration the abscess is thoroughly emptied by syringe suction. The incision is closed completely and on no account should a drainage tube be employed. Its use leads to invasion of its track by amœbæ and in some cases a fatal spreading infection of the abdominal wall Amœbiasis cutis (fig. 939).

After Treatment.—A full course of specific drug therapy should be given after aspiration.

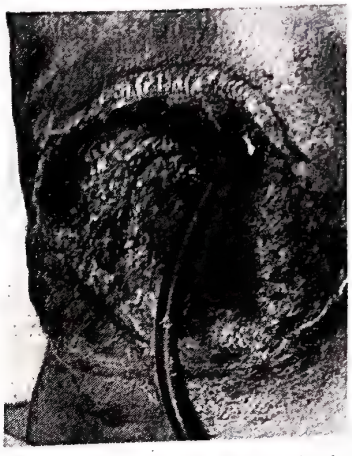

FIG. 939. —Amœbiasis cutis following drainage of a ruptured amœbic abscess. *(Prof. R. Milnes Walker, Bristol.)*

ACTINOMYCOSIS OF THE LIVER

Actinomycosis (p. 33) is due to the fungus *Actinomyces israeli*, and produces the well-known 'honeycomb' liver. Actinomyces reach the organ in one of the following ways:

1. Via the portal vein from actinomycosis of the right iliac fossa (60 per cent).
2. Via the hepatic artery from a more distant primary focus, e.g. facio-cervical actinomycosis—about 30 per cent.
3. From contiguous viscera, e.g. a penetrating peptic ulcer invading the liver—rare.

The disease is slow to develop, and causes swelling of one or other lobe. Gradually the liver tissue is destroyed and replaced by multiple abscesses.

Treatment.—Exploration is essential, and in every case of liver abscess of doubtful origin the pus should be examined for actinomyces. Long-acting penicillin in large doses, or other more suitable antibiotic therapy (p. 16) must be continued for some months. Usually by the time the liver is involved the prognosis is grave, but not hopeless.

TUBERCULOSIS OF THE LIVER

In 50 per cent. of necropsies upon patients who have died from tuberculosis, miliary tubercles are present in the liver. Local tuberculosis of the liver is usually diagnosed at necropsy, but occasionally at laparotomy. There is a large mass containing necrotic material. This lesion may be seen in children, and in negroes with little immunity. Less uncommon is a tuberculous abscess. The symptoms are identical with those of an amœbic abscess.

HEPATIC SYPHILIS

Syphilis, always an accomplished actor, can, and does, deceive the clinician. Gummas give rise to rounded masses in the liver. These swellings may simulate a liver abscess. Syphilis of the liver is now a rarity.

HYDATID DISEASE OF THE LIVER

Although the parasite *echinococcus granulosus* can thrive in many parts of the body, in 80 per cent. of cases it does so in the liver; after ingestion it enters this organ through a radicle of the portal vein, and usually the right lobe is affected.

Source of Infection.—Dogs are the chief mediators of hydatid disease to human beings by direct contact. Humans may also eat salads on which the ova have been deposited. Animals, particularly sheep, are infected by eating contaminated grass (fig. 940). Once in the stomach, the ova burrow through the stomach wall to enter the portal system and the liver. Dogs become infected by feeding on offal of infested sheep and, to a lesser extent, cattle. As would be expected, the disease is relatively common in the sheep-rearing districts of Australasia and South America, Greece, Turkey, Iran

and Iraq, while, for the same reason, in the British Isles, Wales shows the highest incidence.

In other parts of the world where the disease is common the life-cycle can be completed in other animals; thus pigs (not kept in styes) and occasionally horses can take

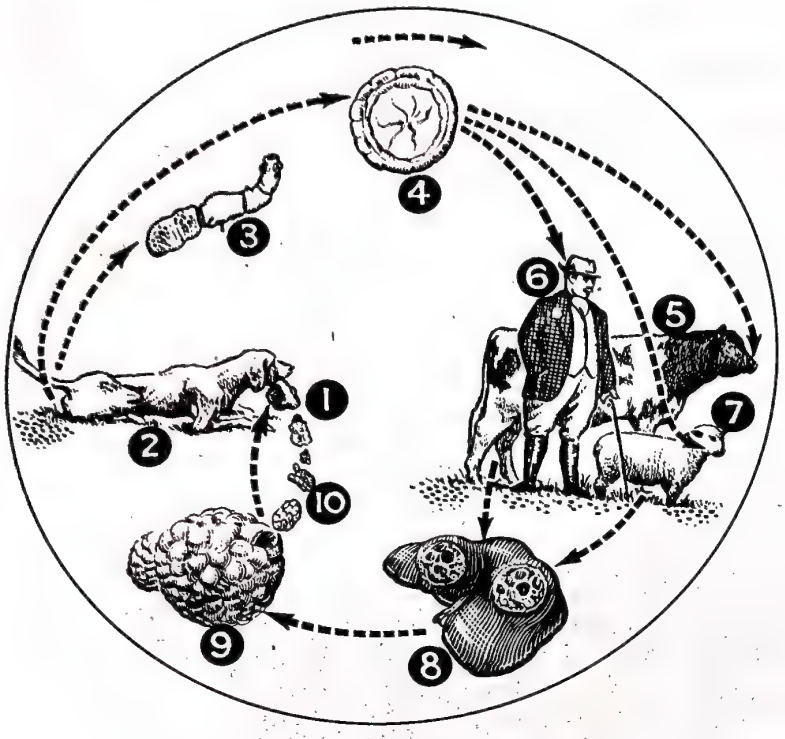

FIG. 940.—The life-cycle of the *echinococcus granulosus*. (1) Offal infected with hydatid cysts is eaten by a dog (2). The *echinococcus granulosus* (3) develops in the dog's intestine. This parasite is about 1 cm long and is made up of a head and three segments, the last of which contains about 500 ova (4). The ova are expelled from the dog's intestine on to grass, vegetables, etc. Cattle (5), human beings (6), or sheep (7) ingest the eggs. The liver (8) is the organ most frequently infested with hydatid cysts, a larval form of *echinococcus granulosus*. Such cysts (9) harbour thousands of heads of the parasite (scolices) (10).

(*After V. P. Fontana, Montevideo.*)

the place of sheep and cattle, while in the frozen North (the disease is common among Red Indians and Eskimo) the wolf → moose → wolf often maintain the cycle.

Pathology.—A hydatid cyst consists of three layers.

1. *The adventitia* (*pseudo-cyst*), consisting of fibrous tissue, the result of reaction of the liver to the parasite, is grey in colour and blended intimately with the liver, from which it is inseparable.

2. *The laminated membrane* (*ecto-cyst*) formed of the parasite itself is whitish and elastic, and contains the hydatid fluid. Indeed, this membrane closely resembles a child's uncoloured balloon filled with water, and unless bacterial infection has occurred it peels readily from the adventitia.

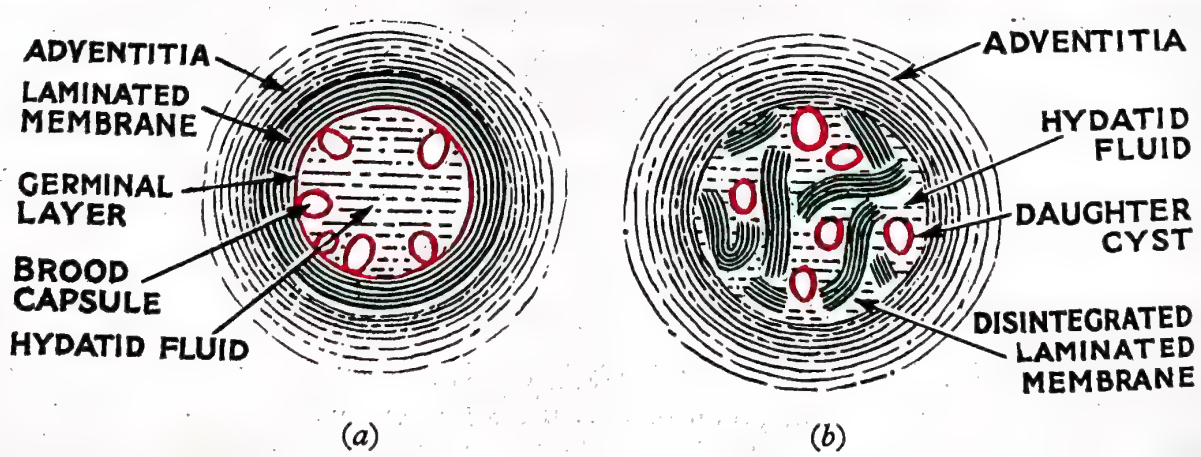

FIG. 941.—(*a*) Typical hydatid cyst.
(*b*) Development of daughter cysts (not common).

Hydatid fluid is crystal-clear; it registers a specific gravity of 1·005–1·009, contains no albumin, and when not too old, hooklets and scolices. The cyst grows very slowly.

3. The only living part of a hydatid cyst is a single layer of cells (germinal epithelium) lining the cyst (*endo-cyst*). This secretes: (*a*) internally: the hydatid fluid; (*b*) externally: the laminated membrane (fig. 941 (*a*)). Brood capsules within the cyst develop from the germinal epithelium and are attached by pedicles to its innermost wall. Within the brood capsules, scolices (heads of future worms) develop. Should the laminated membrane become damaged, it disintegrates (Dew), and the brood capsules, becoming free, grow into daughter cysts (fig. 941 (*b*)). In this event the mother cyst ceases to exist as such, the hydatid fluid and its content being confined by the adventitia only.

Clinical Features. — For a long time, perhaps for some years after the original infestation (which often occurs in childhood), a hydatid cyst remains symptomless (fig. 942). In the course of time a visible and palpable swelling in the upper abdomen is discovered. The size which a hydatid may attain without causing serious disturbance to health, would seem to be limited only by the capacity of the peritoneal cavity.

FIG. 942.—Multiple hydatid cysts in the liver. The patient, who had never left England, died after a street accident.

Naturally, when a patient hails from a locality where hydatid disease is rife, the diagnosis is simplified. In obscure cases radiography (figs. 943, 944 and 945) and immunological tests are of great diagnostic assistance.

The intradermal test (Casoni's test) is comparable to the tuberculin reaction, and is positive (fig. 946) in 75 per cent. of cases.

The complement fixation test, although more complicated, is of greater accuracy.

A blood-count often, but not invariably, shows an eosinophilia (6 per cent. or more).

Hepatic scintiscanning and ultrasonic scanning are invaluable in the diagnosis and localisation of the cyst and in following the course and effects of the surgical treatment.

Course of the Disease.—1. Occasionally the parasite dies. The fluid is absorbed, and all that remains is an encapsuled, laminated, bile-stained membrane. In cases of long standing the walls of the cyst may calcify (fig. 943).

2. Usually the cyst enlarges gradually, and becomes manifest by its size.

Sir Harold Dew, 1891–1962. Professor of Surgery, Sydney, Australia.
Tommaso Casoni, 1880–1933. Physician, Ospedale Coloniale, Vittorio Emanuele III, Tripoli.

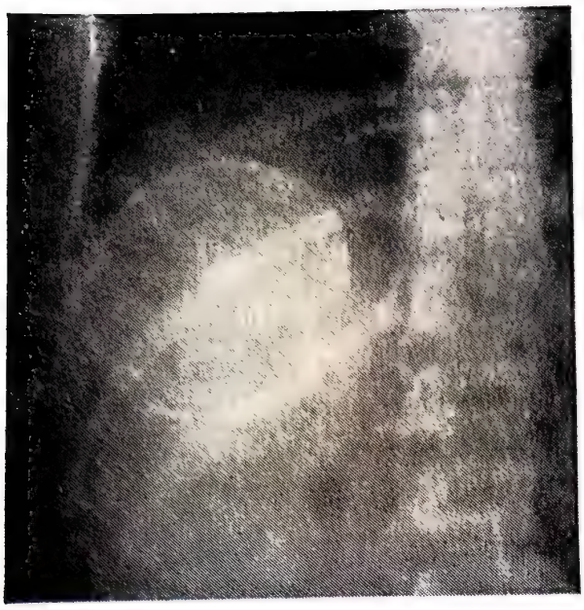

FIG. 943.—Calcification of hydatid cyst of the liver. (*H. Talib, F.R.C.S., Baghdad.*)

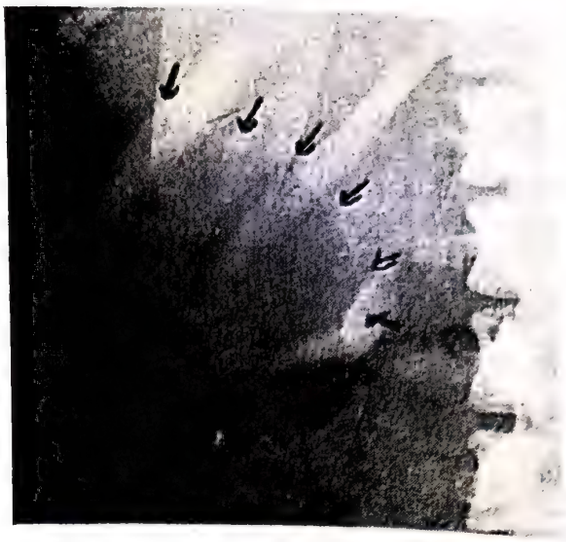

FIG. 944.—Cyst, outlined in the liver displacing the gall bladder (shown by cholecystogram). (*H. Talib, F.R.C.S., Baghdad.*)

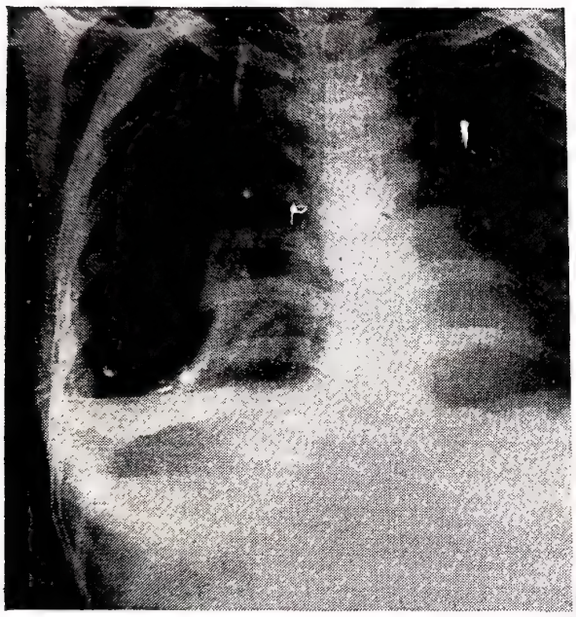

FIG. 945.—Biliary-pleural-bronchial fistula from hydatid cyst of the liver. See fluid levels in cyst and pleural cavity. (*H. Nassir Pur, Teheran.*)

FIG. 946.—Casoni's test. Positive reaction.

Sometimes sessile cysts float in the peritoneal cavity, or they may be confused with mesenteric, pancreatic or renal cysts (Talib).

3. Complications arise. ' It is the onset of complications that makes the morbidity not much inferior to that of malignant disease ' (Fortacin).

Complications

- Jaundice
  - due to pressure of cysts on the biliary ducts
  - due to cysts within the bile ducts
- Rupture
  - Into the peritoneal cavity
  - Into the alimentary canal
  - Into the biliary channels
  - Into a pleural cavity (fig. 945)
- Suppuration

H. Talib, Contemporary. Surgeon, Baghdad University Medical School, Iraq.
José Blanco y Fortacin, Contemporary. Formerly Professor of Surgery, Madrid, Spain.

Rupture into the peritoneum is accompanied by profound shock, and all the signs of diffuse peritonitis. As with any case of rupture of a hydatid cyst, anaphylactic phenomena, notably urticaria, are prone to occur. The treatment of intraperitoneal rupture must be immediate, and directed to combating shock and cleansing the peritoneal cavity. Even in those who survive, the ultimate prognosis is poor, for if, as is usual, the cyst contains brood capsules, however meticulous the cleansing, the disease tends to become disseminated within the peritoneum.

Treatment of Hydatid Cyst of the Liver

The only treatment is surgical, for there is no drug which has the slightest effect upon the course of the disease.

Operation.—The cyst is exposed by an incision that gives the best access. Abdominal packs are arranged meticulously so as to isolate that portion of the liver containing the cyst from the peritoneal cavity. A large black pack, wrung out in 2 per cent. formalin, is tucked around the exposed liver—*black* so that daughter cysts and scolices will show up against the background—*formalin* because this antiseptic kills the parasites. The cyst is aspirated, and a suitable quantity of 10 per cent. formalin solution is injected so as to render the cyst about three-quarters full. An incision is made through the liver overlying the cyst, and the adventitia is opened. This brings the rubbery laminated membrane into view. Very gently the laminated membrane is grasped with sponge forceps and separated from the adventitia with a finger. The aim should be to separate the laminated membrane and deliver the cyst intact; usually this can be accomplished in cysts uncomplicated by the effects of past infection. In complicated cases it is sometimes necessary to remove the laminated membrane piecemeal. When the intact cyst can be enucleated, the resulting cavity in the liver can be closed completely. In less favourable circumstances it is advisable to drain the cavity, particularly when infection is present, when the contents of the cyst are bile stained, or when there is uncertainty of its complete removal. An attempt should be made to remove the adventitia in order to allow the cavity to collapse. Every precaution must be taken to prevent spilling the contents of the cyst into the peritoneal cavity or the layers of the abdominal wall, otherwise dissemination is likely.

NON-PARASITIC CYSTS OF THE LIVER

A solitary traumatic cyst usually follows abdominal trauma and the symptoms are delayed weeks or months after the injury. The clinical manifestations include abdominal pain, frequently referred to the shoulder, a lump that is usually palpable, and less frequently jaundice. In most instances the cyst is located in the right lobe and contains blood and bile. Drainage cures the condition.

A localised collection of cysts is probably the result of sequestration of bile ducts during fœtal life. If large, the mass may require excision.

Congenital polycystic disease of the liver is rare, and a third of the cases are associated with congenital polycystic kidneys. Slow, irregular enlargement of the whole liver in adult life is the only clinical feature. The patient may eventually succumb from renal or hepatic failure, or the effects of portal hypertension.

BUDD-CHIARI'S SYNDROME

This syndrome results from obstruction to the hepatic veins. Neoplastic encroachment from other organs accounts for the majority of cases. The syndrome is also associated with clotting diseases, especially polycythæmia and the use of hormones for contraception and infertility. Some cases, presumably congenital, are caused by an obstruction of the suprahepatic portion of the inferior vena cava with a membraneous web. The importance lies in its potential curability by operation.

An acute form of the disease is seen in Jamaica and may be caused by plant extracts such as Senecio and Crotalaria used in herbal tea.

Clinical Features.—*In acute cases*, nausea, vomiting and severe pain, due to rapid enlargement of the liver as a result of congestion, are often followed by death from hypotensive shock.

George Budd, 1808–1882. Professor of Medicine, King's College Hospital, London. He was probably the first to describe the Budd-Chiari syndrome.
Hans Chiari, 1851–1916. Professor of Pathological Anatomy, Prague.

A less sudden onset is characterised by rapidly accumulating ascites and signs of portal hypertension with a developing collateral circulation. Signs of hepatic insufficiency are usually pronounced, and early death and hepatic coma are the rule. The simultaneous development of œdema of the legs testifies to involvement of the inferior vena cava in the occlusive process.

Chronic cases closely resemble hepatic cirrhosis which, indeed, may develop. Liver function tests indicate severe hepatic parenchymal damage, and rarely does the patient survive more than a few months. A few patients who do not die from hepatic coma succumb to hæmorrhage from œsophageal varices, mesenteric infarction, or intercurrent infection. In short, the Budd-Chiari syndrome, when the occlusion is, or becomes, complete, must be looked upon as a harbinger of death.

Treatment.—In patients with membranous obstruction of the inferior vena cava, a transatrial meatotomy may be considered. In those in whom the portal vein and inferior vena cava are patent, a portacaval shunt should be tried for the relief of portal hypertension (but *not* an end-to-side shunt, fig. 960).

CIRRHOSIS OF THE LIVER

Hepatic cirrhosis is essentially a necrosis of the liver followed by fibrosis and regeneration of liver cells, and involving the whole organ.

Ætiology.—It is convenient to divide the ætiological factors into those occurring in infancy and childhood and those occurring in adult life. It will be understood that some of the factors appertaining in early life take years to manifest themselves as hepatic cirrhosis. Obstructive jaundice is a cause common to all ages.

Causes in Infants and Children:

1. *Atresia of the bile ducts.*—The commonest cause in infants is congenital atresia of the bile ducts (p. 884), irremediable by operative means. The jaundiced child soon shows signs of hepatomegaly, splenomegaly, ascites, and œsophageal varices. Most survive only a few months; a few up to three or more years.

2. *Nutritional.*—(*a*) Infantile cirrhosis in India occurs mainly in high-caste Hindu vegetarians. It often progresses rapidly to an early fatal termination. It is suggested that the condition is due to a susceptibility of protein-deficient children to massive necrosis of the liver during viral hepatitis. (*b*) Kwashiorkor in Africa is characterised by an enlarged liver and peripheral nutritional œdema. This disease is caused by protein malnutrition. Children are most commonly affected 6–18 months after weaning. Generalised œdema and skin disorders develop along with apathy and arrested growth. There is no great evidence that this disease proceeds to cirrhosis. (*c*) Galactosæmia, patients with this inborn error of metabolism who continue to take lactose invariably develop cirrhosis.

3. *Infective.*—A history of severe jaundice in early infancy is obtainable in a number of instances. Virus hepatitis is believed to play a part in the production of cirrhosis.

4. *Cardiac Cirrhosis.*—Chronic venous congestion of the liver due to tricuspid incompetence, constrictive pericarditis, or chronic congestive failure.

5. *Congenital Hepatic Fibrosis.*—An abnormality often associated with medullary sponge kidney. The liver shows a dense, fibrous band surrounding normal hepatic lobules. Portal hypertension is common. If hæmorrhage occurs, these patients are excellent candidates for shunt operations.

6. *Erythroblastosis Fœtalis.*—Isolated instances have occurred.

Causes in the Adult:

1. *Alcohol.*—Over-indulgence in alcoholic beverages is a leading cause. Nutritional deficiency is probably an accessory factor.

2. *Virus Hepatitis.*—The exact percentage of cases in which cirrhosis is an aftermath of virus hepatitis is debatable, and it varies in different localities.

3. *Chronic (Surgical) Biliary Obstruction*, leading to Secondary Biliary Cirrhosis.—This is to be distinguished from Primary Biliary Cirrhosis (Hanôt) an autoimmune disease of middle-aged women. In the latter the mitochondrial immunofluorescence test is positive (in 98%, Sherlock).

Sheila Patricia Violet Sherlock, Contemporary. Professor of Medicine, Royal Free Hospital, London.

4. *Infestation of the liver by schistosomiasis* undoubtedly is a principal cause of the condition in districts where schistosomiasis is rife (p. 1074).

5. *Nutritional Deficiency*.—In the tropics this appears to be a major factor. Its mode of action is as follows: some toxic agents and mild infections, harmless to the well-nourished, are liable to have a deleterious effect on the liver of protein-deficient individuals. Therefore protein deficiency is indirectly responsible for the cirrhosis.

6. *Hæmochromatosis* (Bronzed Diabetes).

7. *Hepato-lenticular degeneration* (p. 867).

8. *Chemical poisons:* carbon tetrachloride, arsenic, chloroform.

9. *Unknown*.—In many instances the cause is obscure. These account for half the cases seen in Great Britain (Sherlock).

Morphological Types

Three anatomical types are recognised:

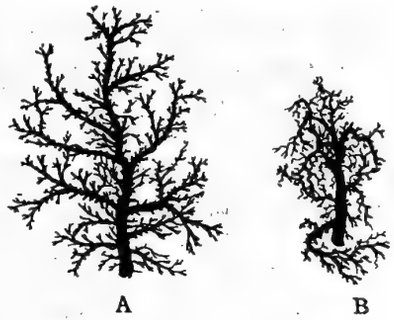
(*a*) *micronodular* is characterised by irregular thick bands of fibrous tissue and by small regenerating nodules. It is often associated with alcoholism.

(*b*) *macronodular* is characterised by bands of fibrous tissue of varying thickness and nodules of variable size. This type is also called postnecrotic.

(*c*) *mixed*—liver shows both micro- and macronodular features.

Pathology.—As a result of widespread parenchymal destruction and overgrowth of fibrous tissue, the tiny radicles of the portal and hepatic veins become compressed and distorted (fig. 947). In some cases there may be spasm of the portal veins. Arterioles resist this compression for a longer time than veins. As a consequence the cirrhotic liver becomes dependent upon the hepatic artery for the major portion of its blood supply, and in the desperate effort to maintain the circulation through the liver in these adverse circumstances, extensive intrahepatic communications develop between branches of the hepatic artery and the portal vein, and between the tributaries of the portal and hepatic veins.

Nature's intrahepatic shunts, combined with the opening up of the better-known extrahepatic porta-systemic communications, divert a large portion of the portal blood past the hepatic parenchyma into the systemic venous system. Thus the remaining hepatic cells are deprived of their fair share of portal blood.



A B

FIG. 947.—A, Cast of branches of a normal portal venule; B, Those of the branches of a portal venule of a cirrhotic liver, showing their attenuation and distortion. (*After I. S. Ravdin.*)

FIG. 948.—Portal cirrhosis.

Usually there is a fine fibrosis producing slight nodularity (Laënnec's cirrhosis[1] or hob-nail liver) (fig. 948), but coarse lobulation may result from larger regeneration nodules (fig. 949).

Clinical Features:

The early stages of cirrhosis may be quiet and long. The liver hypertrophies. In some cases there are repeated attacks of slight jaundice with epigastric pain and vomiting. At each attack areas of the liver are destroyed and replaced by fibrous tissue, while the remainder hypertrophies.

[1] Laënnec introduced the term from the Greek χιρρός = tawny, as the nodules are orange-yellow in colour.

René Théophile Hyacinthe Laënnec, 1781–1826. Professor of Medicine, College de France, invented the stethoscope in 1819.

Cirrhosis results in two major events—hepatocellular failure and portal hypertension. Later the liver commences to shrink. The spleen becomes enlarged, and usually increases in size with the raised portal blood pressure of which hepatic cirrhosis is the principal cause in adults. Functioning liver tissue is gradually destroyed and hepatocellular failure develops. About this time, especially in alcoholic subjects, two classical signs may appear: *Spider nævi*[1], which are usually located around the face, neck, shoulders and the upper arms. Histologically they prove to be an overgrown end-artery with branching arterioles (fig. 950). *Palmar erythema*—the hands are warm, and the palms are bright red.

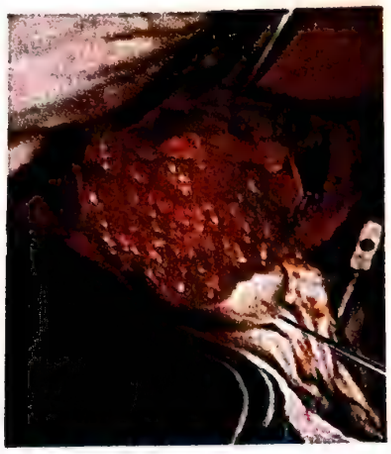


FIG. 949.—Portal cirrhosis with large regeneration nodules. (*Prof. R. Milnes Walker, F.R.C.S., Bristol.*)

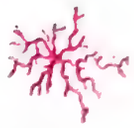

FIG. 950.—Spider nævus.

Bleeding from œsophageal varices (p. 868) occurs in a high proportion of cases, and may be the first evidence of the disease. Not infrequently the superficial veins radiating from the umbilicus enlarge, forming a Caput Medusæ. Progressive ascites occurs (fig. 951). Testicular atrophy and gynæcomasia are common in cirrhosis, no doubt due to increase of œstrogens in the blood. The failing liver is unable to neutralise these substances. In women there is a tendency to masculinisation. Dupuytren's contractures may develop.

Once hepatic decompensation has occurred (if the patient escapes death

FIG. 951.—Caput Medusæ, and striæ in cirrhosis with ascites.

Medusa, one of three Gorgons whose fine hair was turned into snakes (Greek mythology).

from torrential hæmorrhage from œsophageal varices), liver failure (p. 849), like a sword of Damocles, sooner or later falls upon the sufferer from this disease.

Clinical Pathological Associations.—Cirrhosis, whatever its type, has certain clinical and pathological associations including splenomegaly, pancreatitis (especially in the alcoholic), gastrointestinal bleeding from varices, peptic ulcer or gastric erosions, primary liver cancer and liability to infections.

Liver Function Tests (p. 850).—In compensated cirrhosis, tests may be normal, the most frequent abnormality being impairment of B.S.P. clearance. In decompensated disease, urobilinogen is usually present in the urine in excess and the plasma albumin is depressed.

Liver biopsy (p. 851) is usually necessary only for the diagnosis of a well-compensated case in order to confirm the diagnosis and assess prognosis.

Treatment.—There is no specific remedy for established cirrhosis, but the following measures may be helpful: (*a*) increased glucose intake; (*b*) alcohol forbidden; (*c*) high protein diet if there is no evidence of liver failure; (*d*) Steroids should only be given in active chronic hepatitis.

Hepato-lenticular degeneration (*syn.* Wilson's disease) is an uncommon condition that is confined to children and young adults due to an hereditary error in copper metabolism. In infants the symptoms are those of cirrhosis. In adolescents a coarse tremor is commonly an initial symptom. As the disease progresses, muscular rigidity dominates the picture. Kayser-Fleischer rings in the eyes due to peripheral corneal opacity are present. Liver function tests give varying results. Liver biopsy shows cirrhosis. Treatment is by penicillamine, which may have to be given for several years.

PORTAL HYPERTENSION

Ætiology.—Increase of the portal venous blood pressure is due to an obstruction which can be (1) Pre-hepatic; (2) Intra-hepatic; (3) Post-hepatic.

1. **Pre-hepatic.**—About 20 per cent. of patients belong to this group, most of whom are children. The obstruction arises in one of two ways:

(*a*) *There is congenital absence or abnormality of the portal vein.*

(*b*) *Thrombosis of the portal vein* due to extension of the normal obliterative process of the umbilical vein and ductus venosus (fig. 953) sometimes associated with omphalitis of the new-born (p. 1097).

The vein becomes replaced by a mass of collateral channels which have been described as a 'cavernoma'.

2. **Intra-hepatic** accounts for nearly 80 per cent. of all cases. The cause is usually cirrhosis of the liver, in particular by areas of regeneration in cases of compensated hepatic cirrhosis. Such patients are eminently suitable for shunting operations.

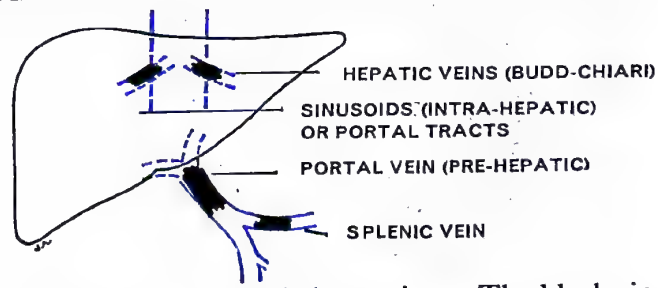

FIG. 953.—Sites of obstruction. The blocks in the veins represent possible sites of thrombus formation. (*After Sir James Learmonth, Edinburgh.*)

3. **Post-hepatic** is rare. It may be caused by constrictive pericarditis and tricuspid valvular incompetence, and it is also a component of the Budd-Chiari syndrome (p. 863).

Damocles, a Greek who was feasted with a sword suspended above his head by a single hair (Greek mythology).
Samuel Alexander Kinnier Wilson, 1878–1937. Neurologist, King's College Hospital, London.
Bernhard Kayser, 1869–1937. German Ophthalmologist.
Richard Fleischer, 1848–1909. German Physician.

Collateral Circulation.—When there is obstruction of blood flow to or from the liver, Nature endeavours to relieve the obstruction by opening up normally insignificant anastomotic channels.

When the obstruction is pre-hepatic, collaterals between the portal vein distal to the obstruction and the portal vein proximal to the obstruction enlarge. Thus almost unheard-of venæ comitantes of the hepatic artery and of the portal vein wax proud. Depending upon the site of the obstruction, some of the collaterals between the portal and systemic venous systems, notably the œsophageal plexus, also become dilated.

When the obstruction is intra-hepatic, anastomotic channels outside the liver between the portal and systemic systems become engorged, dilate, and so

ANASTOMOSES BETWEEN THE PORTAL AND SYSTEMIC VENOUS SYSTEMS

	Site of Anastomosis	*Portal Vessels*	*Systemic Vessels*	*Signs and Symptoms*
1	Plexus around lower end of œsophagus.	Œsophageal branches of left gastric vein.	Lower systemic œsophageal veins.	Hæmatemesis or melæna.
2	Around umbilicus.	Para-umbilical veins (accompany the round ligament of the liver).	Superficial veins of the anterior abdominal wall.	Caput Medusæ.
3	Plexuses around lower third of rectum and anal canal.	Superior hæmorrhoidal vein.	Middle and inferior hæmorrhoidal veins.	Hæmorrhoids (rare).
4	Extraperitoneal surfaces of abdominal organs.	Tributaries of superior and inferior mesenteric veins.	Subdiaphragmatic and retroperitoneal veins.	Silent.

an increasing proportion of the obstructed portal venous blood by-passes the liver. The only ones which are dangerous to life are those in the submucosa of the œsophagus and upper end of the stomach. In patients with portal hypertension, hæmorrhoids, if present, are usually of the idiopathic type (p. 1060).

Œsophageal Varices.—*Although called 'œsophageal', it is important to realise that these varices extend well into the stomach.* Œsophageal varices (fig. 954) are the most important collaterals of the portal circulation. Sometimes, as intra-abdominal pressure rises, e.g. when straining at stool or during heavy lifting, they rupture; in other cases the overlying mucosa becomes abraded by a rough bolus or excoriated by regurgitated gastric juice. Bleeding can occur slowly or catastrophically. The presence of œsophageal varices can be demonstrated by:

FIG. 954.—Barium swallow showing filling defects due to œsophageal varices.

(*a*) *Radiology* after a barium swallow (fig. 954). In the great majority of cases œsophageal collaterals can be revealed by this method as filling defects which may extend even as far up as the pharynx. Varices can also be demonstrated by the injection of a radio-opaque dye percutaneously into the splenic pulp (splenic portography,

p. 831). This investigation is valuable because not only can the cause of portal hypertension be demonstrated, e.g. portal thrombosis or cirrhosis, but the splenic pulp pressure may be determined at the same time as an estimate of portal vein pressure. Occasionally superior mesenteric angiography and umbilical vein catheterisation may have to be performed.

(*b*) *Œsophagoscopy* will demonstrate them in all cases, and should be carried out along with gastroscopy to confirm the presence of varices and determine if they are the source of bleeding. The risks are not great in skilled hands.

Clinical Features.—If the patient is known to have hepatic cirrhosis, it should be assumed that the hæmorrhage is coming from œsophageal varicose veins, although patients with cirrhosis of the liver are particularly likely to suffer also from a gastric or duodenal ulcer. In nearly all cases the spleen is palpably enlarged. Liver function tests, if abnormal, greatly favour hepatic cirrhosis as the cause of the hæmorrhage. They are of value in deciding whether operation should be carried out because in those with a low serum albumin (below 25 g/l) and a high serum bilirubin the results of operation are poor.

The decision to operate in a patient with portal hypertension requires nice judgment and considerable experience. It has been proved beyond doubt that a prophylactic shunt operation, that is an operation to reduce portal pressure in a patient with portal hypertension but who has not yet had a hæmorrhage, is of no benefit and is probably deleterious. In addition, any operation in a patient, especially an elderly one, with severe encephalopathy and marked impairment of liver function is usually followed by high mortality. On the other hand, a patient who is otherwise fit and young, without evidence of a severe liver disease, will probably benefit from an early shunt after he has had a hæmorrhage, especially if there has been a short interval to restore him to hæmodynamic equilibrium by blood transfusion. In general, emergency operations carried out while the patient is still bleeding are followed by poor results.

Treatment of Massive Hæmorrhage from Œsophageal Varices:

1. **Conservative Treatment.**—Rest, sedation, and replacement of blood will carry a few of the patients who are actively bleeding past the emergency period. For transfusion, fresh blood is particularly desirable. Careful monitoring of the blood pressure and central venous pressure is necessary. Encephalopathy may be prevented or minimised by giving magnesium sulphate and neomycin orally or through the Sengstaken tube (p. 870). Occasionally ice water lavage of the stomach may be performed to reduce bleeding and remove clots. Pituitrin (vasopressin) which causes lowering of the portal blood pressure by constricting the splanchnic arterioles, is a valuable adjunct. To obtain the maximum effect, 20 units of Pitressin diluted in 200 ml. of isotonic saline solution is given intravenously over a period of twenty minutes. Side-effects include abdominal griping and coronary artery vasoconstriction. Occasionally vasopressin may be trans-

Robert William Sengstaken, Contemporary. Surgeon, Garden City, New York.

fused directly into the splanchnic circulation via a catheter inserted into the superior mesenteric artery from the femoral artery, but it is doubtful if this route of administration carries greater benefit than the intravenous one. For the prothrombin deficiency consequent upon liver damage, the administration of vitamin K is necessary.

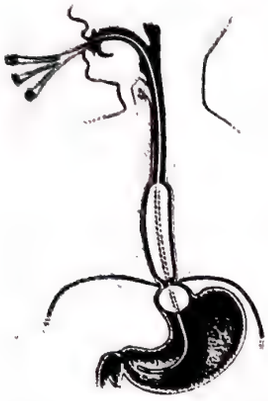

FIG. 955.—The Sengstaken trilumen tube with gastric and œsophageal balloons *in situ*.

2. **Tamponade** is required when the foregoing measures fail after a short trial. A small balloon tied firmly to the end of a gastric aspiration tube can be employed, but the Sengstaken trilumen tube (fig. 955) is better. The œsophageal and gastric balloons are inflated and moderate tension applied by strapping the tube to the forehead. While the Sengstaken tube controls œsophageal hæmorrhage in every case, and is therefore a diagnostic as well as a therapeutic measure, it has its drawbacks. Chief of these is the inspiration of saliva into the lungs, which must be anticipated. In addition to respiratory difficulty, ulceration and rupture of the œsophagus may occur if the balloon is retained for more than seventy-two hours. But the greatest danger is renewed hæmorrhage when the balloon is deflated and withdrawn. Therefore, after twenty-four hours the balloon should be deflated, but left in place for four hours. If bleeding recommences, immediate operation is necessary. Provided great care is taken, the Sengstaken tube represents a valuable means of stopping bleeding in the majority of patients.

3. **Urgent Operation for Bleeding Varices.**—If bleeding does not stop with vasopressin, or recurs after removal of a Sengstaken tube, operative intervention is required. Such operative intervention, no matter the procedure, carries a high mortality (40%) especially in those who have evidence of impairment of liver function. Either a shunt procedure (portacaval), or a mesenterico-caval graft can be performed, or the varices may be directly ligated or injected, although after such latter procedures bleeding may recur (see p. 874).

4. **Evacuation of Blood from the Alimentary Tract.**—As soon as possible the alimentary tract must be cleared of blood; otherwise encephalopathy, due to the absorption of protein metabolites, may follow. All unclotted blood must be aspirated from the stomach, and colonic wash-outs given until all blood has been evacuated.

Portal Hypertension *au Froid*

By this is meant that the patient has portal hypertension, but is not bleeding obviously or dangerously. First let us consider how pre-hepatic portal obstruction differs from intra-hepatic portal obstruction.

The patient with pre-hepatic portal obstruction is nearly always young, and often a child. The most usual cause for advice being sought is either a sudden hæmorrhage or listlessness due to anæmia. On examination the liver is impalpable, but the spleen is obviously enlarged (fig. 956). The anæmia is usually due to oozing from œsophageal varices, but sometimes hypersplenism is a factor (p. 847). As the liver is normal, or nearly so, liver function tests remain normal as the disease advances. Ascites does not occur unless there is active phlebitis in the portal system of veins.

Splenoportography (p. 831) will usually display the site of the block, but if the portal vein does not fill, the cause may lie in a reversed flow in the splenic vein. If, therefore, there is suspicion that the portal vein may be obstructed, a venogram may also be done by injection into a mesenteric vein at laparotomy.

The patient with intra-hepatic portal hypertension is usually an adult and suffers from hepatic cirrhosis. Enlarged porta-systemic venous communications are present long before serious œsophageal hæmorrhage occurs. Œsophageal varices can be demonstrated radiologically or seen through an œsophagoscope. Enlargement of veins of the abdominal wall radiating from the umbilicus may be present (fig. 957). As long as hypertrophy of liver tissue is sufficient to compensate for the cellular destruction by cirrhosis, the liver function tests remain within normal limits.

FIG. 956.—Enlargement of the spleen in pre-hepatic portal obstruction.

Measuring the Portal Blood Pressure.—One method is to record the intrasplenic pressure, and this can be done at the same time as transplenic portavenography. In cases of intra-hepatic obstruction an alternative method is to catheterise a hepatic vein. The technique is not especially difficult, and can be undertaken in any centre equipped

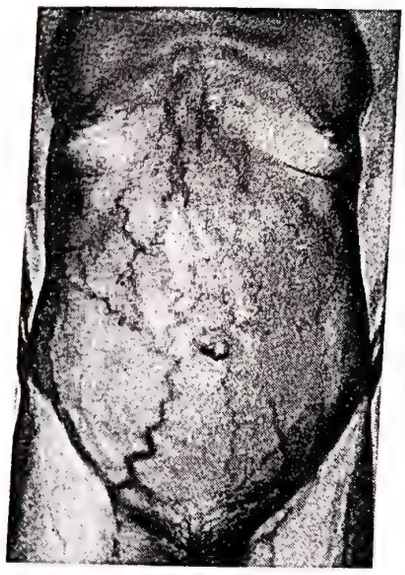

FIG. 957. — Enlargement of the veins of the abdominal wall in a case of portal hypertension. Infra-red photograph. *(The late A. H. Hunt F.R.C.S., London.)*

FIG. 958.—Spleno-portograph in a case of intra-hepatic portal hypertension showing dilated splenic and portal veins. *(Professor R. Milnes Walker, F.R.C.S., Bristol.)*

for cardiac catheterisation. Following local anæsthesia and opening an antecubital vein as for cannulation, a cardiac catheter with only a terminal opening is passed into the vein. The catheter is advanced through the right auricle and inferior vena cava under radiological control. The tip is then insinuated into a hepatic vein until a peripheral radicle is occluded (fig. 959). It is important that the tip of the catheter should be in a peripheral position, so as to obviate obstruction by a bifurcation of the vein, and thus falsify results. Pressure recordings are then taken. The normal portal pressure is 8 to 12 mmHg (1·06–1·6 kPa). In cases of established cirrhosis it may rise

to 30·0 mmHg (4 kPa) or more. The portal pressure is always high in cirrhotic patients who have œsophageal varices. The ascites of cirrhosis does not bear a direct relationship to elevated portal blood pressure, as was formerly believed.

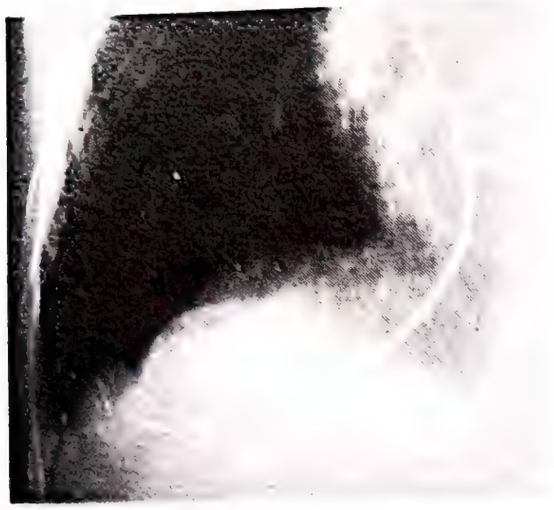

FIG. 959.—Catheter in hepatic vein.
(Dr. Frank Ross, Bristol.)

Indication for a Porta-systemic Shunting Operation:

If bleeding cannot be controlled, emergency operation is required but is followed by high mortality and morbidity rates. If the patient has had several episodes of bleeding in the past, the operation may be performed electively after the patient's condition has been stabilised and provided that hepatic function is not severely impaired.

Contraindications:

1. If the patient's serum albumin[1] is less than 30 g/l (3 g/100 ml).
2. If the patient is jaundiced significantly.
3. Massive ascites. Evacuation of this by suction at operation may lead to death on the table.
4. Operation should not be performed in a patient who has not bled from varices. Prophylactic operations do not prolong life and may reduce it.

Pre-operative treatment is directed mainly to correcting the accompanying hypochromic anæmia; blood transfusion is often required. Control of a bleeding tendency (secondary to impaired production of prothrombin) is

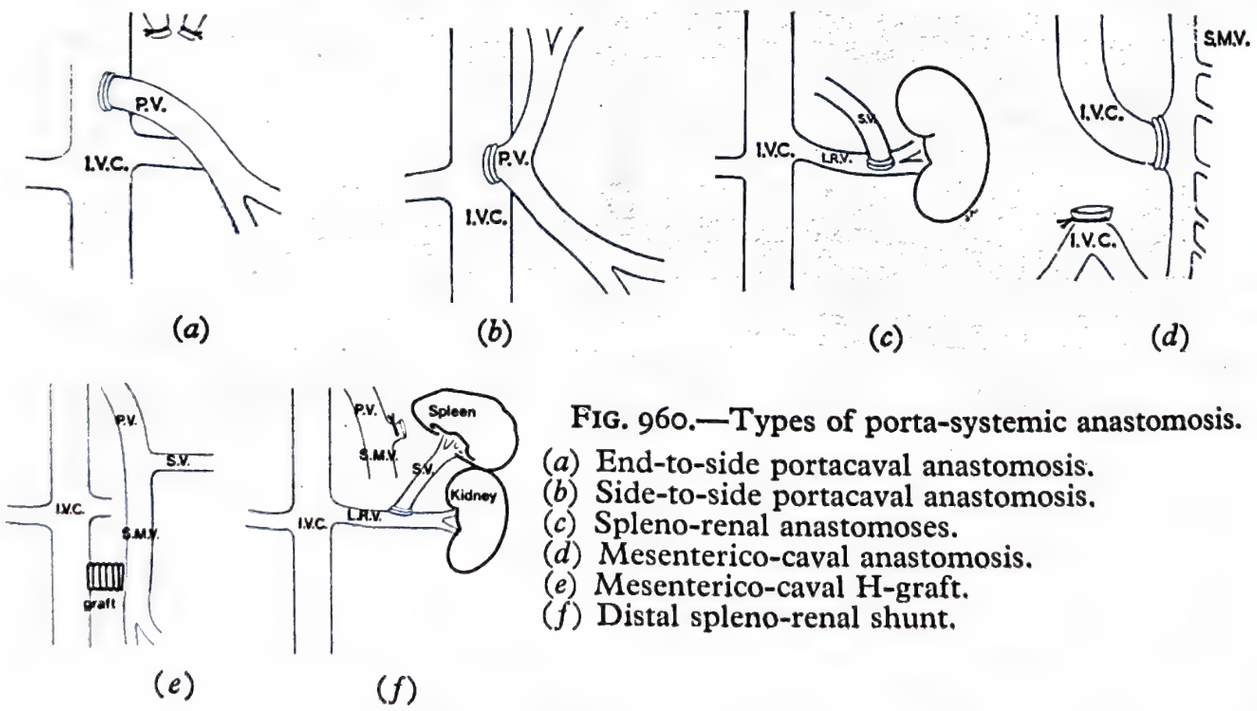

FIG. 960.—Types of porta-systemic anastomosis.

(*f*) Distal spleno-renal shunt.

essential and for this purpose vitamin K is given parenterally. If there is no immediate danger of renewed hæmorrhage, those in whom a porta-systemic shunting operation is indicated are often benefited greatly by a course of pre-

[1] Normal level 3·6 to 4·5 g/100 ml (36–45 g/l).

operative medical treatment. If ascites is present, a low sodium diet, in conjunction with diuretics, often causes absorption of ascitic fluid. If possible, paracentesis should be avoided.

OPERATIONS FOR PORTAL HYPERTENSION

An anæsthetic that allows a high concentration of oxygen to be given is important. Throughout the operation the blood volume is maintained by transfusion.

Operative Portavenography.—When the transplenic portavenographic films are inconclusive, or have not been obtainable because the spleen has been previously removed, the site of the block can be demonstrated by portavenography after the abdomen has been opened. Thirty ml. of contrast material are injected into a suitable vein in the gastro-hepatic omentum, or into the superior mesenteric vein. A radiograph is then taken with a portable machine during the injection of the last few ml. Usually the site of the block can be determined accurately.

1. **Portacaval Anastomosis.**—Unless the portal vein is thrombosed (which renders a portacaval anastomosis impossible), an end-to-side portacaval shunt is nearly always the operation of choice, provided that the liver function is adequate. The serum albumin level should be at least 30 g/l, and the serum bilirubin not more than 17 mmol/l.

The best approach is a subcostal one. The peritoneum is divided along the lower border of the right lobe of the liver and the lateral border of the duodenum. The portal vein is exposed by an incision through the peritoneum forming the anterior wall of the epiploic foramen, and a length of about 3 cm freed. An incision in the peritoneum over the vena cava exposes its anterior surface. The portal vein, or its two main branches, is now ligated at the hilum of the liver, a Blalock clamp placed on its lower end, and the vein divided.

After placing a side clamp on the vena cava, an incision is made in its anterior wall, and an end-to-side anastomosis made using everting fine silk sutures, the wound is closed with drainage.

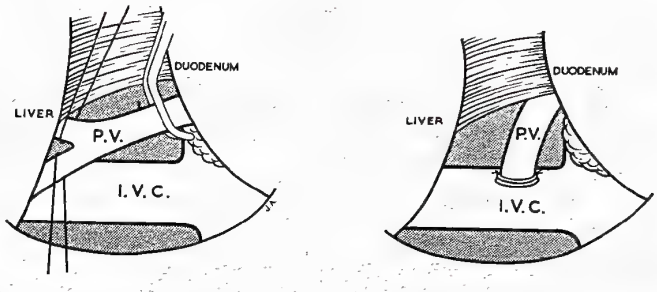

FIG. 961.—Portacaval anastomosis.

With careful selection of cases the mortality is about 6 per cent., and recurrent bleeding from varices after this operation is most unusual.

About 15–20% of patients may have post-shunt encephalopathy because of venous deprivation of the liver and slow deterioration of liver function.

2. **Spleno-renal Anastomosis.**—This may be performed if there is thrombosis of the portal vein, but it is contraindicated if the splenic vein is less than 1 cm in diameter as shown by venography. This operation is less effective than a portacaval anastomosis in preventing further hæmorrhage, but carries a lower risk of encephalopathy. Owing to the small size of the splenic vein, this operation is rarely of value in cases of extra-hepatic obstruction in children.

The operation is performed through a left thoraco-abdominal incision. The spleen is removed but during the dissection of the hilum as great a length as possible of the vein is carefully preserved. Enough vein is separated from the pancreas to allow its apposition to the renal vein, and it is temporarily occluded with a bull-dog clamp. The renal vein is dissected out and occluded by clamps or threads and the splenic vein anastomosed by everting sutures to an opening in its upper surface. To prevent engorgement of the kidney a temporary clamp may be put on the renal artery, but it should be released after fifteen minutes to allow a fresh flow of blood to the kidney.

3. **Superior Mesenterico-caval Anastomosis.**—When the portal vein is thrombosed this alternative may be possible. The inferior vena cava is divided just above its lower end, and ligated below. The proximal end is joined to the side of the superior mesenteric vein in the root of the mesentery. Alternatively, a shunt (Dacron), can be interposed between the superior mesenteric vein and the inferior vena cava. This mesentericocaval shunt (H-graft, ' jump ' graft) is generally simpler to perform than

Alfred Blalock 1899–1964. Surgeon-in-Chief, Johns Hopkins Hospital, Baltimore, U.S.A.

the other operations, an advantage in emergency circumstances. It also can be carried out when the portal vein is occluded by thrombus.

4. **Distal Splenorenal Shunt.**—Distal splenic vein is joined to the renal vein without splenectomy. The extrinsic gastric and lower œsophageal veins are ligated except the short gastric veins draining the stomach into the splenic bed. The objective is to decompress the critical area of the lower end of the œsophagus, yet preserving a venous blood supply to the liver. The incidence of encephalopathy is said to be low. The operation presents technical difficulties in the obese patient and those with splenomegaly.

Other shunt operations are being evaluated, including left gastric venocaval shunt, umbilicocaval shunt and arterialisation of the portal vein with portacaval shunt.

5. **Œsophageal Varices Interruption.**—In an emergency or when the patient's liver function is inadequate for a porta-systemic shunt or there is no suitable patent vein, it is desirable to make an effort to interrupt the communications between the left gastric (portal system) and œsophageal veins (azygos system)—porto-azygos disconnection—so cutting off the flow of portal blood to the varices.

(*a*) **Œsophageal Transection** (Milnes Walker).—The aim of this operation is to cut off the flow of portal blood to the varices. Through a left trans-thoracic approach the lower end of the œsophagus is mobilised and the vagus nerves separated from it. The œsophagus is transected at the level of the hiatus in the diaphragm, and resutured with continuous sutures in the mucosa and submucosa which obliterate the vessels.

(*b*) **Suture of the Varices** after opening the lower part of the œsophagus longitudinally (Crile), just above the diaphragm. The varices, extending through the cardia are underrun with continuous chromic catgut.

(*c*) **Gastric Transection** (Tanner).—The aim is similar to that of œsophageal transection. Through a left thoraco-abdominal approach, the upper part of the stomach is transected and reanastomosed with continuous sutures to obliterate the blood vessels.

All of these operations may be helpful in emergency circumstances or when the splanchnic vessels are thrombosed, thus averting a shunt operation, but rebleeding is common.

6. **Splenectomy.**—This has no place in the treatment of portal hypertension except in the very rare cases of thrombosis confined to the splenic vein, or in combination with some other operation.

7. **Injection of Varices.**—Because of the high mortality of open operation, injection sclerotherapy is being used increasingly (Rodgers, Johnston). Varices can be injected once the bleeding is under control and the site of bleeding confirmed. A good view is necessary, 5–6 ml of 5% ethanolamine oleate is injected into each varix down the rigid 50 cm œsophagoscope using a long Macbeth needle. The lip of the œsophagoscope is rotated to compress the varix that has just been injected. A Sengstaken tube is put down for 12–24 hours to compress the varices and control bleeding. Injections may be repeated before the patient leaves hospital, or if he bleeds again, and prophylactically against further episodes.

Careful anæsthetic technique includes intermittent Althesin (alphaxalone and alphadalone acetate) and suxamethonium, and artificial ventilation with nitrous oxide and oxygen (Ward).

NEOPLASMS OF THE LIVER

Benign:

Hæmangioma occurs more commonly in the liver than in any other internal organ, and usually the neoplasm is of the cavernous type. As a rule, a hæmangioma of the liver is solitary, and is found either at necropsy or incidentally at operation. Exceptionally, it becomes large enough to cause symptoms, in which event laparotomy is required to establish the diagnosis. The compressibility of the tumour makes the diagnosis unmistakable, and on no account should biopsy be performed, for the resulting hæmorrhage is terrific. Radiotherapy is often useful in reducing the size of the tumour. Excision of tumour confined to a lobe necessitates hemi-hepatectomy (p. 876).

Hepato-adenomas are composed of hepatic cells. Frequently multiple and small, they are distinguished with difficulty from the nodular hyperplasia of cirrhosis. There is no evidence that they become malignant. Their removal is unnecessary.

Cholangio-adenomas originate from the bile-ducts and form small subcapsular masses. They are found at operation or necropsy, and can simulate closely metastatic deposits, which should not be assumed without biopsy. They are harmless.

Malignant:

Primary carcinoma of the liver is uncommon in European races, but is by no means rare in African natives, Malayans, Chinese, and Japanese. The highest recorded incidence is in Mozambique where it is a thousand times as common as in most of Europe. In the majority of these patients it arises as a complication of cirrhosis. A similar ratio is not found among the coloured and white North American peoples. Two pathological varieties are described:

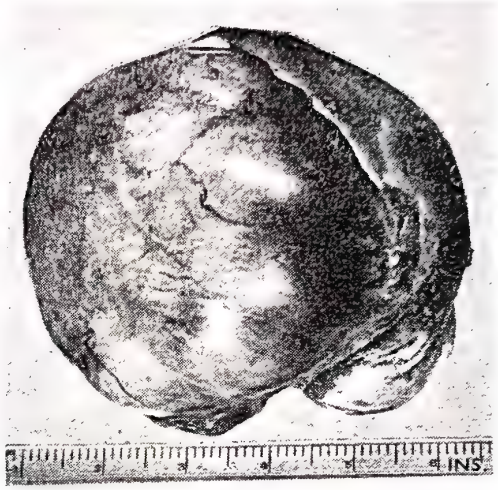

FIG. 962.—Hepatoma resected from the liver successfully.

1. **Hepatocarcinoma** arises in the liver cells. There are great variations in the malignancy of this tumour, which may be multicentric in origin, particularly when it occurs in a cirrhotic liver. At one end of the scale is a relatively benign, firm, slowly growing tumour (fig. 962), and at the other a rapidly growing, soft neoplasm prone to undergo necrosis, which soon metastasises within the liver, or to the lymph nodes in the hilum of the liver, mediastinum or neck.

2. **Cholangiocarcinoma.**—See page 907.

Clinical Features of Primary Carcinoma of the Liver.—These tumours occur in children and in older people, but it is rare between the ages of 20 and 40 except in those countries where the incidence is high and then this is the age group most affected. The usual train of events is anorexia, rapid loss of weight, and asthenia. On examination an enlarged liver is found and often a localised mass. Less frequently the patient presents on account of a swelling he has discovered in the upper abdomen: the swelling may, or may not, be tender, depending on the rate of growth. Neoplastic proliferation is sometimes so rapid as to cause a low pyrexia, in which event, in tropical countries, an amœbic abscess will be considered as a possible diagnosis. Every effort is made to seek a possible primary growth, bearing in mind that, at any rate in white races, secondary carcinoma of the liver is immeasurably more common than primary carcinoma. In patients with primary liver cancer, α-1-fetoprotein (AFP) may be present in the plasma long before clinical features appear. AFP is a normal component of the plasma protein of the human fœtus older than six weeks and disappears a few weeks after birth. It is a valuable screening method for patients with primary liver carcinoma with cirrhosis. Radio-scanning (p. 851) may be helpful and needle biopsy of the liver may establish the diagnosis. Addi-

tional diagnostic techniques include ultrasonic scanning and cœliac axis angiography.

Ascites is present in about 40 per cent. of patients at the time of the first examination; diagnostic aspiration often reveals blood-stained ascitic fluid. Such ascites resists therapy, and re-accumulates rapidly after paracentesis.

SECONDARY NEOPLASMS OF THE LIVER

Secondary Carcinoma.—As is well known, the liver is a favourite site for carcinomatous metastases. Characteristically, secondary growths in the liver, owing to degeneration of cells in the centre, are umbilicated. As a rule, carcinomatous deposits in the liver are multiple (fig. 963). Occasionally at laparotomy a secondary growth in the liver is found to be apparently solitary and accessible. In such circumstances, provided that the primary growth can be or has been resected, excision of that part of the liver containing the neoplasm sometimes results in a long-lasting survival.

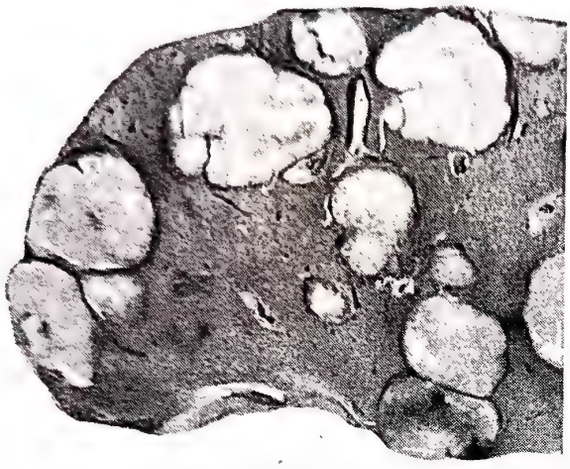

FIG. 963.—Secondary carcinoma of the liver.

Secondary carcinoid (argentaffin) tumours (p. 986) are rare; where they occur they often grow to a large size. There are always many hepatic metastases when malignant carcinoid of the small intestine or bronchus is associated with vasomotor abnormalities and pulmonary stenosis. The increased urinary excretion of 5-hydroxy-indole-acetic acid is helpful in making a diagnosis.

Secondary melanoma occurs particularly when the primary growth is in the eye. Fifteen years or more have elapsed between the removal of the primary growth and the appearance of secondary deposits (p. 501).

Secondary Sarcoma.—The liver is not an uncommon site for secondary deposits in cases of sarcoma, but the lungs show a much higher incidence.

Resection of a Benign Tumour of the Liver.—In order to conserve blood, the hepatic artery and portal vein can be clamped lightly at the porta hepatis, and released every five minutes. Another very important point is that branches of the hepatic artery and the portal vein ramify through the liver in the portal canals: each of these canals is surrounded by a prolongation of Glisson's capsule which, when encountered with a blunt instrument, gives a sense of resistance. Thus, if liver tissue is dissected with the finger, it is possible to divide liver tissue, but spare the vessels, which can be clamped and ligated, or coagulated with diathermy, before division. The resection completed, the resulting raw surfaces of the cut liver are dealt with in the same manner as described for rupture of the liver (p. 852).

Hemi-hepatectomy.—A number of cases of successful removal of the surgical right lobe of the liver for primary and secondary tumours or for carcinoma of the gall-bladder have been reported. Removal of the surgical left lobe is less frequently necessary and left (anatomical) lobectomy usually suffices (Rodney Smith).

Right Hemi-hepatectomy.—After operability has been determined through a right paramedian incision, extension into a right thoraco-abdominal is achieved through the eighth interspace. The liver is mobilised and rotated forwards and upwards into the

Francis Glisson, 1598–1677. Regius Professor of Physic, Cambridge, England.
Sir Rodney Smith, Contemporary. Surgeon, St. George's Hospital, London.

chest to expose the porta hepatis. Working from below upwards, the cystic artery and duct, the right hepatic duct, right hepatic artery, and right branch of the portal vein are successively divided between ligatures. The inferior vena cava is then exposed by mobilising the duodenum and head of pancreas and drawing them over to

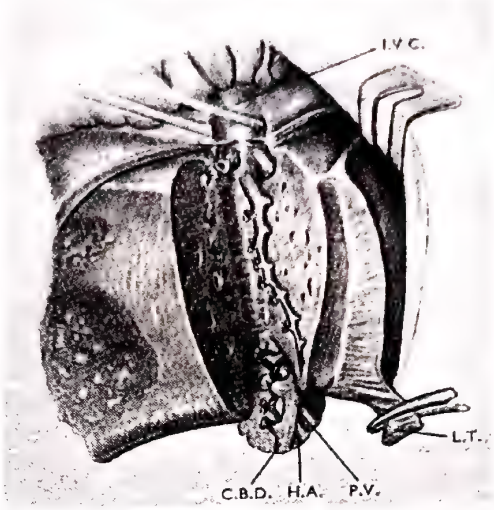

FIG. 964.—Right hemi-hepatectomy almost completed; the hepatic veins remain to be ligated (diagrammatic). I.V.C. = Inferior Vena Cava, C.B.D. = Common Bile Duct, P.V. = Portal Vein, H.A. = Hepatic Artery, L.T. = Ligamentum Teres. (*After C. Rob and R. Smith.*)

the left (Kocher's manœuvre). It is then possible to expose, ligate, and divide the inconstant minor hepatic veins running from the right lobe into the cava, up as high as the site of entry of the right hepatic vein; great care must be taken not to obstruct the venous return in the vena cava. The liver is then divided from in front and above between the surgical lobes by diathermy. The right hepatic vein is then exposed and divided and also the right-sided branches of the middle hepatic vein as they are encountered. The raw surface of the left lobe is covered with the falciform ligament and it is wise to drain the common bile-duct.

Liver Transplantation is dealt with in Chapter 59.

Theodor Kocher, 1841–1917. Professor of Clinical Surgery, University of Berne, Switzerland.

CHAPTER 44

THE GALL-BLADDER AND BILE DUCTS

SURGICAL ANATOMY AND PHYSIOLOGY

The gall-bladder is pear-shaped, 7·5 to 12·5 cm long, with a capacity of about 50 ml., but capable of fifty-fold distension. The anatomical subdivisions are, a fundus, a body, and a neck which terminates in the narrow infundibulum (fig. 965). The angulated distal part of the neck forms a pouch, called Hartmann's pouch, a common site for a solitary gall-stone to lodge. The muscle fibres in the walls of the gall-bladder are arranged in a criss-cross manner, being particularly well developed in the neck. The mucous membrane contains indentations of the mucosa that sink into the muscle coat; these are the crypts of Luschka.

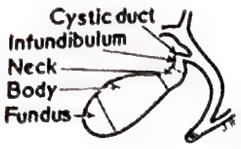

Fig. 965.—The anatomical subdivisions. (*After J. D. Rose.*)

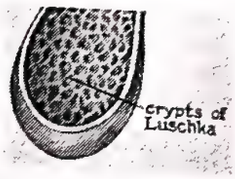

The cystic duct is about 2·5 cm in length. Internal projections of circular muscle fibres account for the spiral valve of Heister, which makes the passage of calculi difficult.

The common hepatic duct is usually less than 2·5 cm long, and is formed by the union of the right and left hepatic ducts.

The common bile duct, about 7·5 cm long, is formed by the junction of the cystic and the common hepatic ducts. It is divided into four parts: 1. *The supra-duodenal portion,* about 2·5 cm long, runs in the free edge of the lesser omentum. 2. *The retroduodenal portion.* 3. *The infraduodenal portion* lying in a groove, but at times in a tunnel in the posterior surface of the pancreas. The right edge of the inferior vena cava lies not far distant behind it. 4. *The intraduodenal portion* passes obliquely through the wall of the second part of the duodenum to open on the summit of the duodenal papilla, which is surrounded by the sphincter of Oddi. Near its opening it may be joined by the main duct of the pancreas (duct of Wirsung), to form the ampulla of Vater (an ampulla indicates a dilatation). The arrangements of the exit are shown in fig. 966.

(*a*) 67 per cent. (*b*) 30 per cent. (*c*) 3 per cent.

FIG. 966.—(*a*) Common orifice occupying one-third to two-thirds of the length of the papilla. (*b*) Two orifices surrounded by the same sphincter. (*c*) An ampulla present.

The Arterial Supply of the Gall-bladder.—The cystic artery is a branch of the right hepatic artery. Usually it is given off *behind* the common hepatic duct, and then runs near (but never on) the cystic duct to the gall-bladder (fig. 967 A). Occasionally an accessory cystic artery arises from the gastro-duodenal artery (fig. 967B). In some instances (25 out of 161 cases, Flint) the right hepatic artery and/or the cystic artery cross in front of the common bile duct and the cystic duct (fig. 967C). The most dangerous anomaly of all is when the main trunk of the hepatic artery takes a tortuous course in front of the origin of the cystic duct (fig. 967 D). There is a possibility of liver infarction in accidental ligation of the common hepatic artery, but chances of recovery in this and right hepatic ligation are improved by giving neomycin

or ampicillin by mouth, and ensuring a high intake of glucose. Hyperbaric oxygen (p. 80) would be useful, if available.

Lymphatics.—The lymph vessels of the gall-bladder (subserosal and submucous), drain into the *cystic lymph node of Lund* (the sentinel lymph node), which lies in the fork created by the junction of the cystic and common bile ducts. Efferent vessels from this lymph node go to the hilum of the liver, and to the cœliac lymph nodes. The subserosal lymphatic vessels of the gall-bladder also connect with the subcapsular lymph channels of the liver, and this accounts for the frequent spread of carcinoma of the gall-bladder to the right lobe of the liver (p. 906).

Embryology (See page 883).

Surgical Physiology

Bile, as it leaves the liver, is composed of 97 per cent. water, 1 to 2 per cent. of bile salts, and 1 per cent. of pigments, cholesterol, and fatty acids. The liver excretes bile at a constant rate, estimated at 40 ml. per hour. Except when active gastro-

FIG. 968.—*Gall Bladder Mucosa.* (Electron micrograph montage. × 1,200.) The mucosal epithelium consists of 'light' and 'dark' columnar cells with a microvillous luminal border. The cells contain numerous organelles and marked endoplasmic reticulum. The structural organisation of this epithelium reflects its absorptive function.

FIG. 969.—*Gall Bladder Mucosa.* (Electron micrograph, × 16,000.) An apical part of a columnar epithelial cell showing 'microvilli'. The cells contain many granular bodies and mitochondria.

(B. L. Dowling, F.R.C.S., Northampton)

Fred Bates Lund, 1865–1950. Surgeon, Boston City Hospital, Boston, Mass., U.S.A.

duodenal digestion is in progress, the sphincter of Oddi contracts and consequently bile leaving the liver passes into the gall-bladder.

The healthy gall-bladder has several functions:

1. **Concentration of Bile** (figs. 968 and 969).—By the active absorption of water, sodium, chloride, and bicarbonate by the mucous membrane of the gall-bladder into the bloodstream and to a lesser extent into the lymphatics, the hepatic bile which entered the gall-bladder becomes concentrated from 5 to 10 times, with a corresponding increase in the proportion of bile salts, bile pigments, cholesterol, and calcium it contains.

2. **Reservoir for Bile.**—Bile is stored until the gall-bladder is full, when the sphincter of Oddi partially relaxes and the overflow trickles into the duodenum. Contraction of the gall-bladder and synchronous relaxation of the sphincter of Oddi is stimulated by *cholecystokinin*, a hormone secreted by the duodenum in response to acid chyme, fats and egg yolk in its lumen.

3. **Changing the Reaction of the Bile.**—The bile excreted by the liver is alkaline (pH 8·2), whereas that in the gall-bladder becomes acid (pH 7·6 to 7·0) as the bile becomes concentrated.

4. **Cholesterol excretion** by the gall-bladder has not been proved, but pathological evidence of the gall-bladder epithelium choked with crystalline cholesterol (p. 894) is suggestive that the gall-bladder may add cholesterol to the bile.

5. **Secretion of Mucin.**—About 20 ml. is secreted each twenty-four hours.

RADIOLOGICAL INVESTIGATIONS

Plain X-ray will show radio-opaque gall-stones in 10% of cases (fig. 970). It will also show the rare cases of calcification of the gall-bladder (porcelain gall-bladder, fig. 972, and limey (lime water) bile, fig. 973).

FIG. 970.—Plain radiograph showing stones in the gall-bladder and several in the cystic duct.

FIG. 971.—Non-opaque stones in the gall-bladder rendered visible by the medium during oral cholecystography.

FIG. 972.—Porcelain gall-bladder.

Cholecystography is essential in the diagnosis of gall-bladder disease. It is not used in acute cholecystitis, and it is valueless if the patient is jaundiced with a plasma bilirubin level of over 3 mg/100 ml (51 μmol/l), for the poorly functioning hepatic cells are unable to excrete the medium in sufficient concentration to permit shadows to be cast on the radiographic films. Cholecystography is also contraindicated when the renal function is impaired.

Oral cholecystography (Graham-Cole test) remains the most satisfactory method of visualising the gall-bladder (figs. 974 (*a*) and (*b*) and 975):

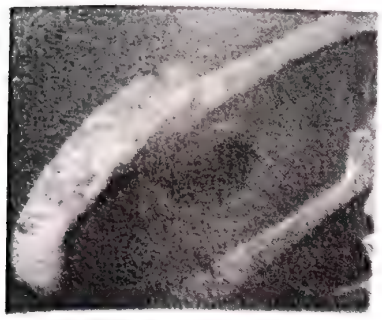

FIG. 973—*Plain radiograph* showing a gall-bladder filled with limey bile. Gall-stones are present also.

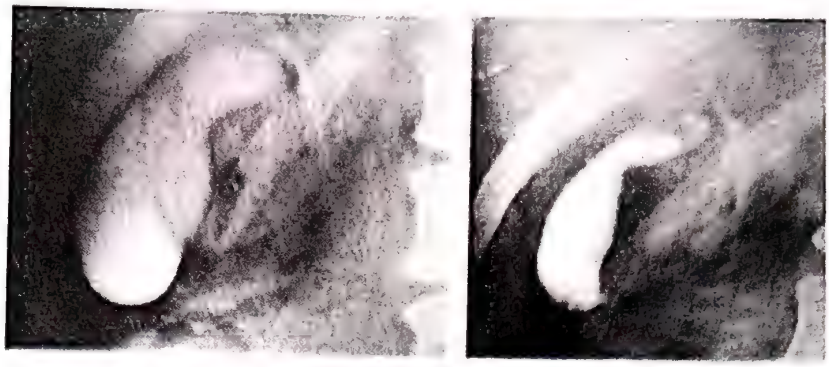

(*a*) (*b*)

FIG. 974. (*a*) A normal cholecystogram. (*b*) Same after a fatty meal.

Telepaque (Bayer Products Ltd.) is the contrast medium employed most commonly in the British Commonwealth and North America, but Biloptin and Solubiloptin (Schering (Germany)) and Orabilix (France) are also used. On the evening before the radiological examination, the patient partakes of a light supper of non-fatty food between 9 and 10 p.m. After this the patient swallows the six uncrushed tablets, one at a time, and drinks water in moderation until bed-time. On the following morning nothing to eat or drink is allowed until the radiological examination has been made. After two or three films have been exposed, the patient is given a drink of ' Prosparol ', a 50 per cent. emulsion of arachis oil in a dose of two to four tablespoonfuls, which is effective in stimulating gall-bladder contraction. Ten and twenty minutes later films are taken, in order to ascertain if the gall-bladder contracts after this fatty stimulus. By giving Biloptin in the evening and Solubiloptin on the next morning, followed three hours later by radiography, it is hoped to visualise the bile ducts as well as the gall-bladder (double contrast technique).

Intravenous cholangiography (Biligrafin[1]) permits radiological visualisation of the intra- and extrahepatic bile ducts (fig. 975).

FIG. 975.—Simultaneous oral and intravenous cholecystography and cholangiography revealing a dilated gall bladder, a distended common bile duct, and a ' cut off ' at the lower end of the duct due to a stone.

The contents of the ampoule (20 ml.) must be injected very slowly, taking at least three minutes. Biligrafin appears in the bile in a few minutes, achieving a concentration 30 to 100 times that of the blood, thus permitting radiological visualisation of the bile passages: here lies its peculiar and inestimable value. For the gall-bladder, it is inferior to oral cholecystography; nevertheless, it is indicated for that purpose when the patient is liable to vomit, or when absorption from the alimentary tract is impaired by diarrhœa. Intravenous cholecystography possesses another clear advantage when early confirmation or exclusion of acute gall-bladder disease is required urgently for purposes of differential diagnosis. Macroglobulinaemia is a contraindication.

Safety Precautions.—Substances containing iodine can give rise to severe reactions (imperceptible pulse, stertorous respirations, cyanosis). A test dose is usually given

[1] Iodipamide, known in the U.S.A. as cholografin.

Evarts Ambrose Graham, 1883–1957. Bixby Professor of Surgery, Washington University, St. Louis, Missouri, U.S.A.

Warren Henry Cole, Contemporary. Emeritus Professor of Surgery, University of Illinois, Chicago, U.S.A.

first, from a supplementary small ampoule which is supplied with each package by the manufacturers. The contents of this are injected into a vein the day before (or, in urgent cases, an hour before) the examination, in order to ascertain if any reaction is likely to occur. The treatment is to administer nikethamide, antihistamine drugs, and oxygen.

A good method of visualising the bile ducts is to give an oral contrast medium in the evening, followed by an intravenous contrast medium in the morning, and to employ tomography.[1] This allows demonstration in the ducts free from overlying gas shadows (Carstairs).

Per-operative Cholangiography (figs. 976, 977 and 978).—A cassette tunnel is placed beneath the patient (fig. 976) at a level that will include the entire biliary tract. The cystic duct is opened and a fine polythene catheter is passed through into the common bile duct for 3 cm. A ligature tied round the cystic duct and catheter prevents leakage. The catheter is filled with normal saline prior to insertion (bile should be aspirated after insertion), so that there are no air bubbles present which would have a similar X-ray appearance to a radiolucent gall-stone. Instruments and packs which might obscure the X-ray are removed, and then two injections (3 ml. and 10 ml.) are given of 30% Hypaque or Urografin (sodium diatrizoate or diatrizoate salts). An X-ray exposure follows each injection; respiration being interrupted to obviate any movement which would blur the picture. A normal cholangiogram is sufficent evidence that exploration of the common bile duct is unnecessary. If the medium, even after injection of a greater volume, fails to pass into the duodenum, and especially if the ducts concerned are dilated or if a filling defect is visualised, choledochotomy and exploration of the interior of the common bile duct is the first consideration. In about 20% of cases the medium flows along the pancreatic duct of Wirsung. This is not necessarily pathological.

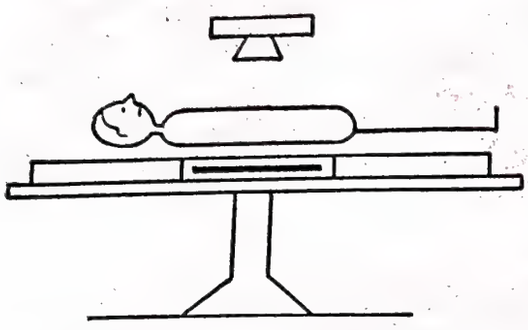

FIG. 976.—Per-operative cholangiography using a radiolucent table-top.

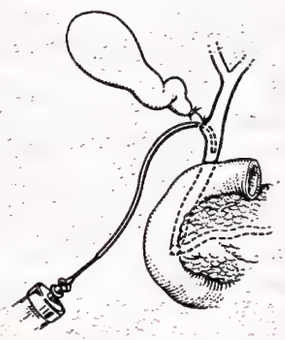

FIG. 977.—Per-operative cholangiography. Method of introducing the medium.

Radiomanometry.—The resistance to the flow of bile through the biliary sphincter in the intraduodenal part of the common duct and through the papilla can be displayed and measured. Under X-ray image intensifier with T.V. control (figs. 979 and 980), a graduated burette containing Hypaque is raised slowly against a scale until the contrast is seen to flow into the duodenum. The height of the meniscus in the burette at this point gives the yield pressure, normally up to 20 cm contrast. Alternatively, a constant flow infusion technique is employed and the pressure is recorded. High yield pressures tend to be associated with stones in the ducts, pancreatitis, a thickened or fibrosed papilla (papillitis) or a carcinoma. Occasionally an increased resistance may be due to an underlying malfunction of the sphincter and the duodenum (so-called dyskinesia[2]).

Per-operative Post-exploratory Cholangiography.—A cholangiogram via a catheter or the T-drainage tube (p. 901) may be performed at the end of the operation, after choledochotomy, to make sure that all stones have been removed, and that there is no obstruction to the flow of bile into the duodenum.

Post-operative Cholangiography is performed some ten to fourteen days after choledochotomy via the T-tube. The absence of stones and a normal flow of bile into the duodenum indicates that the T-tube can be removed (p. 901).

---

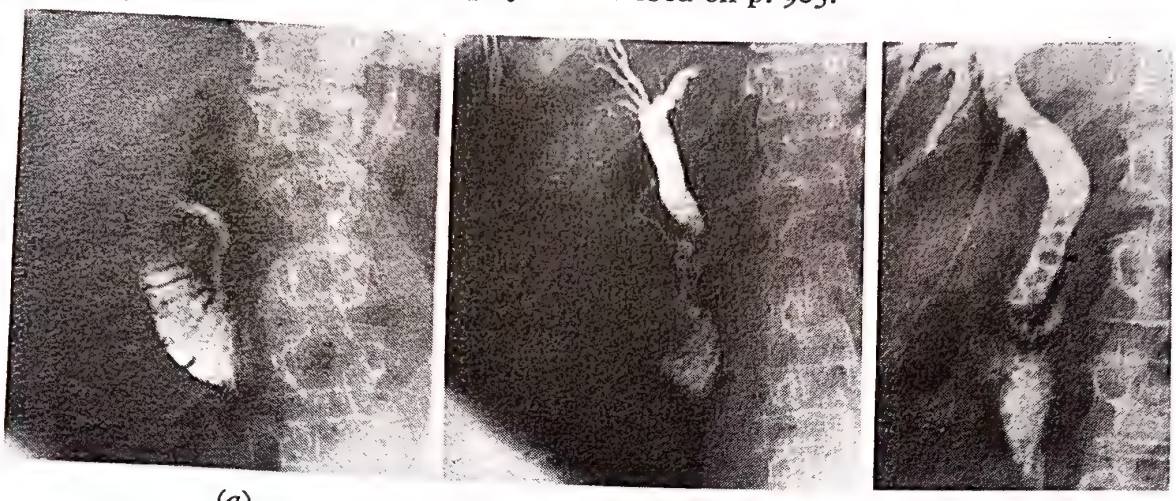
[1] Tomography = a method of placing one given plane into sharp focus while blurring others.

[2] Dyskinesia = impairment of movement.

Lindsay Steven Carstairs, Contemporary. Radiologist, Royal Northern Hospital, London.

Endoscopic Retrograde Cholangio-Pancreatography (ERCP) is described on pages 904 and 905.

Transhepatic cholangiography is described on p. 905.



(*a*) (*b*) (*c*)

FIG. 978.—Per-operative cholangiography (choledochography). (*a*) Gentle infusion of contrast, passing without hindrance into the duodenum. A normal duct with no problems. (*b*) The duct is dilated and there is a slight hold-up of contrast. No stones and no real indication to operate on the sphincter of Oddi (see Sphincterotomy). (*c*) All the ducts are dilated and contain many stones. There is narrowing of the lower end of the duct with reflux of contrast into the pancreatic duct. Sphincterotomy was performed.

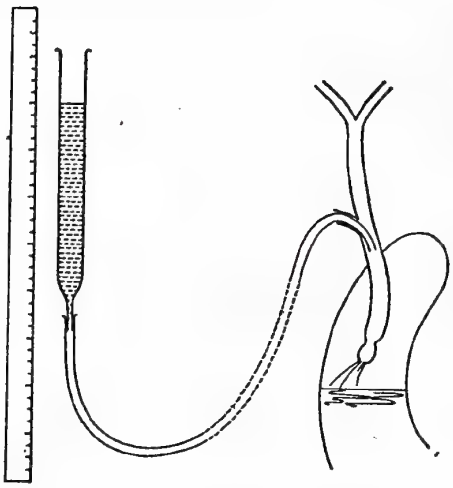

FIG. 980.—Radiomanometry

CONGENITAL ABNORMALITIES OF THE GALL-BLADDER AND BILE DUCTS

Embryology.—The hepatic diverticulum arises from the ventral wall of the foregut and elongates into a stalk to form the choledochus. A lateral bud is given off, viz.——→ which is destined to become the gall-bladder and cystic duct. The embryonic hepatic duct sends out many branches which join up with the canaliculi attached to the liver cells. As is usual with embryonic tubular structures, hyperplasia obliterates the lumina of this ductal system, but normally recanalisation occurs subsequently and bile begins to flow. During early fœtal life the gall-bladder is entirely intrahepatic.

A congenital anomaly of the biliary tract is found in 10 per cent. of necropsies.

Absence of the Gall-bladder.—Occasionally the gall-bladder is absent in man. Stones have been found in the common bile duct in nearly 50 per cent. of cases.

The Phrygian cap[1] (fig. 981(*a*)) is present in 2 to 6 per cent. of cholecystographies, and may be mistaken for a pathological deformity of the organ.

Floating Gall-bladder.—Normally between one-quarter to one-third of the circumference of the gall-bladder lies in a shallow bed on the under-surface of the liver. Occasionally the gall-bladder has a mesentery, which simplifies cholecystectomy, but renders the organ liable to undergo torsion (p. 886).

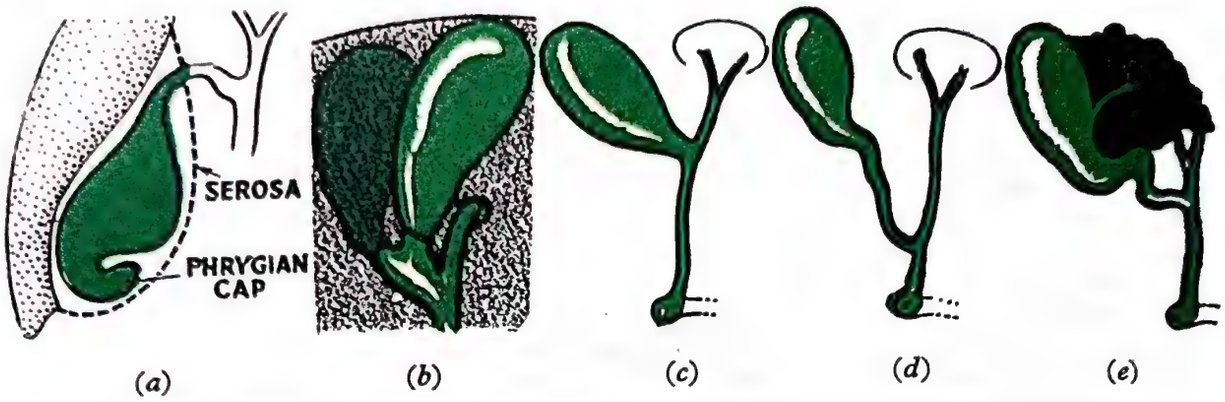

FIG. 981.—Some anatomical anomalies of the gall-bladder and bile passages.

Double Gall-bladder.—Rarely (fig. 981(*b*)), the gall-bladder is double. One of the twins may be intrahepatic. Cholecystography often fails to be diagnostic, because the shadows of the two gall-bladders are superimposed. Double cholecystectomy should be performed.

Absence of the Cystic Duct (fig. 981(*c*)).—Injury of the common duct is liable to occur when cholecystectomy is performed in a patient with this abnormality. The only way of avoiding the accident is to divide the neck of the gall-bladder and accurately to close the opening in the common duct with sutures.

Low Insertion of Cystic Duct (fig. 981(*d*)).—The cystic duct opens into the common duct near the ampulla. This is the commonest anomaly. A portion of the cystic duct may be left behind during cholecystectomy, so that symptoms may return, or are unrelieved.

An Accessory Cholecystohepatic Duct (fig. 981(*e*)) may open into the gall-bladder and cause leakage after cholecystectomy (p. 895). In the very rare anomaly where the right hepatic duct terminates in the gall-bladder, cholecystostomy or partial cholecystectomy should be performed.

CONGENITAL ATRESIA OF THE BILE DUCTS

Ætiopathology.—The probable explanation of many of the varieties is that recanalisation fails to occur in fœtal life (see above). One of the anomalies shown in fig. 982 is present. The extrahepatic bile ducts may have no lumen, or a tiny lumen blocked with epithelial debris, and perhaps biliary sand. In (*c*), a few have lumina connected with scattered bile-filled cysts. The liver, which is greatly en-

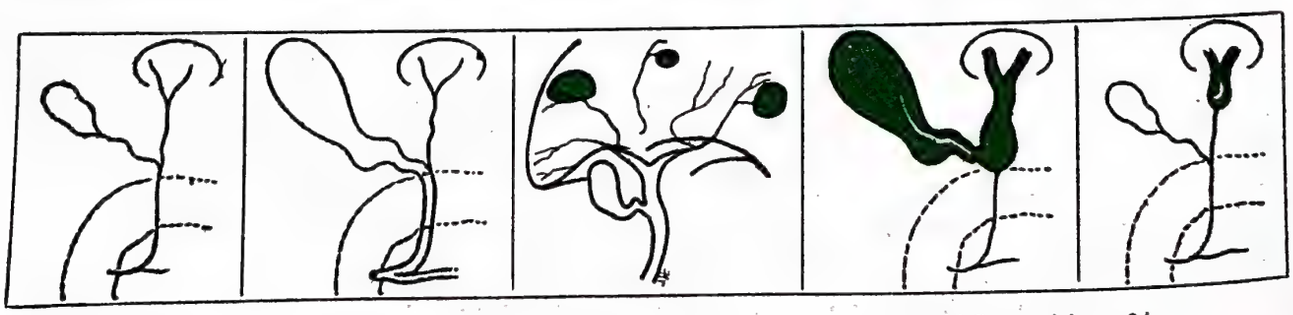

FIG. 982.—Types of congenital obstruction of the bile ducts.

[1] The Phrygian cap refers to hats worn by peoples of Phrygia, an ancient country of Asia Minor. The cap was rather like a liberté cap of the French Revolution.

larged and stained dark green, exhibits varying degrees of biliary cirrhosis. Surprisingly, a few infants have lived for several months.

Clinical Features.—Sometimes a slight icteric tinge is present at birth; more usually jaundice appears within two or three days thereof; occasionally it is delayed for up to several weeks. The urine is bile-laden and dark brown. The first meconium is often normal, i.e. greenish-black in colour; it is said to be formed during the fourth month of fœtal life. Thereafter the stools are white or clay-coloured. Gradually the liver enlarges, and on palpation feels unduly hard. Unrelieved, death usually results in three to six months.

Differential Diagnosis.—The jaundice could also be due to (*a*) erythroblastosis fœtalis (p. 864); (*b*) hereditary spherocytosis (p. 837); (*c*) jaundice of hæmolytic sepsis; (*d*) congenital syphilis; (*e*) homologous serum hepatitis (serum jaundice), if the child has had blood-transfusion or plasma infusion, and (*f*) neonatal hepatitis. The last, which is now more recognised, is the most diagnostically difficult to differentiate from atresia. In neonatal hepatitis the baby is likely to be more ill than is the case in atresia; also the stools are not without pigment. Liver-function tests need to be supported by the findings of a liver biopsy.

Treatment.—Pre-operative measures include the correction of dehydration, if present, and one or two small blood-transfusions. Vitamin K_1 is always necessary to combat prothrombin deficiency in patients with obstructive jaundice. Ampicillin should be administered before and after operation.

Operation.—The anæsthetic of choice is open ether and oxygen. Muscle relaxants must be used with caution. A midline incision affords adequate exposure, though the enlarged liver impedes dissection of the minute ducts.

Operative cholangiography (figs. 976–978) may show the site of the stricture. Even when the ducts seem to be fibrous cords it is worth finding out if a tiny lumen is present. After introducing a needle into the gall-bladder, or a duct, syringing sometimes has proved successful in clearing the ducts of inspissated material. With this exception, the operative measure should be as follows:

Gall-bladder present. Cystic and hepatic ducts distended. Atresia lower end of common bile duct.	Cholecystojejunostomy + jejuno-jejunostomy (fig. 1055).
Gall-bladder functionless or absent. Atresia lower end of common bile duct.	Choledochoduodenostomy (fig. 1004).
Common hepatic duct alone present, and contains bile.	Hepaticodochojejunostomy (Roux-en-Y).

If the atresia is of types (*a*) and (*b*) (fig. 982) it is conceded generally that the case is hopeless. In (*c*) it may be possible to unite the gall-bladder to a distended intrahepatic duct by intubation and later, possibly, by a conduit made from jejunum.

CHOLEDOCHUS CYST

Congenital choledochus cyst is due to a specific weakness in a part, or the whole, of the wall of the common bile duct, and is classified accordingly as cystic dilatation, diverticulum, and choledochocele. Contrary to expectation, only occasionally does the distension involve the cystic and hepatic ducts and the gall-bladder is never distended, viz.:——→ This is a rare condition affecting females four times as commonly as males, Japanese being more prone to the condition than other races. The symptoms and signs seldom become manifest before the age of six months (only half the cases present before the age of twenty). The cyst may contain as much as 1 to 2 litres. The cyst wall shows inflammatory changes and an absence of lining epithelium.

Clinical Features.—There are attacks of jaundice of the obstructive type, which are usually accompanied by upper abdominal pain and pyrexia due to infection.

César Roux, 1857–1934. Professor of Surgery and Gynæcology, Lausanne, Switzerland.

FIG. 983.—Choledochal cyst outlined by intravenous cholangiography. (*W. O. Kirwan, F.R.C.S., Edinburgh.*)

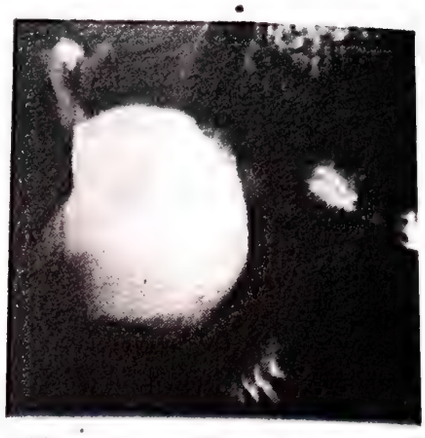

FIG. 984.—Choledochal cyst outlined by operative cholangiography.

In most cases a swelling is detected in the upper abdomen. It is unusual for the cyst to be delineated by contrast X-rays (fig. 983). Untreated, the condition ultimately proves fatal, due to ascending cholangitis, biliary cirrhosis, or diffuse peritonitis following rupture of the cyst.

Treatment.—For cystic dilatation, choledochocystojejunostomy, and for diverticulum and choledochocele excision of the cyst, is recommended.

INJURIES

1. **Traumatic rupture of the gall-bladder or the bile passages** is a rare injury usually the result of a run-over accident. The physical signs are identical with those of rupture of the small intestine, with one notable addition—unmistakable jaundice, which appears within two or three hours of the accident in 65 per cent. of cases. When the abdomen is opened, bile is found within the peritoneal cavity.

Treatment of the various lesions is depicted in fig. 985, but when there is a small hole in the gall-bladder (such as can occur from a penetrating wound), suture of the rent with drainage of the peritoneal cavity is indicated.

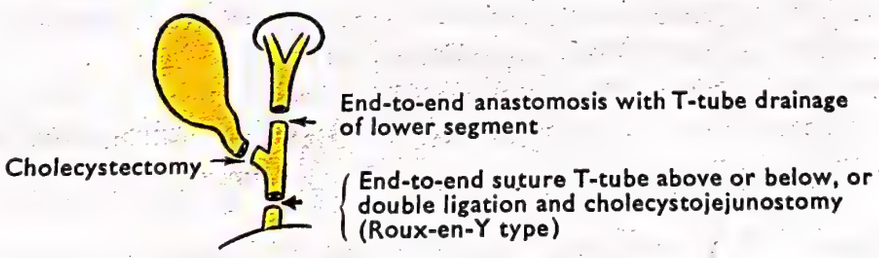

FIG. 985.—Methods of treating early complete tears of the biliary tract.

2. **Injuries of the Bile Ducts incurred during Operation** are discussed on p. 902.

TORSION OF THE GALL-BLADDER

Torsion can occur in those rare instances where the gall-bladder has a comparatively long mesentery—the so-called 'floating' gall-bladder. There is a sudden agonising pain, with vomiting and shock. If the gall-bladder becomes gangrenous or ruptures, the pain passes off instantaneously, but signs of diffuse peritonitis soon follow. Cholecystectomy is the treatment.

GALL-STONES (Cholelithiasis) (fig. 986)

Gall-stones vary in composition. Sometimes they consist entirely of cholesterol, or of calcium bilirubinate. More often they are composed of alternating layers of cholesterol and calcium bilirubinate, or cholesterol and calcium carbonate and phosphate. Protein is another constituent.

Types of Gall-stone. (1) **A cholesterol stone** is usually solitary (the cholesterol 'solitaire'). It is oval or rounded in shape, up to 1·25 cm in diameter, or larger (fig. 986). It is light in weight as well as in colour. In its absolutely pure state it is very pale yellow in colour and, like tallow, it

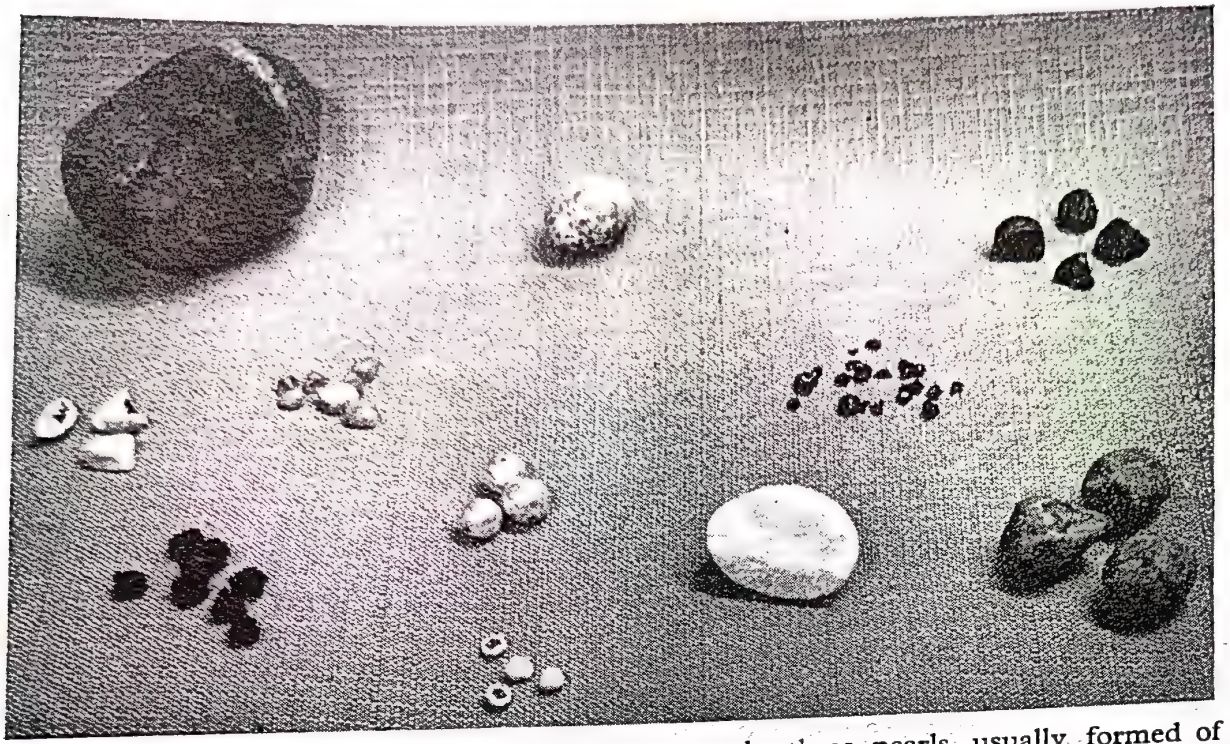

FIG. 986.—Gall-stones (see text). Note, however, the three pearls, usually formed of calcium carbonate in the oyster around a parasite or a grain of sand.

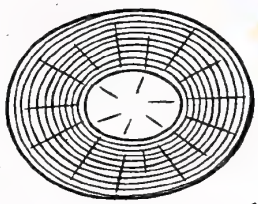
is feebly translucent. More often bile pigments are deposited within it. On section it has a radiating crystalline interior. Cholesterol stones, which make up some 6 per cent. of all gall-stones, are believed to be formed primarily in aseptic static bile (in a 'stasis' gall-bladder). They tend to reside in Hartmann's pouch. A brood of mixed (secondary or inflammatory) gall-stones (see below) may be formed later, or a mixed covering of pigment and cholesterol may form around the primary cholesterol stone, viz. ——→ This is known as a combination stone.



(2) **Pigment stones** (calcium bilirubinate) comprise about 12 per cent. of the total. Black in colour, they range in shape and size from irregular, mulberry or coral-like iridescent concretions of about 5 mm down to sludge particles. Often they are simply soft putty-like masses. On section all pigment stones seem to be amorphous.

(3) **'Mixed' stones** constitute the majority (80 per cent.) of gall-stones found at operation. Nearly always multiple, they become faceted by mutual pressure or by friction one against the other. Dozens or hundreds of such stones are often present, frequently the gall-bladder being packed to capacity. On section each is found to be laminated ——→ The central nucleus may contain epithelial debris and bacteria,

which suggests that the cause in that particular case is inflammatory. Whatever the composition of the central core, alternating layers of cholesterol and calcium carbonate and/or calcium bilirubinate are deposited upon it.

Gas in Gall-stones.—Rarely, the centre of a stone may contain radiolucent gas in a tri-radiate or bi-radiate fissure and this gives rise to characteristic dark shapes on X-ray—the *Mercedes Benz* or *Seagull* signs viz. ⟶

Limey bile.

'Lime-water' bile is revealed in a plain radiograph (fig. 973) more clearly than if the gall-bladder has been visualised by cholecystography. The opacity is the result of the gall-bladder becoming filled with a mixture of calcium carbonate and calcium phosphate, usually the consistency of toothpaste. The condition always arises in conjunction with chronic infected cholecystitis and cystic duct obstruction, and organisms are rarely grown from the emulsion.

Incidence of Gall-stones.—A Fat, Fertile, Flatulent Female of Fifty is the classical sufferer from gall-stones.[1] Useful as is this clinical memorandum, it should be tempered with the knowledge that cholelithiasis occurs in both sexes, quite often at a much earlier age—even in childhood—and is more common in old age. Stones occur in 20 per cent. of women during the child-bearing period and in 20 per cent. of both sexes in old age.

Causal Factors in Gall-stone Formation

Certain factors are likely to be responsible for the formation of gall-stones. These are: (1) Metabolic; (2) Infective; (3) Bile stasis.

(1) *The metabolic factors* are concerned with the solubility of cholesterol in bile acids. The bile acids are produced in the liver from cholesterol itself. They have an affinity for the mother substance (cholesterol) and other fats, and also for water (i.e. they are amphipathic). This physico-chemical phenomenon is due to the aggregation of their molecules into *micelles* (fig. 987), along with phospholipids, which causes them to behave in the duodenum rather like modern fat-dissolving detergents used in the kitchen sink. The normal ratio of bile acid to cholesterol is 25:1. The critical level for precipitation of cholesterol is 13:1 (fig. 988). The amount of bile acid in the body is called the 'bile acid pool'. Reduction of all or one of the bile acid constituents of the pool may be related to dietary factors, e.g. excessive sucrose intake, liver damage, disease or removal of the ileum which interrupts the enterohepatic circulation of bile acids (Heaton), a Polya type of partial gastrectomy, and, locally, gall-bladder stasis or infection. Such a bile is 'lithogenic' and cholesterol is likely to be thrown out of solution.

Bile pigment stones commonly follow the *excessive haemolysis* that occurs in types of hæmolytic anæmia, e.g. acholuric jaundice, septic hæmolysis and malaria.

(2) *Infection.*—Organisms are frequently found in gall-stones (streptococci, coliforms, typhoid, actinomyces), and have long been blamed as a cause. They reach the gall-bladder via the blood-stream, from a focus of infection elsewhere (tonsils, bowel, dental tartar, and caries) or from the bowel via the lymphatics, and cause an exudation from, and an exfoliation of, the mucosal cells to act as a nidus on which the stone forms. There is some truth in Moynihan's aphorism that 'a gall-stone is a tombstone erected to the memory of the organism within it'. *Infestation* with a round worm (Ascaris) is a cause of stones being formed around ova in the common bile duct. Other foreign bodies like rolled-up plum or tomato skins have been found in the centres of stones. In one case, a lady swallowed a few pins (deliberately) and one turned up in a gall-bladder stone 5 years later (Harman).

---

[1] It is a sign of the times, and a signpost to causation that gall-stones are being seen increasingly in Postpartum Primipara who were Prepregnancy 'Pill' takers (contraceptive pill).

Kenneth Willoughby Heaton, Contemporary. Lecturer in Medicine, Bristol, England.
Berkeley George Andrew Moynihan, (Lord Moynihan), 1865–1936. Professor of Clinical Surgery, Leeds, England.
Michael John Harman, Contemporary. Radiologist, Essex County Hospital, Colchester, Essex, England.

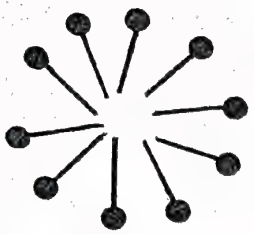


FIG. 987.—Diagram representing a spherical micelle formed by aggregation of bile-acid molecules. The rounded end of each molecule is water-loving (hydrophilic), whilst the stick-end is the hydrophobic part to which the water-insoluble cholesterol is adsorbed.

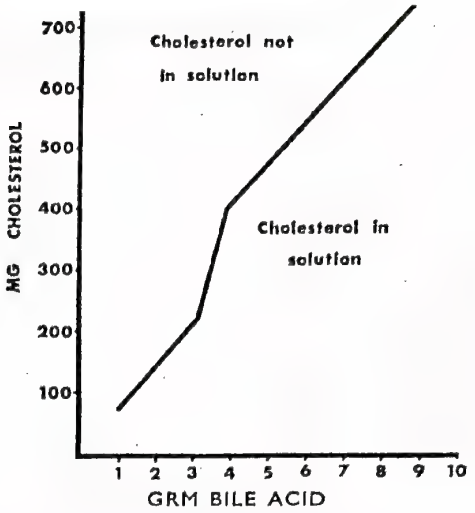

FIG. 988.—Solubility of cholesterol in bile acids.

(3) *Bile Stasis.*—Without some kind of stasis, stones would not grow to the sizes commonly found. They would be voided while still in a particulate or gravel form. Stasis is usual during pregnancy and this, rather than hypercholesteræmia, may explain the increased incidence of stones in multipara. Also in the gall-bladder, the incoming bile tends to form layers owing to differences in specific gravity (fig. 971). At the interface between layers, the solubility of cholesterol is disturbed.

GALL-STONES IN RELATION TO OTHER DISORDERS

Saint's Triad.—(i) Gall-stones, (ii) Diverticulosis of the colon, and (iii) Hiatus hernia frequently coexist. Possibly obesity is the common factor. It is important to find out which lesion is the cause of the patient's dyspeptic symptoms.

The Cardiac Link.—When the heart is the seat of a proclaimed or a latent disorder, vagal reflexes from a diseased gall-bladder may bring about decreased coronary blood flow, arrhythmia or heart-block; the 'cholecystic heart'. Electrocardiographic abnormalities without other evidence of cardiac disease often revert to normal following removal of a diseased gall-bladder. Likewise, patients with angina pectoris, and pseudo-angina have benefited. These sufferers should be advised to undergo cholecystectomy, not only because of possible improvement of the cardiac condition, but to avoid an operation at a later date, when circumstances may be less favourable.

THE EFFECTS AND COMPLICATIONS OF GALL-STONES

Gall-stones are usually found in the gall-bladder, but in 20 per cent. of cases stones will also be present in the bile ducts. Nearly always it is just one stone amongst many which is responsible for the patient's suffering. The effects and complications of gall-stones can be summarised as follows:

1. **In the gall-bladder**—Silent stones.
   —Flatulent Dyspepsia.
   —Gall-stone Colic.
   —Mucocele.
   —Acute cholecystitis { perforation→peritonitis. / gangrene. / penetration→fistula. / empyema.
   —Chronic cholecystitis→acute cholecystitis.
   —Carcinoma.

Charles Frederick Morris Saint, 1886–1973. Emeritus Professor of Surgery, Cape Town, South Africa.

2. **In the bile ducts** —Obstructive jaundice. Liver failure. White bile
—Acute or recurrent pancreatitis.
—Cholangitis.

3. **In the intestine** —Acute intestinal obstruction (p. 1001).

Silent Gall-stones.—It is possible for a calculus or calculi to be present in the gall-bladder and to give rise to no symptoms during a long lifetime. At least 8 per cent. of necropsy subjects of over fifty years of age have gall-stones in the gall-bladder that have not contributed to the cause of death. As 10 per cent. of gall-stones are radiopaque, they may be discovered accidentally on X-ray for another condition, e.g. by an X-ray to determine whether a rib is fractured. Cholecystectomy should be advised on account of the likelihood of complications, particularly when a cholecystogram reveals a non-functioning gall-bladder, or the stones are large and obviously fill a gall-bladder devoid of function. A follow-up of 112 patients with symptomless gall-stones in the gall-bladder found on routine examination at the Mayo Clinic showed that 51 developed symptoms within a few years.

Flatulent Dyspepsia.—Apart from gall-stone colic, stones in the gall-bladder may be related to flatulent dyspepsia. This relationship is uncertain as only about 70 per cent. of patients with these symptoms are relieved by cholecystectomy. The symptoms include a feeling of fullness after food, belching and heartburn—all worse after a large or fatty meal, and they occur also in people with a normal cholecystogram. A thorough investigation of other organs is necessary, especially to rule out œsophageal hiatus hernia, and as far as possible, chronic pancreatitis (p. 917).

Gall-stone Colic.—Suddenly the patient experiences excruciating pain across the upper part of the abdomen.[1] The pain may shoot to the back or between the shoulder-blades. In severe cases it 'doubles her up', and she rolls in agony on the floor. The attack, which lasts for upwards of two hours and is often accompanied by vomiting and retching, passes off nearly as suddenly as it came. Colic usually occurs at night, as in the horizontal position small calculi tend to congregate at the neck of the gall-bladder.

Occasionally the acute pain lasts longer, and the patient abandons hope. Sir Walter Scott, after an attack lasting many hours, 'called his family, and bidding them farewell, turned his face to the wall to await death. Nevertheless, next morning he was up betimes and in fair spirits'.

Physical Signs.—It is impossible to examine the abdomen satisfactorily during an attack of colic. Exceptionally palpation reveals an enlarged gall-bladder.[2]

Murphy's Sign.[3]—If continuous gentle pressure is exerted over the right hypochondrium while the patient takes a deep breath, there is a 'catch in the breath' just before the zenith of the inspiration.

---

[1] The biliary apparatus is bilaterally innervated, and pain may be under the right costal margin and left costal margin. In 4 per cent. of cases it is under the left costal margin alone.

[2] Sir Zachary Cope, 1881–1975. Surgeon, St. Mary's Hospital, London, described feeling his own tense gall-bladder during colic, and before the onset of the signs of acute cholecystitis (p. 891).

[3] This sign is also named after Bernard Naunyn, 1839–1925, Professor of Medicine, Strasbourg, who described it in 1890, thirteen years before Murphy.

The Mayo Clinic, Rochester, Minnesota, U.S.A. (*see footnote, p. 631*).
Sir Walter Scott, 1771–1832. Scottish poet, and master of the romantic historical novel.
John Benjamin Murphy, 1857–1916. Professor of Surgery, North-western University, Chicago, U.S.A.

Jaundice follows an attack of gall-stone colic in 18 per cent. of cases, and mostly is due to a stone obstructing the common bile duct.

Radiography.—A plain X-ray will show radiopaque stones in 10% of cases. A cholecystogram is delayed for about three days after an attack of colic because liver function is depressed, and it is valueless if there is jaundice (more than 3 mg/100 ml serum bilirubin).

Treatment:

(*a*) **Of Gall-stone Colic.**—Morphine alone is undesirable as it causes spasm of the sphincter of Oddi (p. 915). Pethidine,[1] also causes spasm. It is essential to give an antispasmodic drug (e.g. atropine or promethazine hydrochloride) before or with the analgesic drug. In most cases heat may relieve the pain, and in old-standing cases a brown pigmentation of the skin over the right hypochondrium tells of frequent hot applications.

(*b*) **Subsequent Treatment.**—Once a patient has had gall-stone colic, no question arises as to the treatment that should be recommended: it is *cholecystectomy*, unless the patient is very old or otherwise enfeebled, when *cholecystostomy* may be substituted. In either case it is essential to examine the common bile duct by all means available for the presence of additional calculi and, if such are present, to remove them (pp. 882, 895).

Mucocele of Gall-bladder.—A mucocele develops as the result of obstruction of the neck of a sterile gall-bladder by a single stone; the contained bile is absorbed and replaced by mucus secreted by the gall-bladder. The organ is thin-walled and translucent and may contain a pint of mucus. The treatment is cholecystectomy.

Dissolving Gall-stones.—The daily oral administration of 1 g chenodeoxycholic acid as its sodium salt may dissolve some cholesterol-containing stones, but *not* when the gall-bladder is non-functioning or the stones are too many or too big or contain much calcium (indicating infection). The treatment, which is likely to cause gastrointestinal upsets and may be hepatotoxic, takes about two years and may have to be continued for life. The stones tend to recur if treatment is stopped.

CHOLECYSTITIS

Ætiology.—Cultures from excised gall-bladders and their contents show: *Contents.*—Bacteria are present in 35 per cent. of cases. *Wall.*—Bacteria are present in 65 per cent. of cases. e.g., *Esch. coli*, *streptococci*, *klebsiella*, *Salmonella paratyphi B*, *staphylococci*.

ACUTE CHOLECYSTITIS

Acute Obstructive Cholecystitis.—If a stone impacts in Hartmann's pouch or the cystic duct (fig. 989), the gall-bladder, especially if already the seat of chronic cholecystitis, becomes intensely inflamed with its mucous membrane swollen, and the wall thickened. Occasionally gangrene occurs in patches (fig. 990). The subsequent events are :

1. When a certain degree of distension of the gall-bladder has been reached, the mucous membrane tends to be lifted away from the sides of the

[1] Pethidine is known in Canada as demerol, and in the U.S.A. as demerol hydrochloride. Should the patient be taking a mono-amine oxidase-inhibitor drug for depression, pethidine is contraindicated as collapse can occur from a severe fall of blood pressure.

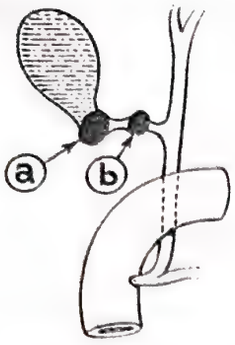

FIG. 989.—The sites of impaction of a gall-stone in acute obstructive cholecystitis: (*a*) In Hartmann's pouch. (*b*) In the cystic duct.

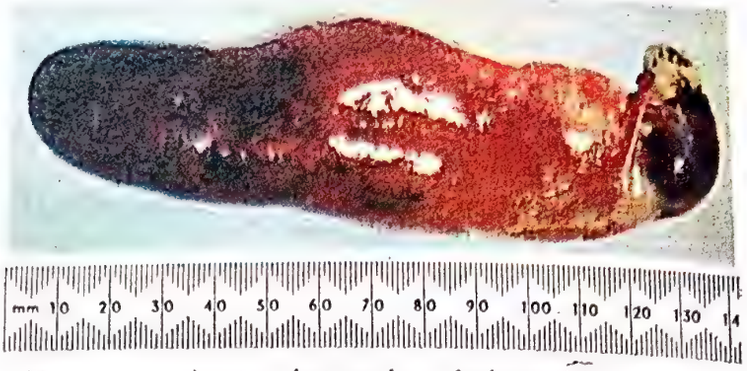

FIG. 990.—Acute obstructive cholecystitis. A stone has impacted in Hartmann's pouch. Gangrene is occurring.

stone and as a consequence the stone may slip back into the body of the gall-bladder, viz. ⟶ and any mucoid (from a mucocele—see above) or muco-purulent contents of the gall-bladder escape by way of the cystic duct.

2. Less frequently the impaction persists and an empyema (pyocele) of the gall-bladder results (p. 894).

3. On rare occasions the distended, inflamed gall-bladder perforates. Doubtless the infrequency of perforation is due to the thickened walls of an organ that has long been the seat of chronic cholecystitis.

Perforation of the Gall-bladder.—The site of perforation is either at the fundus, which is farthest away from the blood-supply, or, less commonly, at the neck from pressure necrosis of an impacted calculus. The sequelæ are:

(*a*) **Local Abscess.**—On account of the present, and probably past, attacks of cholecystitis, there are adhesions between the gall-bladder, the greater omentum, and the parietal peritoneum. Consequently, when an infected, obstructed gall-bladder perforates the usual outcome is a local abscess.

(*b*) **Perforation into the general peritoneal cavity** is uncommon, and the patient is usually a man. If the bile is infected diffuse peritonitis supervenes readily and rapidly, and the mortality is about 50 per cent. (Ellis). This catastrophe occurs in only 0·5 per cent. of cases undergoing conservative treatment for acute cholecystitis.

Internal Fistula of the Gall-bladder (see page 908).

Acute non-obstructive cholecystitis is less frequent than the obstructive variety. All grades of acute inflammation, from catarrhal to gangrenous cholecystitis, occur. In fulminating cases *Cl. welchii* may be implicated. Typhoid and paratyphoid cholecystitis also occur. Perforation is exceptional, save in acute typhoid cholecystitis.

Clinical Features of Acute Cholecystitis.—The onset is sudden, and pain—agonising in the obstructive variety, more gradual in the non-obstructive—is located mainly in the right hypochondrium. Severe nausea and vomiting are features in the early stages. Pyrexia, sometimes to 38° C. or more, is usual; occasionally fulminating cases are ushered in by rigors.

On examination tenderness and rigidity are found in the right hypochondrium. If the patient can be persuaded to relax, a mass consisting of the inflamed gall-bladder with adherent greater omentum attached may be felt,

Harold Ellis, Contemporary. Professor of Surgery, Westminster Hospital, London.

particularly in obstructive cases. In mucocele of the gall-bladder pyrexia is absent and a piriform swelling can be palpated in the right hypochondrium.

Differential Diagnosis.—The differential diagnosis between high retrocæcal acute appendicitis and acute cholecystitis and a leaking duodenal ulcer is often difficult, and when there is doubt, conservative treatment (see below) is not advised. Acute pancreatitis must be excluded by all means possible (p. 914). It is also necessary to eliminate acute pyelonephritis, and other infections of the right kidney. In relevant cases an electrocardiograph should be taken to differentiate acute cholecystitis from coronary thrombosis.

Boas's sign, if positive, is sometimes most helpful in distinguishing acute cholecystitis from other conditions. There is an area of hyperæsthesia between the ninth and the eleventh ribs posteriorly on the right side.

Radiography.—*A plain radiograph* may be negative (p. 891). In children the calculi are usually opaque (Forshall). *Oral cholecystography* is usually carried out when the acute phase is subsiding. A non-filling gall-bladder supports the diagnosis of cholelithiasis. The rare presence of gas[1] in the gall-bladder is due to infection with *Cl. welchii* and operation should be performed without delay. Gas in gall-stones is described on page 888.

Treatment:

(*a*) **Conservative Treatment followed by Cholecystectomy.**—Experience shows that in more than 90 per cent. of cases the symptoms of acute cholecystitis subside with conservative measures. Non-operative treatment is based upon four principles:

1. *Rest to the inflamed gall-bladder* and the biliary and pancreatic systems by gastric aspiration for three to five days. Nothing is given by mouth. Fluid and electrolyte balance are maintained by continuous intravenous dextrose-saline solution, with the usual precautions (p. 89).

2. *Analgesics.*—The recommendations are given on p. 915.

3. *An anticholinergic drug* is given to reduce gastric and pancreatic secretion, and therefore loss of electrolytes by aspiration, and to relax the sphincter of Oddi. Propantheline is probably the most satisfactory for this purpose.

4. *Antibiotics* of the tetracycline group reach the interior of the gall-bladder *via* the blood-stream even in the presence of occlusion of the cystic duct. These drugs may be given intramuscularly, but oral administration should be commenced as soon as the patient is permitted to take fluids by mouth.

5. *Subsequent Management.*—When the temperature, pulse, and other physical signs show that the inflammation is subsiding (usually by the third day), after the bowels have been emptied, e.g. by a suppository, the gastric aspiration tube is removed, and, commencing with flavoured dextrose drinks, fat-free clear fluids are given for one day, and a soft fat-free diet on the next. A full fat-free diet is then given. A cholecystogram is performed about two weeks later (see Radiography, above). Eight to ten weeks after the acute symptoms have subsided *cholecystectomy* is carried out.

Conservative treatment is not advised (*a*) when there is uncertainty

[1] The causes of air (or gas) in the bile ducts or the gall-bladder are: (i) following operative choledocho-duodenostomy (p. 902), (ii) following cholecyst-duodenostomy, or a stone perforating into the duodenum (p. 907), and (iii) rarely, the presence of gas-forming organisms.

Ismar Isador Boas, 1858–1938. Gastroenterologist, Augusta Hospital, Berlin.
Isabella Forshall, Contemporary. Formerly Surgeon, Royal Liverpool Children's Hospital, Liverpool, England.

about the diagnosis, e.g. when early high retrocæcal appendicitis or a leaking duodenal ulcer cannot be excluded, (*b*) in typhoidal cholecystitis, because of the frequency of perforation in these cases.

Conservative treatment must be abandoned: If the pain and tenderness spreads across the abdomen and the pulse-rate rises. Cholecystectomy should be undertaken forthwith. In the very ill and the elderly patient it may be advisable to limit the operation to *cholecystostomy*[1]—usually a dependable, safe operative procedure (p. 895).

(*b*) **Routine Early Operation.**—Some surgeons advocate urgent operation as a routine measure in cases of acute cholecystitis. Provided the operation is undertaken within forty-eight hours of the onset of the attack, the surgeon is experienced and excellent operating facilities are available, good results are obtained, but no better than those that accrue from the delayed method described above which is associated with far fewer operative injuries to the main ducts.

It is not proposed here to enter into a controversy on the merits and demerits of early and delayed operation for acute cholecystitis, but to state categorically that the most dangerous period for operation is between the seventh and fourteenth days of the attack. Should operation become imperative during this period, when the ducts are often obscured by œdema and immature fibrous tissue and the liver function is at a low ebb, it is often prudent to perform a simple cholecystostomy (p. 895) rather than a difficult cholecystectomy (see footnote p. 900).

Empyema of the Gall-bladder.—This is a curious condition in which an inflamed, obstructed gall-bladder becomes filled with creamy 'pus'. This 'pus' is really a cream of calcium carbonate, cholesterol crystals, and epithelial cells, and may be sterile on culture. The treatment is cholecystectomy.

Chronic Cholecystitis.—The gall-bladder wall is thickened, with loss of the normal mucous membrane pattern. Stones may or may not be present. Many of these gall-bladders are examples of the cholecystoses (see below). Calcification of the wall of the gall-bladder (porcelain gall-bladder fig.972) is uncommon. Patients with chronic cholecystitis may present with biliary dyspepsia and be diagnosed by cholecystography, or they develop acute cholecystitis.

Typhoid Gall-bladder.—Typhoid carriers 'harbour' living *Salmonella typhi*[2] in their gall-bladders and their gall-stones.[3] The organisms are discharged into the alimentary tract from time to time, and are present in the fæces. Cholecystectomy in such cases may rid the patient of the infection, and the community of a potential danger. The patient must be 'barrier nursed', and given a course of ampicillin. In conjunction with the Public Health Authorities, the patient is kept in an isolation hospital until it has been proved over a sufficiently long period that the fæces are *Salmonella typhi* free.

THE CHOLECYSTOSES

(Cholesterosis, Polyposis, Adenomyomatosis, Cholecystitis Glandularis Proliferans)

This is a not uncommon group of conditions affecting the gall-bladder in which there are chronic inflammatory changes with hyperplasia of all the tissue elements. Endocrine, metabolic, and dyskinetic factors have been

[1] Elective cholecystectomy is still indicated in due course, in suitable patients. Cholecystostomy may relieve all symptoms, but some patients continue to suffer, and they may have an intermittent mucopurulent discharge from the drainage wound.

[2] 'Typhoid Mary', a cook-general who passed *Salmonella typhi* in her fæces and urine, was responsible for nearly a score of epidemics of typhoid in and around New York City.

[3] Surgeons should not give patients their stones after operation if there is any suspicion of typhoid!

Daniel Elmer Salmon, 1850–1914. Veterinary Pathologist, Chief of the Bureau of Animal Industry, Washington, D.C., U.S.A.

suggested as the cause of the hyperplasia. Malignant change does not occur.

Cholesterosis (*syn.* **Strawberry Gall-bladder**).—In the fresh state the interior of the gall-bladder looks something like a strawberry; the yellow specks (submucous aggregations of cholesterol crystals and cholesterol esters) correspond to the seeds (fig. 991). The presence of macrophages stuffed with the esters (foam cells) indicates that the condition is inflammatory in nature and not, as previously thought, an expression of hypercholesteræmia and cholesterol excretion. Cholesterosis *per se* is symptomless. Symptoms, if any, are generally due to associated gall-stones or cholecystitis. Cholesterosis is often accompanied by one or more cholesterol stones, supposedly derived from the deposits in the mucous membrane. On cholecystography the concentration of the contrast medium is frequently very dense and the edge of the gall-bladder may appear slightly blurred.

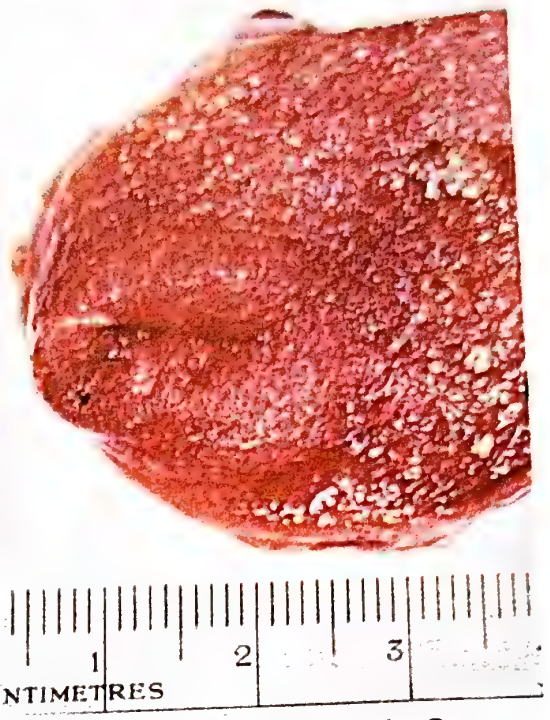

FIG. 991.—The interior of the Strawberry gall-bladder.

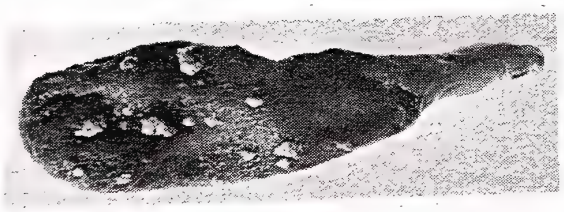

FIG. 992.—Cholesterol polyposis.
(D. J. Oakland, F.R.C.S., Hereford.)

Cholesterol Polyposis of the Gall-bladder (fig. 992).—Cholecystography shows negative shadows in a functioning gall-bladder. The shadows, which are adjacent to the wall of the gall-bladder, remain constant in position and in relation to one another in all films of the series. Histologically, cholesterol polyposis is similar to the cholesterol-laden projections of the strawberry gall-bladder, but the lesions are much less numerous and are relatively gigantic. The treatment is cholecystectomy.

Cholecystitis glandularis proliferans (polyp, adenomyomatosis, and intramural diverticulosis). Fig. 993 summarises the varieties of this condition. A polyp of the mucous membrane is fleshy and granulomatous. All layers of the gall-bladder wall may be thickened, but sometimes an incomplete septum forms which separates the hyperplastic from the normal. Intraparietal 'mixed' calculi may be present which can be complicated by an intramural and, later, an extramural abscess. *Diverticulosis of the gall-bladder* is usually manifest as black pigment stones impacted in the outpouchings of the normal lacunæ of Luschka. Diverticulosis of the gall-bladder may be demonstrated by cholecystography, especially after the gall-bladder contracts after a fatty meal: there are small dots of contrast medium just outside the gall-bladder (fig. 994). A septum may also be present (to be distinguished from the Phrygian cap—fig. 981). The treatment is cholecystectomy.

CHOLECYSTECTOMY AND CHOLECYSTOSTOMY

1. **Preparation for Cholangiography** (p. 881).—Provision is made for per-operative cholangiography by placing the patient on an operating table

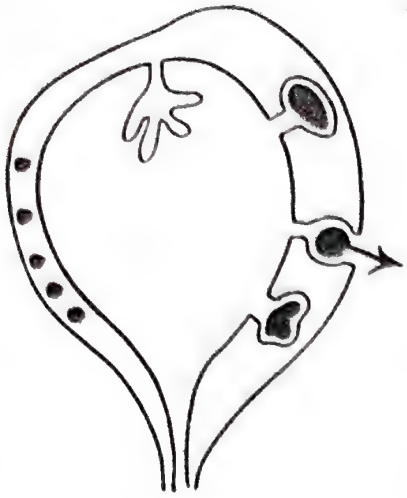

FIG. 993.—Types of cholecystitis glandularis proliferans (polypus, intramural or diverticular stones, and fistula).

FIG. 994.—Cholecystogram showing cholecystitis glandularis proliferans.

equipped with a radiolucent top, so that X-ray exposures may be made without disturbance (fig. 976, p. 882). If the table is not so equipped, a cassette holder and film is placed beneath the patient at the appropriate level. Some tables are designed for the use of an X-ray image-intensifier and television control so that the surgeon can see what is happening while he injects the contrast medium (fig. 979, p. 883).

Routine cholangiography is preferable to haphazard periodic attempts. It may be omitted in acute cholecystitis.

2. **Laparotomy.**—A right paramedian or rectus splitting incision is satisfactory. It has the advantage of extensibility.[1] After the peritoneum has been opened, the gall-bladder and the common bile duct are inspected and palpated.

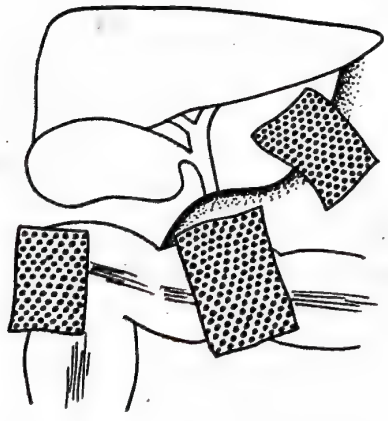

FIG. 995.—Cholecystectomy. Positions of the packs after identifying the colon, the duodenum and the stomach.

N.B.—It is essential before commencing a standard cholecystectomy to examine the other abdominal organs. By so doing the writer has discovered an early carcinoma of the stomach, and on two occasions one in the colon. Naturally resection of the growth takes precedence to cholecystectomy, although in favourable cases this may also be possible.

3. **Cholecystectomy.**—The area is now isolated with packs (fig. 995). If the gall-bladder is greatly distended, it is aspirated through the fundus by means of a trochar and cannula attached to a suction apparatus. The fundus is then grasped with sponge-holding forceps, thereby sealing the puncture. These forceps, and another pair applied to the neck of the gall-bladder, serve as excellent tractors.

[1] Big surgeons make big incisions.

Then the very important dissection to display the junction of the cystic, the common hepatic, and the common bile ducts is commenced.[1] During the course of this dissection the cystic artery is found, and its relation to the common hepatic artery verified (p. 879). The artery is then divided between ligatures at least 5 mm away from the hepatic duct (fig. 996). Cholangiography (p. 881) is performed at this stage. The cystic duct is then ligated. Forceps are applied to the gall-bladder side and cystic duct is divided. From below, upwards, the gall-bladder is dissected from its bed, dividing the peritoneum on the gall-bladder (fig. 997). The gall-bladder having been removed and hæmostasis assured, the abdominal wall is closed with drainage of the operation instituted via a separate ' stab ' wound.

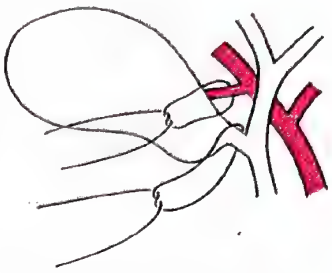

FIG. 996.—Ligatures are passed and tied round the cystic artery and cystic duct.

Modifications of the operation under various difficult circumstances are to be found in special monographs on the subject.

A cholecystohepatic duct (fig. 981(*e*)), is present in about 0·5 per cent. of cases, and is usually the size and colour of No. 60 thread. Its possible presence must be remembered when separating the gall-bladder from its bed, and, if recognised in time, it can be ligated. If avulsed from the liver, a persistent ooze of bile occurs from the ruptured end, which should be sutured.

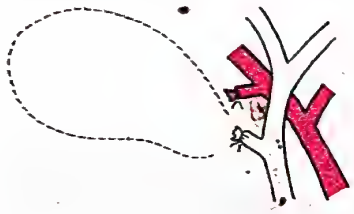

FIG. 997.—The gall bladder has been removed.

Cholecystostomy.—The gall-bladder is displayed through a suitable incision, and the fundus isolated by packs. Two stay sutures are inserted on either side of the fundus, in order to steady the organ, the fluid contents of which are aspirated. The fundus is opened and stones are removed from the interior by Desjardins' forceps, aided, always, by a finger milking up a stone or stones from Hartmann's pouch. Minute calculi are often dislodged by strips of dry gauze passed into the interior. A 6-mm drainage tube is passed into the gall-bladder, and there retained by a transfixion stitch. The opening in the gall-bladder is closed about the tube. The tube is brought through a portion of greater omentum, which is anchored to the gall-bladder by the original stay sutures. The tube is then brought to the surface through a separate stab incision. The abdominal incision is closed, and the tube is joined by a connection to more tubing, which leads to a sterile polythene bag. Seven to ten days later Hypaque injected down the tube may be seen on X-ray to flow easily into common bile duct and duodenum if no obstruction exists, in which case removal of tube will be followed by closure of the biliary fistula within a week.

Bacteriology at Operation.—At every biliary operation cultures are taken of the bile and, if removed, from the gall-bladder wall (p. 891). In acute inflammatory disease a broad spectrum antibiotic will be needed immediately and changed subsequently according to the bacterial sensitivity report (see Sepsis, Chapter 1).

Indications for Choledochotomy following Cholecystectomy (above).—In the absence of peroperative cholangiography, opening and exploring the common bile duct is indicated when: (1) Stones can be felt in the ducts. (2) There is jaundice or a history of jaundice, or rigors. (3) A dilated common bile duct (10 mm diameter or more) is present and particularly if the cystic duct is dilated (implying that stones may have migrated from the gall-bladder to the common duct). (4) Intravenous cholangiogram has shown the presence of a stone. Choledochotomy is described on p. 900.

---

[1] ' It is the left hand of my assistant that does all the work ' (Moynihan). By splaying the fingers to depress the stomach and duodenum, he displays the biliary ducts, aided also by retraction of the quadrate lobe of the liver.

Abel Desjardins. Surgeon, Dispensaire Henri de Rothschild, Paris.

SYMPTOMS PERSISTING AFTER CHOLECYSTECTOMY

In 15% of all cases, cholecystectomy fails to relieve the symptoms for which the operation was performed. The term 'post-cholecystectomy syndrome' should be abandoned. The symptoms are most commonly due to disease of organs other than the biliary tract, such as hiatus hernia, duodenal ulcer, or pancreatitis. If these can be eliminated, one of the following lesions of the biliary tract must be considered:

1. A stone in the common bile duct escaped detection at the original operation.
2. When a comparatively long stump of a cystic duct has been left behind as frequently happens where the cystic duct joins the common bile duct lower than usual (fig. 981(*d*)). This diverticulum may enlarge considerably and may harbour infection. Calculi may form therein.
3. Operative damage to the common bile duct occurred, resulting in stricture of that duct (p. 902).
4. The cause of the original symptoms was biliary dyskinesia (p. 882).

Treatment.—Intravenous cholangiography (p. 881) is valuable in determining the cause which, if possible, is removed.

GALL-STONES IN THE BILE DUCTS

In addition to those in the gall-bladder and cystic duct (p. 855), stones may be present in the common bile duct, the common hepatic and the intrahepatic ducts. They may originate from the gall-bladder, having negotiated their way by a process of dilatation of the cystic duct. Those formed primarily in the hepatic or common ducts may range from large concretions down to sludge. A number may contain a nucleus around which bile pigment and cholesterol have been deposited (e.g. rolled-up fruit skins, ascaris ova or flukes (p. 888)).

Clinical Features.—Usually there is a long history of flatulent dyspepsia, not infrequently punctuated by episodes of biliary colic.

Pain.—There is no fundamental difference between the biliary colic described already (p. 890) and that occasioned by a stone becoming impacted in the common bile duct. In the latter instance the pain is likely to be prolonged, severe, and difficult to relieve, and is followed by jaundice.

Jaundice.—Within forty-eight hours the pain is followed by jaundice, the tinge of which ranges from pale lemon to bright orange. The urine becomes dark with bile, and the fæces become pale. The skin commences to itch, sometimes intolerably. The patient loses weight.

Abdominal Examination.—Usually, soon after the attack of colic, tenderness can be elicited in the epigastrium. As a rule the gall-bladder is impalpable.

Courvoisier's 'Law' [1] states that if in a jaundiced patient the gall-bladder is palpably enlarged, it is probably *not* a case of stone impacted in the common bile duct, because in that case previous cholecystitis has already made the gall-bladder fibrotic.

Sometimes it happens that after an attack of biliary colic, followed by fleeting jaundice, the patient remains well for many months. More often

[1] Courvoisier only made a statement of probability (approximately in 75% of cases). Posterity unwisely considered it a 'law'.

Ludwig Courvoisier, 1843–1918. Professor of Surgery, Basle, Switzerland.

than not, after a varying interval another similar attack occurs, and it is sometimes presumed that another gall-stone has entered the common bile duct. But this is not necessarily the case; it is likely that the same stone has again caused obstruction.

Charcot's biliary triad.—Fluctuating jaundice, recurrent pain, and intermittent fever with rigors[1] constitute this triad. A stone becomes impacted but floats free when the duct dilates, and subsequently impacts again.

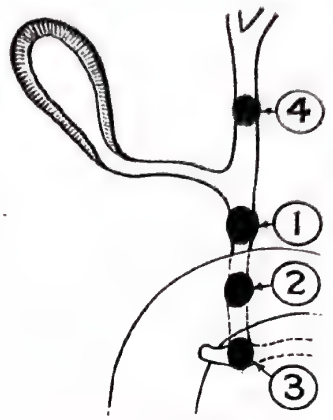

FIG. 998.—Sites of stone impaction. 1. Stone impacted in the supraduodenal portion of the common bile duct (commonest site).
2. Stone impacted in the retroduodenal portion of the common bile duct (second most common site).
3. Stone impacted in the ampulla of Vater (about 10 per cent. of cases).
4. Stone impacted in the common hepatic duct (rare).
Note that the gall-bladder is usually thick-walled and contracted because of chronic cholecystitis (Courvoisier's Law, above).

Atypical Cases:

1. **Jaundice from Pressure of a Stone on the Duct from Without.**—Jaundice can arise from a large calculus in Hartmann's pouch or extrabiliary pathology pressing upon the common bile duct.

2. **Jaundice is the First Symptom.**—In about 3 per cent. of individuals jaundice is the first and only symptom.

3. **Stone in the Common Bile Duct without Jaundice.**—Stones may lie dormant for many years in the common bile duct, giving rise only to vague indigestion.

Differential Diagnosis.—Calculous biliary obstruction is a very frequent cause of jaundice encountered in surgical practice (fig. 999). It is important to differentiate a stone in the common duct from virus hepatitis (p. 853) and carcinoma of the pancreas (p. 925).

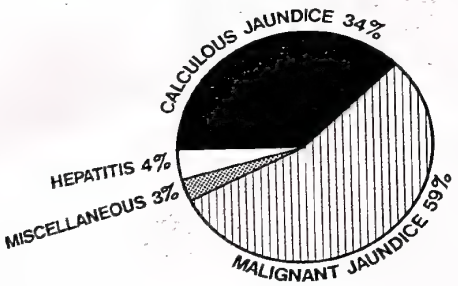

FIG. 999.—Incidence of jaundice in surgical practice (The London Hospital Surgical Unit, 1964–1973, 197 cases).

Laboratory investigations are described on p. 850.

Complications.—If the obstruction is not relieved, one of four (three dangerous) sequelæ ensues:

1. **Liver Function becomes increasingly impaired.**—When liver function becomes seriously depressed, as evinced by the finding at operation of 'white bile' in the bile passages above the site of an impacted calculus, the outlook is serious, but not hopeless, as a brisk recovery often takes place. However, jaundice due to stone lasting for over four weeks tends to cause liver damage, and the operative mortality rises.

[1] In Britain the two common causes for rigors are urinary and biliary obstruction with infection. In equatorial regions, malaria is the commonest cause.

Jean Martin Charcot, 1825–1893. Physician, Hôpital Salpêtrière, Paris.

'White Bile'.—The phenomenon occurs following obstruction of the common bile duct or the common hepatic duct, usually (but not always) when the gall-bladder is absent or not functioning. White bile is mostly mucus derived from the glands lining the ducts, to which has been added a minute amount of cholesterol, and either only traces of bile salts, or none. The term 'white bile' is a misnomer, since it is not bile derived from the liver but mucus, for the liver fails to excrete due to cellular damage or mounting pressure within the bile ducts; also it is not white but opalescent.

2. **Suppurative Cholangitis Supervenes.**—This is a dangerous complication, causing liver failure and death and requires timely surgical intervention and antibiotic therapy (p. 16).

3. **The gall-stone ulcerates through the wall of the common bile duct** and diffuse bile peritonitis supervenes. The perforation may be minute and difficult to find and sometimes occurs into the retroperitoneal tissues. The treatment is to drain the common bile duct, and also the general peritoneal cavity or the retroperitoneal tissues, as the case may be.

4. On rare occasions (as subsequently revealed at necropsy) a stone in the common bile duct ulcerates into the duodenum, and a natural cure follows.

MANAGEMENT OF BILIARY OBSTRUCTION DUE TO STONE

To commence with, a high intake of dextrose is essential to build up the store of liver glycogen, and also to protect the liver.

If the Jaundice Abates.—The depth of the jaundice may diminish, the raised bilirubin level becomes constantly lower, and the stools become increasingly coloured. Such a train of events implies disimpaction of the stone, or possibly the passage of a small stone into the duodenum. In such circumstances diagnostic intravenous cholangiography can be undertaken and laparotomy performed if stones are still present.

If the Jaundice does not Abate.—If the jaundice is found to be increasing rather than decreasing, and particularly when any degree of jaundice is accompanied by pyrexia, operation should be planned to take place within two or three days.

Jaundiced patients tend to ooze from a cut surface. This tendency to bleed may be due to a diminution of prothrombin in the blood, resulting from failure of absorption of vitamin K_1 which is consequent upon diminution of bile salts in the alimentary canal. To raise the prothrombin level in the blood, the patient is given vitamin K analogue (menapthone B.P.) 10 mg twice daily i.m., or vitamin K_1 (phytomenadione) 10 mg, i.m. or i.v. (in an emergency). Blood transfusion is another important ancillary. Antibiotics are given (see p. 897). *Mannitol* (p. 77) may be given intravenously to promote a diuresis and to prevent the renal failure which is a cause of mortality.

In patients who are deeply jaundiced, or who show signs of suppurative cholangitis, operation may be limited in the first instance to draining the common bile duct (choledochotomy), and removing a stone or stones only if they are readily accessible. When the patient has recovered[1] the subsequent elective procedure can be planned.

Choledochotomy.—If a stone (or stones) is present in the common bile duct, its removal should have priority over cholecystectomy. Should the patient be unfit for cholecystectomy, or even cholecystostomy, the gall-bladder should be removed on a future occasion.

---

[1] A living problem is better than a dead 'cert'. (Grey Turner).

George Grey Turner, 1877–1951. Professor of Surgery, Postgraduate Medical School, London.

Supraduodenal Choledochotomy.—Most stones in the common bile duct can be removed by this route. If, as is often the case, a stone can be felt, an attempt is made to manœuvre it into a position midway between the entrance of the cystic duct and the superior border of the duodenum. The stone is steadied between the finger and thumb. The duct is opened longitudinally directly on to the stone, enabling it to be removed by a malleable scoop or Desjardins' gall-stone forceps. The interior of the duct is then explored upwards and downwards with the scoop for further stones.

When the stone cannot be felt, or cannot be manipulated into the optimum position just described, after incising the peritoneum overlying the common bile duct, a length of the underlying structure is displayed. (When there are numerous adhesions, and especially when the gall-bladder has been removed at a previous operation, it is sometimes difficult to be certain whether the structure in question is the common bile duct or the portal vein. Aspiration through a fine hypodermic needle connected to a syringe will settle this point.) As soon as about 2 cm of the common bile duct has been exposed, the duct is transfixed by two stay sutures and a longitudinal incision into the duct is made between them. Escaping bile is mopped up or removed by suction. Through this opening it may be possible to identify the stone and remove it with a scoop or forceps (fig. 1000). After removal of the stone or stones by either of the above methods the common bile duct is cleared of any mud or grit by 'milking' the duct, followed by irrigation with saline solution. The patency of the sphincter of Oddi is tested either by the passage of a sound (3 to 5 mm diameter), or by a confirmatory cholangiogram (p. 881).[1] Usually drainage of the common bile duct is carried out by means of a T-tube (fig. 1001).[2] The transverse limb, shortened if necessary to about 5 cm long, is inserted in the duct which is closed snugly about the vertical limb, using fine catgut on an atraumatic needle. The long limb is brought out through a separate stab wound and securely anchored to the skin. The bile draining from the tube is collected in a plastic bag by the side of the bed, its amount and character being noted. After 10 days the tube may be clamped for increasing periods, and the absence of pain and jaundice, the presence of bile in the stools indicate satisfactory flow into the duodenum. Hypaque is injected down the tube to obtain a cholangiogram (p. 882), and if there are not filling defects in a well-outlined duct, and the 'dye' enters the duodenum freely, the T-tube can be removed by a sharp pull. Subsequent bile drainage is minimal and does not usually persist for more than a day.

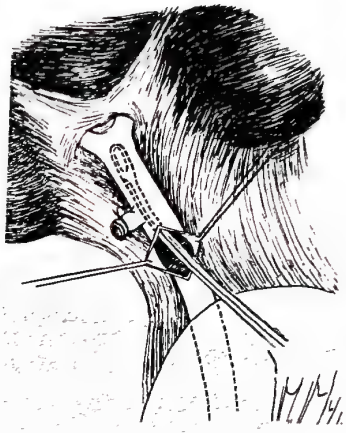

FIG. 1000.—Choledochotomy. The stone is seized with Desjardins' forceps.

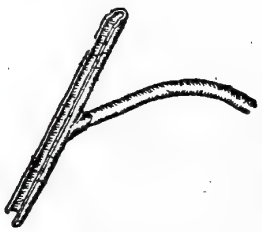

FIG. 1001.—T-tube for draining the common bile duct.

Closure of the Common Duct without a T-tube.—If this procedure is attempted, it is most necessary to provide drainage placed in apposition to the common duct.

Transduodenal Sphincterotomy is indicated when a stone is found to be impacted near the ampulla of Vater (fig. 1002) and it cannot be retrieved from above. Some surgeons prefer the method to supraduodenal choledochotomy.

The duodenum is opened in its second part by a transverse or longitudinal incision between stay sutures, and the region of the ampulla brought into the opening by traction using tissue forceps. Removal of the stone is either easy or requires the division of the duodenal papilla and the sphincter (fig. 1003).

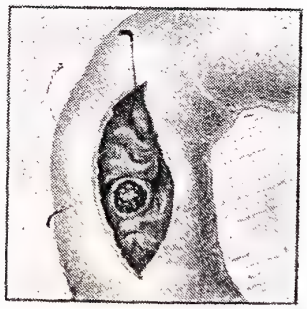

FIG. 1002.—The transduodenal approach to a stone impacted in the ampulla of Vater.

[1] It is estimated that 7 per cent. of patients with cholelithiasis have intrahepatic calculi in addition.

[2] T-tubes should be of latex or rubber and only used once. Plastic tubes are 'hardened' by the bile and are difficult to remove. Latex (and rubber) stimulate the fibrinous adhesion of omentum to liver and colon to form a safe track. There is little reaction to a plastic tube and therefore the risk of biliary peritonitis is greater.

Endoscopic Sphincterotomy and Gall-stone Removal.—Using diathermy, a sphincterotomy can be performed under endoscopic control in lightly sedated patients. Any gall-stones remaining in the bile duct when the patient is re-examined with

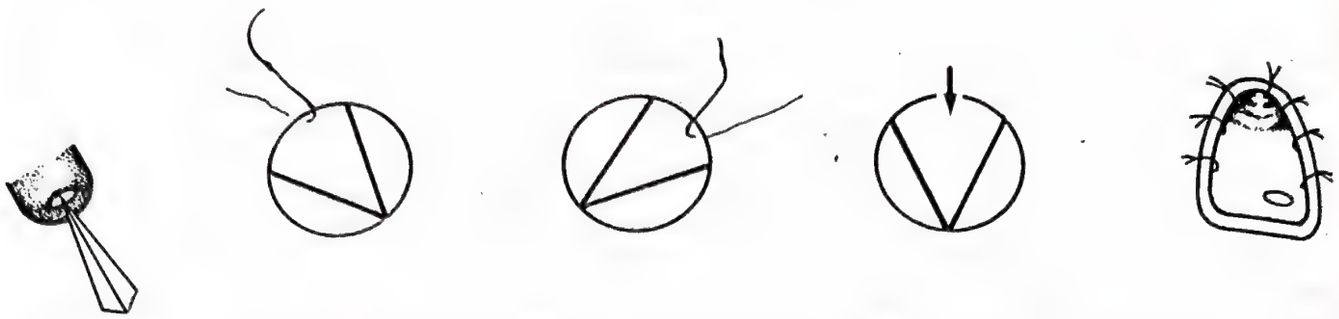

FIG. 1003.—Sphincterotomy.—A fine-pointed grooved director is introduced into the papillary opening. It is turned to 10 o'clock and a catgut suture traverses the duodenal and ampullary mucosæ. It is then turned to 2 o'clock and another suture is introduced. The director is turned to '12 noon' and an incision is made. This routine is repeated until a satisfactory opening is obtained. Care is taken to resite the director to avoid the pancreatic duct. The operation is concluded by tying the sutures (mucosa to mucosa).

(after R. Hunter, F.R.C.S.)

E.R.C.P. (p. 904), 7 to 10 days later may be removed under screening control, using a long Dormier type stone basket passed down the biopsy channel of the duodenoscope. This procedure may be of value in a small selected group of patients who are a poor operative risk due to age, medical illness or previous biliary surgery.

Choledochoduodenostomy is indicated when the common duct is grossly dilated because of an unresolved problem in the region of the biliary sphincter and papilla, e.g. due to stone, sludge, pancreatitis and papillary fibrosis, in the older patient where imprecise operative trauma to this delicate region is likely to be followed by acute pancreatitis. Also in overt carcinoma of the lower end of the bile ducts where palliation only is possible this operation is to be preferred to cholecystenterostomy when involvement of the cystic duct is imminent (see low insertion of cystic duct p. 884). The operation is contraindicated if the common duct is not 1 cm or more in diameter or it is impossible to make a stoma of 2–3 cm. The stoma is fashioned to extend as low as possible in order to reduce the collection of sludge in the 'sump' necessarily left in the retroduodenal portion of the duct. It must permit free entry and egress of fluid, for if it is large enough, regurgitant cholangitis does not occur and liver function is not impaired. The two openings are approximated with catgut, with several reinforcing fine silk sutures and a drain inserted (fig. 1004). The convalescence is usually surprisingly placid.

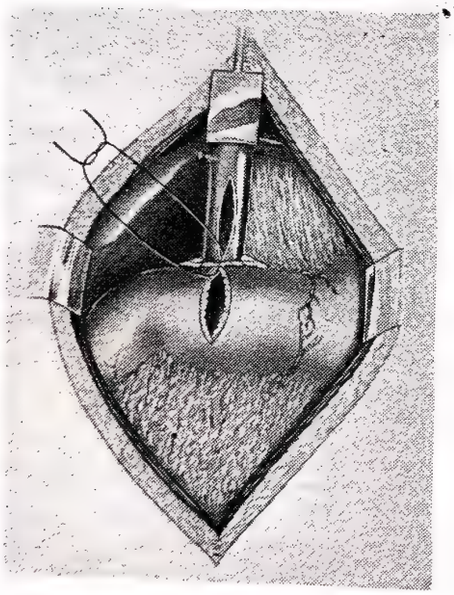

FIG. 1004.—Choledochoduodenostomy. The stoma must be 2–3 cm long.

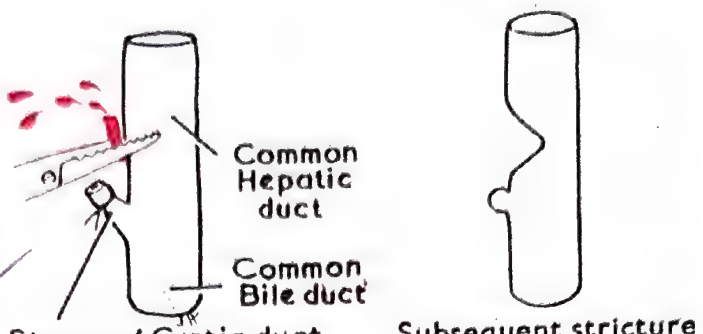
STRICTURE OF THE COMMON BILE DUCT < **BENIGN** < **Post-operative 80%** / **Inflammatory 20%**; **MALIGNANT** (p. 904)

Post-operative stricture concerns either the common bile duct or the common hepatic duct. In a few cases only the right hepatic duct is implicated. The stricture is the result of a preventable error in technique, during the performance of cholecystectomy:

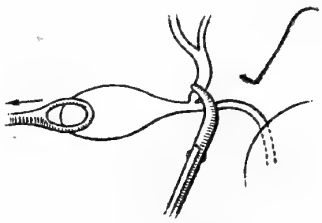
1. Blind plunge application of a hæmostat to a bleeding cystic or accessory cystic artery, or to the right hepatic artery, is likely to damage the common

hepatic duct, viz.



The prevention of this tragic happening is standardised. All unexpected hæmorrhage in this region should be controlled initially by inserting an index finger into the foramen of Winslow, and pinching the free edge of the gastro-hepatic omentum between the finger and thumb. Temporary compression of the hepatic artery in this way allows the bleeding-point to be visualised and ligated accurately (Hogarth Pringle's manœuvre).

2. Should cholecystectomy be performed by dissecting from the fundus (the fundus-first operation) too much traction applied to the freed gall-bladder may so tent the common bile duct that any forceps intended for the cystic duct grasp the angulated main channel,[1] viz.



3. Ignorance of the anatomical anomalies of the bile ducts (p. 884).

4. Laceration of the common bile duct while exploring it for stones or contracture of Oddi's sphincter.

5. In 3 per cent. of cases of stricture of the common bile duct, injury occurs during partial gastrectomy for a penetrating duodenal ulcer.

About 15 per cent. of injuries to the bile ducts are recognised at the time of the operation. In 85 per cent. of cases the injury declares itself post-operatively by: (*a*) a profuse and persistent discharge of bile if drainage has been provided, or bile peritonitis if such drainage has not been provided; (*b*) by deepening obstructive jaundice. When the obstruction is incomplete, jaundice is delayed until subsequent fibrosis renders the lumen of the duct inadequate.

Inflammatory strictures may result:

(1) From pooling of bile around the common bile duct, such as occurs after insecure ligation of the cystic duct during cholecystectomy or when the duct is improperly drained.

(2) Stenosis can also follow cholecystectomy or choledochostomy when the mucous membrane of the ducts is acutely inflamed (' red-hot ' duct).

(3) Occasionally stricture of one or more ducts (usually the hepatic ducts) occurs as a result of what is known as stenosing cholangitis, the ætiology or which is obscure.

(4) Asiatic cholangio-hepatitis (p. 906).

Radiological Investigation of Biliary Strictures

(1) Intravenous cholangiography (p. 881) with tomography may be helpful providing the serum bilirubin is less than 3 g/100 ml.

(2) Cholangiography *via* a T-tube if present.

(3) E.R.C.P. (see pp. 904 and 930).

(4) Transhepatic cholangiography.

[1] Forceps should not in fact ever be used for grasping the cystic duct prior to ligature (fig. 996).

Jacob Benignus Winslow, 1669–1760. Professor of Anatomy, Physic and Surgery, Paris.
James Hogarth Pringle, 1863–1941. Surgeon, Royal Infirmary, Glasgow, Scotland.

E.R.C.P.—Endoscopic Retrograde Cholangio-Pancreatography will demonstrate the entire biliary tree (fig. 1005) and will help to distinguish between a medical and a surgical cause of obstructive jaundice.

FIG. 1005.—E.R.C.P.: Normal cholangiogram.

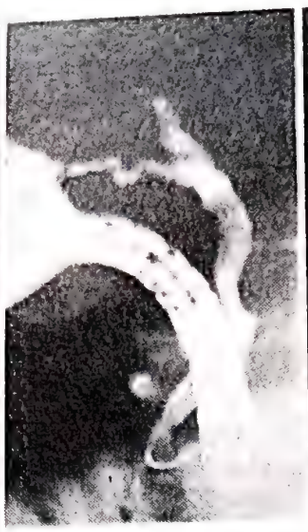


FIG. 1006.—E.R.C.P.: Complete occlusion of common hepatic duct due to cholangiocarcinoma.

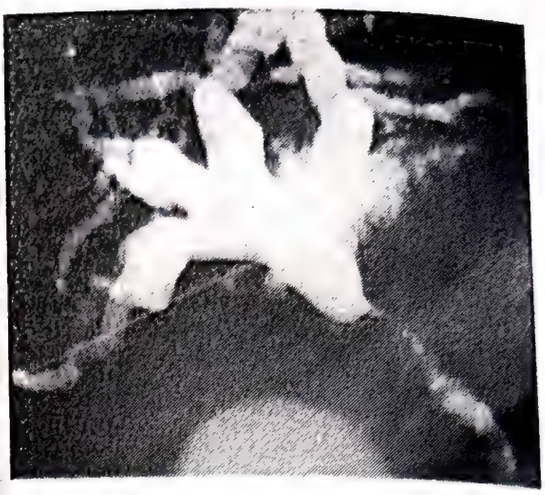

FIG. 1007.—Percutaneous transhepatic cholangiogram in the same patient as fig. 1006. Demonstrates the upper extent of the malignant stricture.

Malignant bile duct strictures.—E.R.C.P. will show the lower extent of obstruction, and a percutaneous transhepatic cholangiogram immediately pre-operatively determines the upper extent (fig. 1007). A pancreatogram will differentiate between duct cancer and pancreatic cancer (figs. 1008 and 1009).

FIG. 1008.—E.R.C.P.: Partial occlusion of bile duct by malignant stricture.

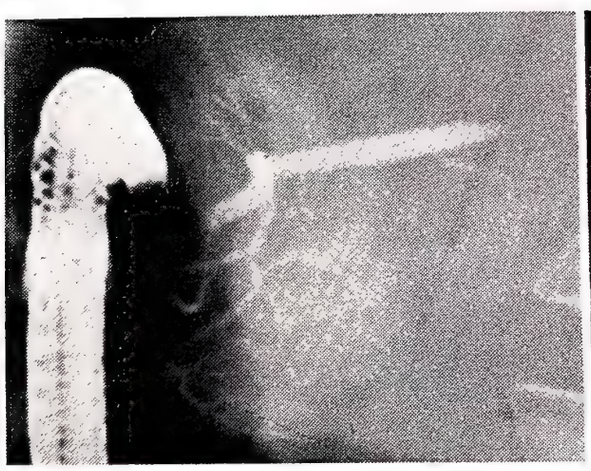

FIG. 1009.—E.R.C.P.: Same patient as fig. 1008. Complete block to main pancreatic duct indicates a pancreatic carcinoma.

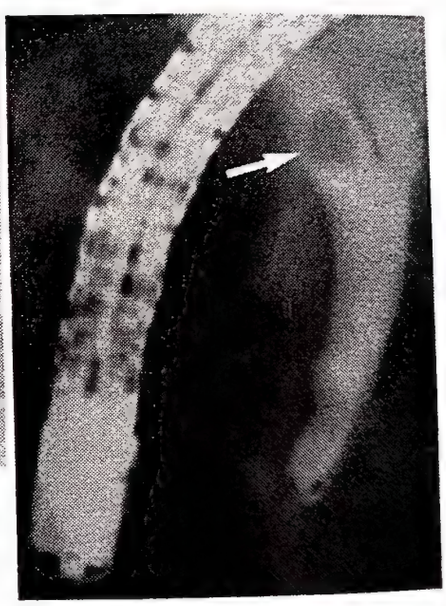

FIG. 1010.—E.R.C.P.: Small solitary gall-stone in bile duct following cholecystectomy.

Gall-stones are well shown, in patients who have previously had biliary surgery (fig. 1010) and in obstructive jaundice (fig. 1011). If the bile duct is dilated it is prudent to inject a more dilute contrast (Hypaque 25%) than is used for pancreatography, otherwise small multiple stones may be obscured (fig. 1012).

Acute cholangitis may follow E.R.C.P. when a dilated obstructed duct is filled. Antibiotics and expeditious surgery are then required.

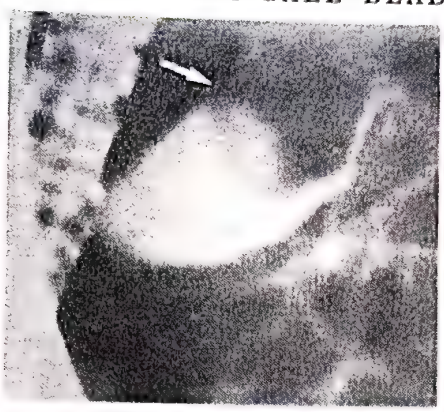

FIG. 1011.—E.R.C.P.: large gall-stone impacted at lower end of bile duct.

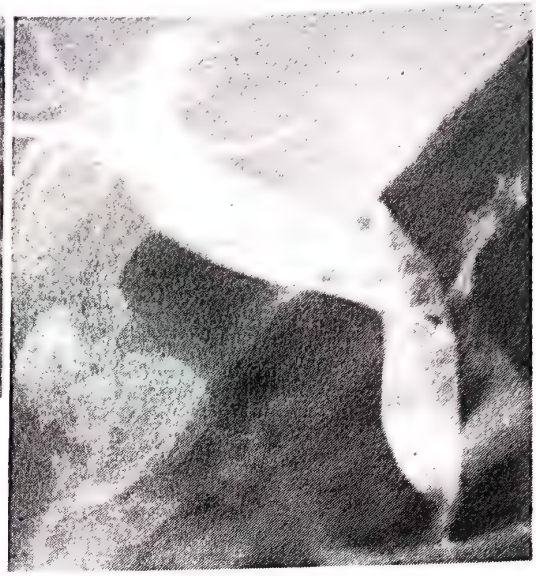

FIG. 1012.—E.R.C.P.: Small multiple gall-stones in dilated bile duct following cholecystectomy. (See operative cholangiography, p. 882.)

Transhepatic Cholangiography (fig. 1013).—The prothrombin level should be normal or raised to normal by i.m. injection of Vitamin K_1, and an intravenous test dose of 1 ml. of the medium given to exclude hypersensitivity (p. 881). Either the percutaneous (general anæsthetic) or the per-operative laparotomy approach is used. In the former case the needle is introduced just to the right of the xiphisternum. The needle is 15 cm long, gauge 20, ensheathed by a flexible polypropylene tube, and it is passed into the substance of the right, and, if necessary, the left lobe of the liver. The needle is withdrawn and trial-and-error aspiration is performed until bile (usually white bile, p. 900) enters the syringe, whereupon 20 to 40 ml. of 45 per cent. Hypaque (sodium diatrizoate) is injected and an X-ray exposure made. Visualisation by using an X-ray image intensifier is helpful. Several attempts are made to find bile before it is presumed that no dilatation of the intrahepatic bile ducts exists (as in hepatitis). A sample of the bile is always examined for bacteria—coliform organisms are often present (George).

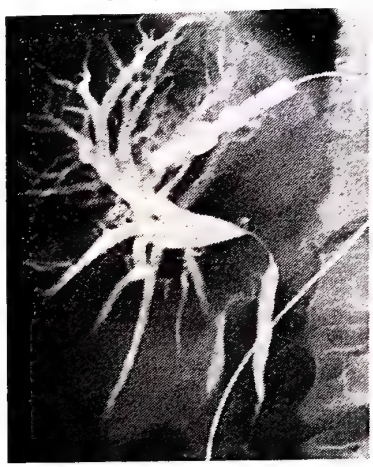

FIG. 1013.—Transhepatic cholangiography (see text), showing a stricture of the common hepatic duct. *(Miss Phyllis George, F.R.C.S., London.)*

Treatment.—As these patients with strictures or biliary fistulæ are debilitated, efforts should be made to improve their poor condition by diet, vitamins, transfusions (including intravenous albumin), and antibiotics. Various operative procedures are employed, according to the site of the stricture:

1. **Choledochoduodenostomy** (p. 902) is applicable if the duct protrudes more than 2 cm below the porta hepatis. The duodenum can easily be mobilised upwards after mobilisation. A wide stoma is essential, otherwise stricture will occur.
2. **Hepaticojejunostomy,** using a jejunal conduit (Roux loop), is performed when choledochoduodenostomy cannot be undertaken. A mucosa-to-mucosa anastomosis (Rodney Smith) is best but an effective alternative is to sew the open end of the jejunum to the liver around the opening of the duct. Any temporary post-operative

Phyllis Ann George, Contemporary. Surgeon, Royal Free Hospital, London.
Sir Rodney Smith, Contemporary. Surgeon, St. George's Hospital, London.

drainage of the duct, and any splintage of the anastomosis, is obtained by suitably fenestrated latex tubes emerging from the jejunum, the liver or from both.

3. Should the gall-bladder by chance still be in situ it can be used as an intermediate conduit between the ducts above the obstruction and the duodenum or jejunum below.

ASIATIC CHOLANGIO-HEPATITIS[1]

Obstruction to the common bile duct due initially to infection by liver flukes (*clonorchis sinensis*), which live in the biliary passages of a mammalian host, is frequently encountered in the Far East. The patient presents with pain, jaundice, and intermittent pyrexia. The urine contains bile. Clay-coloured stools are less frequently observed. Secondary infection of the obstructed ducts has almost always occurred by the time the patient seeks relief. Laparotomy should be undertaken as soon as the patient can be rendered fit to undergo the operation.

Operation.—The gall-bladder is frequently distended but is not often acutely inflamed. Palpation of the common bile duct reveals the presence of calculi and it is not unusual for the whole of the accessible system to feel solid with impacted stones. On opening the common bile duct, thick purulent bile, often containing adult clonorchis, gushes out and is removed by suction. The common bile duct and hepatic ducts are cleared of stones and mud by scoop and forceps, aided by irrigation with saline. Strictures frequently exist in the intrahepatic bile ducts which may render complete evacuation difficult or impossible. Choledochoduodenostomy at the initial exploratory operation gives better results than T-tube drainage, but if the duct is not very dilated transduodenal sphincterotomy may be adequate. A wide stoma allows stones to pass to the duodenum and helps to prevent a recurrence, although if intrahepatic biliary strictures are present multiple liver abscesses may form and the prognosis is then poor. Cholecystectomy should always be combined with choledochoduodenostomy or sphincterotomy, for if it is not done the accumulation of stagnant and infected bile within the gall-bladder frequently results in a secondary cholecystitis (Stock).

CARCINOMA OF THE GALL-BLADDER AND BILE DUCTS

Carcinoma of the gall-bladder and bile ducts accounts for 1 per cent.[2] of all malignant neoplasms. In 90 per cent of cases gall-stones are present, so this condition is more common in women than in men. It is rare under the age of forty.

The usual type is a scirrhous adenocarcinoma, a hard infiltrating tumour, usually starting in the fundus. If it arises near the neck of the gall-bladder a mucocele may follow from obstruction. A squamous carcinoma may follow the squamous metaplasia of the mucous membrane due to chronic irritation by gall-stones.

Malignant spread occurs early to the liver either directly or through the cystic lymph node and lymph nodes in the portal fissure. Involvement of the latter results in obstructive jaundice and, later, ascites. In many cases a past history of cholecystitis can be obtained, but pain, if present, tends to be continuous, with nausea, loss of appetite and weight. In over a third of cases a firm non-tender tumour is palpable in the gall-bladder area.

Treatment and Prognosis.—In view of the relationship with chronic cholecystitis and gall-stones, all gall-bladders on removal should be sectioned. In cases where a very early lesion is found, good results may be expected. Otherwise the prognosis is dismal (2 per cent. surviving five years). For the

[1] This condition may occur in all countries where watercress, especially if wild, is eaten. Sheep and cattle are prone to the condition.

[2] In Great Britain.

Francis Edgar Stock, Contemporary. Formerly Professor of Surgery, Liverpool, England.

comparatively early definite cases, cholecystectomy with excision of adjoining liver is performed, but in many cases, especially where deep jaundice is present, no surgical treatment is possible.

Carcinoma of the major bile ducts (cholangiocarcinoma) is less common than carcinoma of the gall-bladder. Gall-stones co-exist in 38 per cent. of cases. The primary lesion can be intrahepatic or extrahepatic. When occurring in the portahepatis it obstructs the left and right hepatic ducts. In such a case and in others situated above entry of the cystic into the common bile duct the gall-bladder is flaccid. The diagnosis may be confirmed by hepatic scintiscanning (a hilar defect), percutaneous transhepatic cholangiography (p. 905) and E.R.C.P. (p. 904). In most cases the state of affairs is only recognised at laparotomy for jaundice.

This cancer may grow slowly, but eventually spread throughout the liver occurs and hepatic coma heralds the termination.

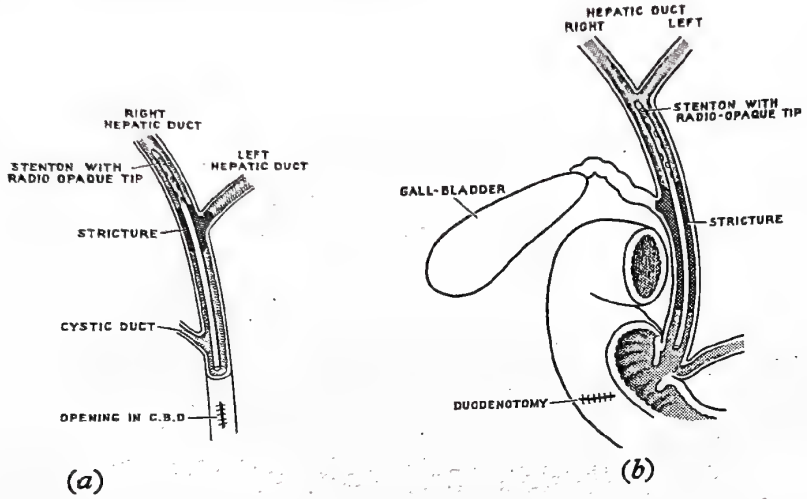

FIG. 1014.—Insertion of a stenton for (*a*) a high lesion and (*b*) a low lesion (*after Ritchie and MacLean*).
(*from Annals of the Royal College of Surgeons*)

Treatment.—Early laparotomy affords the patient a slender chance of prolonged survival. Rarely is the growth found to be resectable. Sometimes palliative procedures such as choledochoduodenostomy (p. 902) or hepaticojejunostomy (p. 905) or the insertion of a tubular stenton (fig. 1014) are possible, and symptomatic relief of the jaundice is afforded thereby.

Carcinoma of the Ampulla of Vater is discussed on page 925.

BILIARY FISTULÆ

(*a*) **External Biliary Fistula**—In days gone by, gall-stones and bile were sometimes discharged with the pus after a superficial abscess of the abdominal wall had been incised, or had ruptured. Even spontaneous extrusion of gall-stones through the

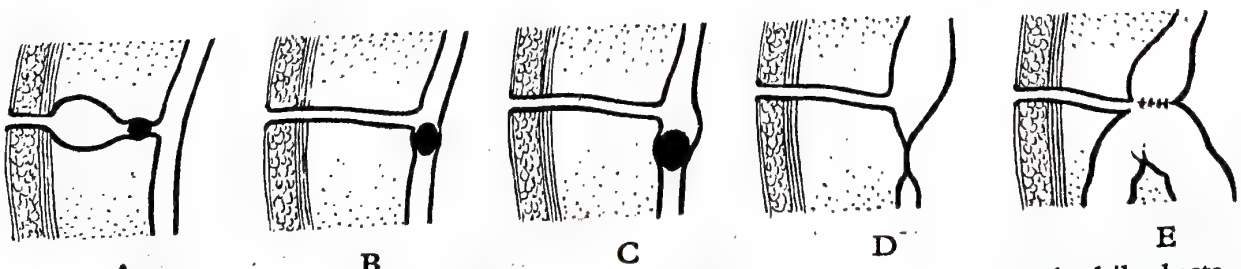

FIG. 1015.—Underlying causes of an external fistula of the gall-bladder or the bile ducts.
(*After J. J. Byrne.*)

Alexander David Willard MacLean, Contemporary. Surgeon, The London Hospital.

umbilicus has been reported. Today nearly all external biliary fistulæ follow operations upon the biliary tract. When the neck of the gall-bladder or the cystic duct is occluded by a calculus (fig. 1015A), the discharge is mucus. Should a stone be occluding the common bile duct, and cholecystostomy is performed, bile will continue to be discharged externally (fig. 1015B). If cholecystectomy has been performed in these circumstances, again a biliary fistula (fig. 1015C) will result. By far the most common cause of a biliary fistula is injury to the common bile duct during cholecystectomy (fig. 1015D). A leakage after cholecysto-jejunostomy (fig. 1015E) or cholecystduodenostomy also will give rise to a fistula discharging bile. Other causes of fistula are division of an aberrant right hepatic duct or a hepaticocystic duct (p. 884).

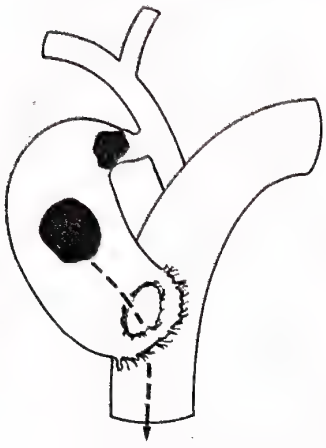

FIG. 1016.—Fistulation of gall-stone into duodenum.

After investigating by cholangiography the origin of the leak, the continuity of the main bile duct must be restored (p. 905) or, in the case of a mucous fistula, the gall-bladder or its remains must be removed.

(*b*) **Internal biliary fistula** is due to a stone ulcerating through the wall of the gall-bladder or the common duct into a hollow viscus, viz. :

1. *Into the duodenum*—a large and usually single gall-stone sometimes ulcerates into the duodenum (fig. 1016); this is the commonest internal biliary fistula. The stone may impact there causing duodenal obstruction. If smaller, it may pass on to obstruct in the lower ileum (gall-stone ' ileus ', p. 1019). There is evidence that such a fistula will close spontaneously. Later, if symptoms persist, the gall-bladder can be removed.

2. *Into the colon*—as a rule no untoward complications ensue, but a large stone occasionally becomes impacted in the pelvic colon or the rectum. A hitherto silent carcinoma may be brought to light in this way.

3. *Into the stomach*—the patient may vomit the stones.

CHAPTER 45

THE PANCREAS

Surgical Anatomy.—Every student is familiar with the head, neck, body, and tail of the pancreas. From the lower and left part of the head projects the uncinate process (fig. 1017), upon which rest the superior mesenteric vessels. The posterior surface of the neck is grooved deeply by these vessels, and more superiorly by the portal vein. In spite of the intimate contact of the portal vein with the pancreas, except in the case where it is bound down by inflammatory adhesions or in neoplastic infiltration, it can be separated from the pancreas with comparative ease. The arterial supply of the head comes from the pancreaticoduodenal arteries while the body and the tail are nourished mainly by branches of the splenic artery. The lower part of the common bile duct lies between the second part of the duodenum and the head of the pancreas.

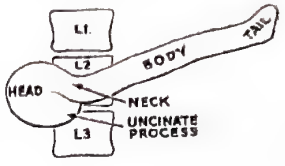

FIG. 1017.—The parts of the pancreas. *(After Rodney Smith, P.R.C.S., London.)*

The ducts of the pancreas (fig. 1018). The main duct (Wirsung) discharges its contents through the duodenal papilla. This papilla is surrounded by Oddi's sphincter. The ampulla of Vater, which is the dilatation formed by the junction of the common bile duct and the duct of Wirsung, lies within the base of the papilla. In 10 per cent. of persons the accessory duct (Santorini) becomes the main secretory duct of the pancreas, in which event the bulk of the secretion of the gland is ejected into the duodenum through a superior papilla (fig. 1018).

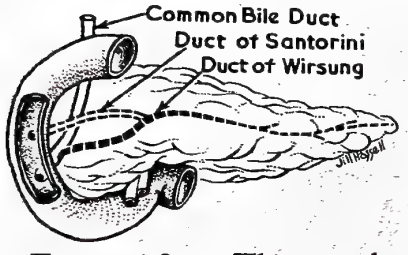

FIG. 1018. — The usual arrangement of the ducts.

Innervation of the Pancreas.—Apparently all the pain fibres are limited to the greater splanchnic nerves (T5–T10) (the sympathetic). Parasympathetic fibres reach the gland through the vagus nerves and terminate in the intrinsic pancreatic ganglia.

Surgical Physiology.—The external secretion of the pancreas is controlled by nervous and humoral mechanisms of which the latter is the more important:

(*a*) *Nervous.*—Vagal stimulation evokes a viscid secretion rich in enzymes. Vagotomy, however, does not appear to affect it.

(*b*) *Humoral.*—This mechanism involves two hormones—*secretin* and *pancreozymin*. Both are liberated from the mucous membrane of the duodenum and proximal jejunum chiefly by acid but also by food. The hormones are carried via the bloodstream to the pancreas. *Secretin* alone produces a thin watery alkaline secretion poor in enzymes but rich in sodium bicarbonate. *Pancreozymin*, probably the same hormone as cholecystokinin (Jorpes), evokes a juice rich in enzymes. Gastrin may also play a part.

Pancreatic juice, which contains the enzymes amylase, lipase, trypsinogen, chymotripsinogen, proclastase, procarboxypeptidase, prophospholipase and ribonuclease, is strongly alkaline. The alkalinity, due to the sodium bicarbonate it contains, is about pH 8·3, and no less than 3 to 4 g sodium is secreted daily in this way. It is therefore not surprising that sodium deficiency develops if the juice is lost to the exterior. The normal adult secretes about 1 to 2 litres of pancreatic juice daily. It contains up to 40 g of protein mainly in the form of these enzymes.

Tests of pancreatic function are described on p. 918.

CONGENITAL ABNORMALITIES

Annular pancreas is due to failure of complete rotation of the ventral segment during development so that a collar of pancreatic tissue surrounds the second part of

the duodenum. Usually it does not cause symptoms. In a minority it causes duodenal obstruction (fig. 1019), which is characterised by a typical gas shadow seen on a plain, X-ray film, and known as the 'double bubble', viz.: One-third of those with symptoms are infants—the remainder are adults.

FIG. 1019.—Annular lobe of the pancreas causing duodenal obstruction.

Treatment.—Since excision may be followed by pancreatic fistula the usual treatment is duodeno-jejunostomy, anastomosing the jejunum to the dilated first part of the duodenum. Sometimes, in adults, duodeno-duodenostomy is possible and this is ideal.

An ectopic pancreas is found in the submucosa of some part of the stomach, duodenum, or small intestine (including Meckel's diverticulum), the gall-bladder, adjoining the pancreas (e.g. in the hilum of the spleen) or, (in 2 per cent. of carefully conducted necropsies) within the liver. Ectopic pancreas in the wall of the intestine is apt to be the starting-point of an intussusception. Ectopic pancreas in the wall of the stomach is liable to undergo cystic degeneration.

Congenital cystic disease of the pancreas sometimes accompanies congenital disease of the kidneys and liver.

Mucoviscidosis (*syn.* fibrocystic disease) of the pancreas

This condition is but one manifestation of a hereditary congenital abnormality of mucus secretion. Mucoviscidosis affects all mucus-secreting glands, in particular those of the pancreas and bronchioles. Viscid mucus obstructs the pancreatic ducts, and retention of pancreatic secretions results; some of the alveoli rupture, pancreatic enzymes escape and become activated by tissue juice (Bodian). Thus, from birth or before it, the infant suffers from pancreatitis with subsequent fibrosis. Intestinal obstruction, often in the ileum, is another manifestation. The meconium sets into a sticky mass (see below). The secretion of abnormally viscid mucus into the bronchial tree predisposes to respiratory infection. The sweat glands produce sweat containing two or four times more sodium chloride than normal. Thus, this remarkable disease affects not only mucus-secreting glands but all exocrine glands.

Clinical Features.—The life of one afflicted with fibrocystic disease of the pancreas is fraught with dangers.

At Birth.—In 10 per cent. of cases the infant is born with meconium intestinal obstruction (p. 1010), or more rarely with meconium peritonitis (p. 944).

During Infancy.—In most cases a few weeks or months after birth bronchiolitis develops. There is dyspnœa, with inspiratory indrawing of the lower chest and the suprasternal notch, and a distressing spasmodic cough. In a number of instances the chest becomes barrel-shaped, and a radiograph shows bronchiectasis. In 90 per cent. of cases steatorrhœa is present, and usually the stools are unduly frequent, greasy, and offensive. In the absence of severe respiratory distress the appetite is voracious, in spite of which the infant is marasmic, except for a distended abdomen.

In Older Children.—Steatorrhœa with wasting (fig. 1020) continues, and is distinguished from cœliac disease by the early onset, the excellent appetite, the almost constant accompaniment of attacks of respiratory infection, and, possibly, by a history of death in infancy from intestinal obstruction or pneumonia of siblings. In hot weather excessive loss of electrolytes in sweat sometimes results in severe dehydration and even death. Cirrhosis of the liver and hypertension frequently develop; indeed, one-third of all cases of portal hypertension at this time of life occur in subjects with this disease. If the patient reaches late childhood

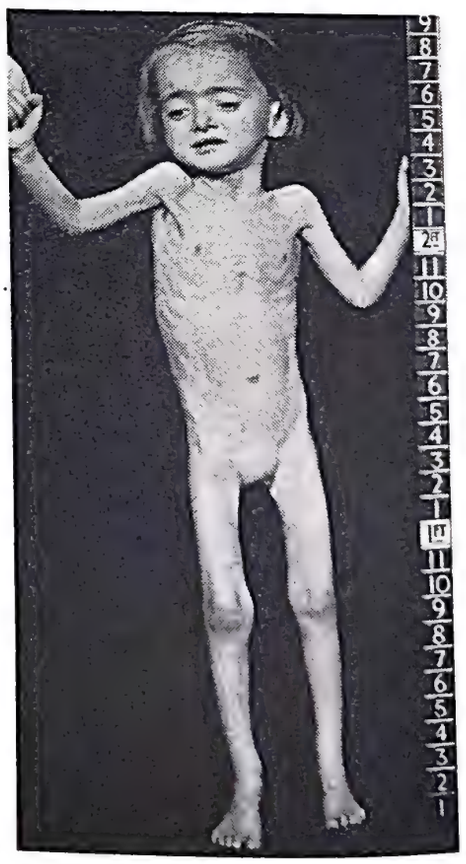

FIG. 1020.—Fibrocystic disease of the pancreas in a girl two years of age. (*Dr. A. P. Norman, London.*)

Johann Friedrich Meckel (The Younger), 1781–1833. Professor of Anatomy and Surgery, Halle, Germany.
Martin Bodian, 1910–1963. Pathologist, Hospital for Sick Children, Great Ormond Street, London.

without gross pulmonary or hepatic damage, improvement is remarkable and often sustained.

In Adults : (*a*) Middle-aged patients with long-standing pulmonary suppuration and steatorrhœa should always be suspected of suffering from mucoviscidosis. Opacities in the vitreous humour, choroiditis, and bilateral enlargement of the sub-maxillary salivary glands are frequent accompaniments.

(*b*) Staphylococcal infections are frequent and difficult to eradicate. This organism thrives in a medium containing a high concentration of sodium chloride.

(*c*) The maintenance of fluid balance following any operation on a patient with mucoviscidosis is a severe test of applied physiology. The amount of sodium, potassium, and chloride generally allowed in making up fluid balance charts is so much exceeded (because of loss of these ions in the sweat) as to call for "courage lest we falter."

Confirmatory Tests:

1. The amount of trypsin in the duodenal content is very low or absent.

2. *Sweat Tests:* Neither in health nor in any other disease does sweat contain more than 70 mEq/l (70 mmol/l) sodium, 60 mEq/l (60 mmol/l) chloride, or 20 mEq/l (20 mmol/l) potassium. In 99 per cent. of patients suffering from mucoviscidosis these figures are (often greatly) exceeded. Because of the dangers of heat stroke, the method of sweat collection whereby the patient was encased in a polythene bag has been largely superseded by pilocarpine iontophoresis. An anode is placed on a pad soaked with pilocarpine nitrate on the anterior surface of the forearm and a cathode soaked with a suitable conducting solution is placed on the posterior surface. A current of 4 mA at 15–20 v D.C. is passed for a few minutes. The area under the anode is washed with distilled water and dried. Sweat is then collected on a filter paper placed over the treated area which is covered by a polythene 'bandage'. Analysis for sodium concentration is then performed.

3. The electric conductivity of saliva secreted by healthy persons declines after stimulation. In mucoviscidosis alone the value remains constant, or even increases.

Treatment should aim at controlling respiratory infection, which is nearly always staphylococcal. A major problem is development of resistance by the organisms to one antibiotic after another.

Much can be done for fibrocystic disease of the pancreas by symptomatic treatment. Extra proteins should be given. The sugar intake should be high, but that of starch must be moderate. Fat is curtailed drastically, whereby the frequency, bulk, and foulness of the stools are diminished. Provided this diet is adhered to and enteric-coated capsules of pancreatin, 5 to 10 g are taken before feeds, and 200 units of vitamin D and 10,000 units of vitamin A are given daily, there is nearly always a substantial gain in weight.

Meconium intestinal obstruction is discussed on p. 1010.

Lastly, there should be liberal salting of food. In hot weather extra salt, 2 g per day, should be supplied. The dietetic regimen must be followed throughout life.

INJURIES TO THE PANCREAS

Injuries to the pancreas are rarely seen, because the trauma severe enough to produce this usually kills the patient. Traffic accidents are often the cause; but stabbing is a cause in some countries.

There are two types: (*a*) Laceration, with symptoms due to bleeding, and (*b*) General trauma, with symptoms due to the release of enzymes (e.g. high serum amylase). This type may present later as a pseudocyst (p. 921).

Treatment.—Excise or repair.

PANCREATITIS

Classification.—The classification of pancreatitis has always been a problem. Two useful classifications are as follows:

A. Classification by clinical presentation (Marseilles[1]):—

1. **Acute Pancreatitis**
2. **Relapsing Acute Pancreatitis**

} *These return to normal when the primary cause is removed.*

3. **Chronic Pancreatitis**
4. **Relapsing Chronic Pancreatitis**

} *In these, even if the cause is removed, functional or structural damage still remains.*

B. Classification according to ætiology[2]:—

1. **Biliary Tract Disease** — 55%
2. **Alcoholism** — 2%
3. **Post-operative** — 5%
4. **Traumatic** — 1%
5. **Rare causes** (e.g. mumps, hyperparathyroidism, vascular disease) — 2%
6. **Idiopathic** — 35%

Ætiology is very important in relating the natural history of the disease to prognosis, long term treatment, and prophylaxis.

ACUTE AND RELAPSING ACUTE PANCREATITIS

Acute pancreatitis is a serious disorder and carries a mortality of 20 per cent. Fortunately only about 5 per 100,000 suffer from it per year. The term relapsing acute pancreatitis does not convey the point that the patient recovers and remains well for months or years between attacks.

Causal theories.—The basic process in acute pancreatitis is one of autodigestion following activation of trypsinogen. There are many hypotheses as to the mechanism of this. Some postulate reflux of bile or of duodenal juice into the pancreatic duct system due to anatomical or mechanical causes, or pressure differences between the pancreatic and biliary system. Others claim to find pancreatic duct obstruction or infection, in addition to the vascular and metabolic conditions mentioned already. It is important to add, however, that evidence is accumulating that the process may start as an intracellular derangement. Recently enzymes have been cited as ætiological factors. Amongst those which have been incriminated are activated phospholipase A and elastase. Viral theories are also gaining popularity and there is some evidence that minor epidemics may occur. There is no evidence that it is an auto-immune disease. None of these theories gives adequate explanation of the disease and the actual cause remains unknown. Hereditary factors appear to be important in a few cases.

FIG. 1021. — Widespread fat necroses of omentum. A test-tube has been filled with the blood-stained peritoneal fluid. This specimen was rich in amylase. *(G. D. Adhia, F.R.C.S., Bombay.)*

Pathology.—Hitherto, the terms œdematous pancreatitis and hæmorrhagic pancreatitis

[1] The Marseilles classification was adopted in 1963 in order to standardise analysis of this condition.

[2] Based on an analysis of 520 cases (Trapnell). Note the size of the group with no known cause (idiopathic). .

John Eliot Trapnell, Contemporary. Surgeon, Royal Victoria Hospital, Bournemouth, England.

have been used. These are not really separate conditions, but different stages of one process.

(*a*) **The peritoneal cavity** contains a blood-stained exudate; the omentum and subperitoneal fat are studded with areas of fat necrosis (fig. 1021).

Fat necroses are dull, opaque, yellow-white areas suggestive of drops of wax. They are most abundant in the vicinity of the pancreas, but are widespread in the greater omentum and the mesentery. At necropsy they can sometimes be demonstrated beneath the pleura and pericardium, and even in the subsynovial fat of the knee joint. Fat necroses consist of small islands of saponification caused by the liberation of lipase, which splits fat into glycerol and fatty acids. Free fatty acids combine with calcium to form soaps = fat necrosis.

(*b*) **The Pancreas.**—In the mildest form the whole or part of the organ is œdematous, but if severe, it may be grossly hæmorrhagic and sometimes necrotic. The retroperitoneal tissues around the pancreas may then be engorged with blood-stained fluid.

(*c*) **Associated Pathology.**—Gall-stones and infected bile are frequently found.

When the lesser sac has been drained and the patient survives, portions of necrotic, pancreatic, and peri-pancreatic tissue may be discharged through the wound as putty-like material. On analysis this material has been shown to be composed largely of calcium stearate.

Clinical Features.—Unlike acute cholecystitis, acute pancreatitis shows no predilection for obese persons, no sex discrimination, and while the age of the patient is extraordinarily variable, the maximum incidence is between fifty and sixty years. The salient features of acute pancreatitis are as below, but it must be pointed out that in the early stages there may be little in the way of physical signs (tenderness and guarding) in contrast to the severity of the symptoms. This state of affairs should suggest the diagnosis.

Onset.—The attacks come on at any time but frequently follow the ingestion of a heavy meal and/or alcohol.

Pain is agonising, mainly epigastric, radiates to the back (fig. 1022) and slowly rises to a crescendo over several hours (in contradistinction to the pain of perforation). Moynihan described it as 'illimitable agony'.

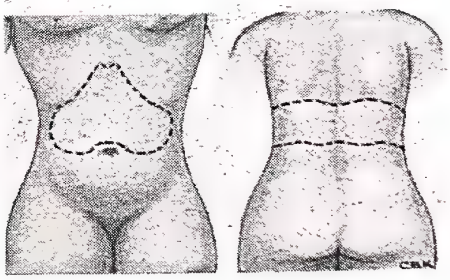

FIG. 1022.—The usual distribution of the pain of acute pancreatitis.

Vomiting and retching, repeated and noisy, are a marked feature.

Rigidity, like pain, develops slowly and may become generalised.

Tenderness may be elicited by firm and deep palpation over the pancreas and occasionally in the left renal angle where the tail of the pancreas is comparatively near the surface.

Profound shock as a *presenting* symptom is uncommon (10 per cent. of cases), but when it occurs the patient is sweating and collapsed, the nose is cold, and the blood-pressure depressed. This feature calls for urgent infusion of plasma. The shock may be due partly to circulating 'kinins' which are formed by the action of trypsin on the plasma proteins.

Cyanosis.—Cyanosis is not as common as currently believed.

Faint jaundice may sometimes be seen especially during the second day Probably it is obstructive, and due to œdema of the head of the pancreas.

Berkeley George Andrew Moynihan (Lord Moynihan of Leeds), 1865–1936. Professor of Clinical Surgery, Leeds, England.

Ileus in the early stages is limited to the duodenum and proximal jejunum. The gas-filled solitary loop may show on plain X-ray. Unless a severe paralytic ileus is prevented by gastro-intestinal aspiration, peristalsis diminishes after twelve hours and abdominal distension supervenes.

A tender, palpable mass may appear in the epigastrium towards the end of the second week. This is usually a pseudo-cyst (p. 921). If the mass appears later—after the third week—it is due to abscess formation.

Discoloration of the skin is a rare manifestation of acute pancreatitis seen in cases of two or three days' standing. Grey Turner first described it in the loins, and likened it in appearance to that of late extravasation of urine. Cullen described a similar discoloration around the umbilicus. The cause of the phenomenon is the action on the subcutaneous fat of pancreatic ferments that have escaped from the retroperitoneal tissues, either directly or via the round ligament of the liver.

Laboratory and Other Investigations: (fig. 1023).

Leucocyte Count.—A leucocytosis above 10,000 per cu mm (10×10^9/l) occurs frequently, and it may rise as high as 30,000 (30×10^9l).

The Serum-amylase Estimation.—The normal value is 80 to 150 Somogyi units; 400 units is suggestive of abnormality. A level of 1,000 units is the minimum necessary to support a diagnosis of acute pancreatitis. The highest level is attained within an hour after the onset of symptoms. Subsequently there is a fall to normal level within 3–5 days.

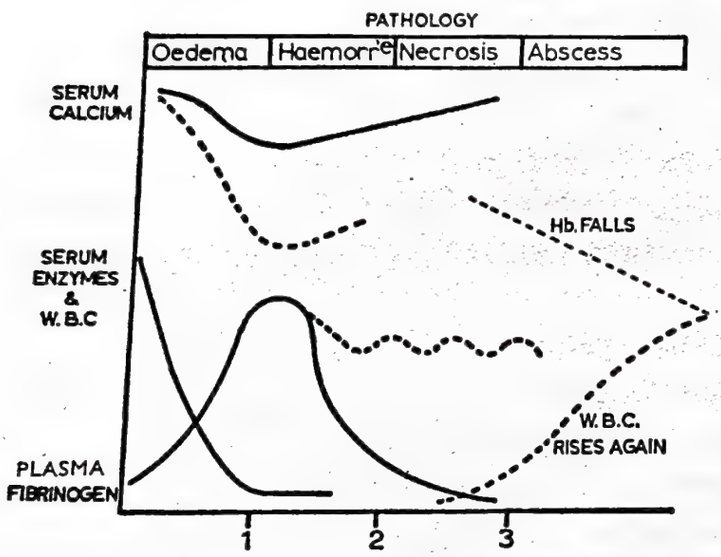

FIG. 1023.—Relation of the natural history of acute pancreatitis to laboratory investigations. 1, 2, 3 = weeks. The broken lines are intended to show the variations from normal in complicated cases and indicate a worsened prognosis associated with the appearance of methæmalbumen. (*John Trapnell F.R.C.S., Bournemouth.*)

The diastatic index of the urine is normal (below 50 units) during the early hours of the attack. After twelve to twenty-four hours it often rises to 100 units or more; sometimes it is as high as 500 and, rarely, 1,000 units.

Glycosuria may be present.

The serum calcium (normal—10 mg/100 ml (2·5 mmol/l)) undergoes a delayed fall about 5–8 days after the attack. Concentrations below 7 mg/100 ml (1·75 mmol/l) are often followed by the death of the patient, in spite of the administration of calcium. The test is of some prognostic value as is the appearance of tetany. The serum calcium level may be an indication of the amount of calcium fixed in the formation of calcium soaps.

The serum bilirubin (normal—not exceeding 0·2 mg/100 ml (3·4 mmol/l)) is nearly always raised, even when no icteric tint of the sclera is apparent.

The plasma fibrinogen is raised at the end of the first week and should return to normal in the third. This is of considerable prognostic value (fig. 1023).

George Grey Turner, 1877–1951. Professor of Surgery, Postgraduate Medical School, London.
Thomas Stephen Cullen, 1868–1953. Professor of Gynæcology, Johns Hopkins University, Baltimore, U.S.A.
Michael Somogyi, 1883–1971. Biochemist, Jewish Hospital, St. Louis, Missouri, U.S.A.

Methæmalbumen—the presence of this in the blood indicates a hæmorrhagic necrosis and is associated with a bad prognosis.

Electrocardiographic Changes.—It is by no means uncommon to find abnormal electrocardiographic recordings in patients with acute pancreatitis; in a few the record is so abnormal as to support a provisional diagnosis of myocardial infarction. These electrocardiographic changes disappear with recovery of the patient, but may return during subsequent attacks (Pollock).

Radiography.—A gas shadow and fluid level is seen in the region of the duodeno-jejunal junction. Curiously, this is most often clearly seen *after* the diagnosis has been made.

Differential Diagnosis.—The most important point in diagnosis is to remember it as a possible cause in every case of upper abdominal pain and to request a serum amylase. Coronary occlusion, high intestinal obstruction, perforated peptic ulcer, leaking dissecting aortic aneurysm, and gall-stone colic are the conditions that may have similar features. The absence of gas beneath the diaphragm helps to exclude a perforated peptic ulcer.

Abdominal pain with raised serum amylase

The significance of a serum amylase above 1,000 units associated with abdominal pain is of great importance. The following conditions should be considered:

1. *Afferent loop obstruction* following gastrectomy (p. 802). Back pressure in the distended loop up the pancreatic duct is presumed to raise the serum amylase (sometimes up to 3,000 units or more).
2. *Absorption through the peritoneum* as in biliary peritonitis—due to a perforated duodenal ulcer, leaking duodenal stump, a leak following biliary surgery or perforation of the gall bladder.
3. *Damage to the Pancreas or its blood supply*—as in direct trauma, thrombosis of the aorta or the inferior vena cava or a ruptured aortic aneurysm.
4. *Spasm* at the sphincter of Oddi.

Raised serum amylase has also been reported in ectopic gestation and after head injuries.

Treatment of Acute Pancreatitis.—This should be conservative providing that there is no doubt about the diagnosis. Contrary to past teaching, if there is any doubt it is better to perform a laparotomy and see if there is pancreatitis. This procedure may save a patient's life if, for example, he has a perforated peptic ulcer, a leaking aneurysm, a stone in the common bile duct, or a mesenteric thrombosis.

1. **Conservative treatment** is as follows:—*Relief of Pain and Rest for the Pancreas.*—Morphine or Pethidine[1] should *not* be used alone as they cause spasm of the sphincter of Oddi (Boulter). Vagal influence can be abolished by atropine 0·6 mg. four-hourly, or propantheline 15 to 30 mg. intravenously in a slow drip, repeated, with caution, in six hours, if necessary. Hormonal stimulation (secretin and pancreozymin) is best subdued by continuous and efficient gastric suction and nothing must be given by mouth. These measures, by resting the pancreas, contribute greatly to the relief of pain.

Replacement of Fluid and Electrolytes.—The patient needs large quantities of fluid (saline, plasma and blood). Rapid correction is urgent and life-saving. In bad cases a central venous pressure monitoring catheter should be introduced (p. 69). Calcium gluconate 10 ml. of a 10 per cent. solution i.v. should be given daily.

[1] Pethidine is known as demerol in Canada, and as demerol hydrochloride in the U.S.A.

Alan Victor Pollock, Contemporary. Surgeon, Scarborough Hospital, Scarborough, Yorkshire, England.
Patrick Stewart Boulter, Contemporary. Surgeon, Royal Surrey County Hospital, Guildford, Surrey, England.

Antibiotics.—Large doses of an antibiotic such as a tetracycline should be used to prevent secondary infection.

Other therapy.—*Low-molecular weight* (40,000) *Dextran*, i.v. has been shown to be helpful (p. 77), and besides maintaining proper perfusion and oxygenation of the pancreas it has similar effects upon such vital organs as the kidneys and the adrenals which can be damaged by vasoconstriction (p. 77).

Hydrocortisone, 100 mg. i.v. is used in repeated doses for persistent hypotension.

Dorso-lumbar paravertebral block (cf. p. 131) with local anæsthetic interrupts the afferent pain fibres of the sympathetic splanchnics and has long been advocated.

Trasylol (aprotinin—an antitryptic substance) i.v. is not proven as an effective treatment and is under trial.

Glucagon which tends to inhibit pancreatic secretion has been said to improve prognosis if given early in the disease, in a dosage of 1 mg i.v. stat and 1–1·5 mg four-hourly for three days.

2. **Procedure if the diagnosis is made at laparotomy.**—The pancreas must not be manipulated in any way, but an assessment can be made of the extent of the condition. If, and only if, there is evidence of gallstones, or there is jaundice, the gall bladder or the common bile duct may be drained (cholecystostomy, p. 897, or choledochotomy, p. 900). The latter procedure is rarely feasible on account of the extensive bile-stained œdema and hæmorrhagic extravasation. No attempt should be made to manipulate anywhere near the ampulla of Vater.

Nothing else is done and the abdomen is closed with non-absorbable sutures.

Complications of Acute Pancreatitis.—While the treatment of acute pancreatitis is preferably non-operative, the treatment of most of its complications requires surgical intervention. In epitome the complications are:

1. *The development of a pseudo-cyst* occurs in about 12 per cent. of cases (p. 921).
2. *Abscess formation* (rare), which gives rise to a swelling most commonly in the left flank, a swinging temperature (sometimes masked by antibiotics), and a raised plasma fibrinogen level (fig. 1023). An abscess should be drained extraperitoneally.
3. *A collection of blood in the lesser sac* (rare), characterised by the very early and sudden appearance of an epigastric swelling, is best treated by evacuation of the clot —a measure which slightly improves the very poor prognosis.
4. *Hæmatemesis and melæna* is uncommon and carries a bad prognosis.
5. *Renal Failure.*
6. *Toxic Psychosis.*

Convalescence and Subsequent Management.—The diet should be bland, consisting essentially of small frequent meals avoiding fried foods, spices, and thick soups. Alcohol is forbidden. Food is best eaten dry, fluids being taken between meals. An antispasmodic, i.e. tinct. belladonna, just before meals may be beneficial. Some patients derive considerable benefit from the regular use of the slow-release glyceryl-trinitrate preparation 'Sustac'. By far the most important feature of convalescence is to determine those cases likely to have recurrences, in particular those with associated biliary disease. I.V. cholangiography is mandatory but should be delayed for a month. In those cases with stones, cholecystectomy and choledocholithotomy should be done as a safeguard against recurrence. If biliary tract disease is fully eradicated the attacks should cease. In the other cases ætiological factors should be attended to where possible (e.g. the alcoholic should stop drinking, a parathyroid tumour should be removed). *The prognosis* with regard to recurrence is now clearer. Of the idiopathic group, 20 per cent. have another attack within 1–2 years of the first attack and it is usually milder than the initial episode. Death from a recurrence is very rare. If a patient lives 6 years without recurrence he may be considered 'cured'. In general, however, acute pancreatitis or relapsing acute pancreatitis does not proceed to chronic pancreatitis.

Post-operative acute pancreatitis.—In this condition, the mortality is greater than 50 per cent. It occurs most commonly after operations on the biliary tree or stomach. Manipulation in and around the sphincter of Oddi such as E.R.C.P. (p. 929) or the insertion of long-arm T-tubes is sometimes a cause of this condition. The essential treatment lies in early diagnosis and conservative management as described.

CHRONIC AND RELAPSING CHRONIC PANCREATITIS

These conditions are separate entities from acute pancreatitis. The essential change in the pancreas is slowly progressive with destruction of acini, increasing fibrosis, and often with corresponding functional failure. In some, there may be calcification in the gland—this is seen especially if there is a background of alcoholism or where hereditary or endocrine factors are prominent.

In *chronic pancreatitis* there are five main types of presentation:

(1) Upper abdominal *pain* passing through to the back (p. 913). (2) As a cause of obstructive *jaundice*. (3) As a *malabsorption* disorder—i.e. failure of external secretion, with steatorrhœa, weight loss, and vitamin deficiencies. (4) As *diabetes*—i.e. failure of internal secretion. (5) Sometimes the diagnosis is made solely by palpation of the pancreas during *laparotomy*. The features may include nodularity, irregularity, fixity, induration, or the presence of a mass. It is unwise to make the diagnosis on nodularity alone (the normal pancreas may be nodular when it is turgid with secretion).

Age, Sex, and Habitude.—Unlike cholecystitis, chronic pancreatitis occurs much more frequently among men than among women. There is no predilection for fat persons, and the age incidence, while having a more restricted ambit, is not dissimilar from that of carcinoma of the pancreas.

The hall-mark of *relapsing chronic pancreatitis* is recurrent attacks of *pain* in the epigastrium and in the back which may exceptionally last for only an hour but usually continue for two or three days. As opposed to recurrent acute pancreatitis the patients are not well between the attacks.

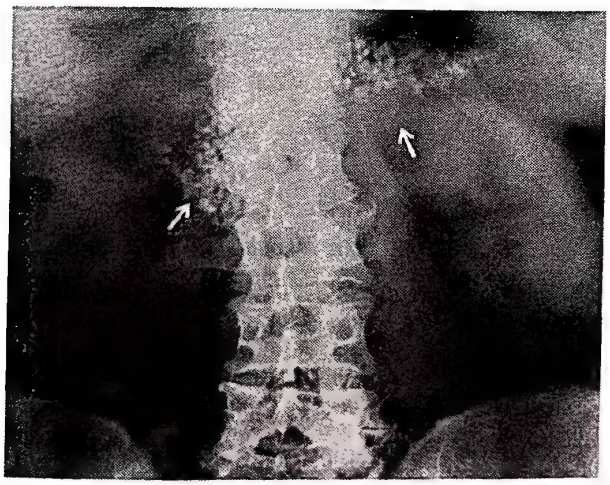

FIG. 1024.—Diffuse pancreatic calcinosis.

Periodicity.—The attacks vary in frequency; they may occur as often as once a week or as seldom as three times a year. As a rule, with the passage of time the attacks become more frequent.

Vomiting occurs in some 50 per cent. of cases.

Weakness or fatigue is common, and it is not unusual for this to herald an oncoming attack by two or three days.

Jaundice is exceptional in under 15 per cent. of cases. In the more advanced cases it is the result of pressure upon the terminal part of the common bile duct.

Atherosclerosis and chronic relapsing pancreatitis often go hand in hand (Saint). *Alcoholism or drug addiction* is so often present (40 to 50 per cent.) that either is to be regarded as important in diagnosis. The habit is often acquired in an endeavour to seek relief from the intolerable pain.

Radiography.—It is important to have a plain film before any barium series to ascertain whether there is any pancreatic calcification (fig. 1024). When this is present it is usually para- or intra-ductal. The barium series may show widening and indentation of the duodenal circuit. Routine cholecystography should always be done. If the gall-bladder has been removed, an intravenous cholangiogram is necessary. E.R.C.P. may be diagnostic (p. 929 and fig. 1052).

Special Tests of Function

Serum Amylase.[1]—This may be of use in the relapsing cases. It is increased during the attack. The elevation may not be great but it must be related to the base-line level obtained between attacks.

Stools.—Steatorrhœa is present when chemical examination (to measure the fatty acids) shows the fat content to be greater than 18 g in three days.

The stools become bulky, pale, frothy, offensive, and float on water. Malabsorption occurs late in the disease and only appears when some 80 to 90 per cent. of the gland has been destroyed. Having recognised the presence of steatorrhœa, pancreatic disease can only be identified for certainty by duodenal intubation tests to determine the presence or absence of pancreatic enzymes.

Duodenal Intubation (Howat)—*The Secretin-Pancreozymin Test.*

Pancreatic secretory capacity can be measured by collecting duodenal contents quantitatively after stimulating the pancreas with secretin and pancreozymin (1 unit/kg body wt)—i.v. A double-lumen radio-opaque tube (Dreiling) is passed and so sited

	Volume (ml)		HCO_3^- (mmol)		Amylase (Units × 1000)		Lipase (Units)	
	Mean	Lower Limit	Mean	Lower Limit	Mean	Lower Limit	Mean	Lower Limit
Post Secretin (30 minutes)	111	48	6·1	1·7	49·6	13·8	1427	436
Post Pancreozymin (30 minutes)	141	51	7·5	1·7	65·4	10·3	2133	631
Post Secretin and Post Pancreozymin (60 minutes)	252	124	13·6	5·4	114·9	23·5	3560	1552

FIG. 1025.—Normal Values for Exocrine Pancreatic Function Studies (Boot's Secretin and Pancreozymin 1 unit/kg i.v.) Amylase in Somogyi units per litre; lipase measured by the method of Cherry and Randel.

Volume	Bicarbonate	Enzyme	Diagnosis
Low	Low	Low	Carcinoma of the head of pancreas
Low	Normal	Normal	Carcinoma of the pancreas
Normal	Low	Normal or low	Chronic pancreatitis
Normal	Normal	Low	Nutritional or metabolic pancreatic fibrosis
Increased	Low	Normal	Hæmachromatosis

FIG. 1026.—Diagnostic Significance of Altered Exocrine Pancreatic Function.

[1] The test is now in tablet form (Phadebas® Amylase test—Pharmacia Ltd.).

Eric Galton Saint, Contemporary. Professor of Medicine, University of Western Australia, Perth.
Henry Taylor Howat, Contemporary. Physician, Royal Infirmary, Manchester, England.
David A. Dreiling, Contemporary. Associate Professor of Surgery, Mount Sinai Hospital, New York.

that one lumen drains the stomach, the other the duodenum; in this way duodenal contents can be collected free of gastric contamination. Continuous suction with negative pressure not greater than 50 mmHg (6·7 kPa) is applied and the duodenal contents collected in fractions. After requisite control periods, secretin is given and the duodenal contents collected in 10-minute fractions for 30 minutes. Then pancreozymin is given and the collection is continued for a further 30 minutes. Normal values are shown in fig. 1025.

The diagnostic help which can be obtained is summarised in fig. 1026.

The feature which distinguishes chronic pancreatitis from an attack of relapsing pancreatitis in which restitution to normal takes place, is a permanently diminished concentration and output of bicarbonate after secretin. The output of enzymes after pancreozymin is a more sensitive index of pancreatic damage than a reduction of bicarbonate, particularly in carcinoma of the head of the pancreas. Since pancreozymin is probably identical with cholecystokinin, which contracts the gall-bladder, the secretin-pancreozymin test in early obstructive jaundice is a useful guide to the site of the primary obstruction either in the pancreatic or bile ducts. Impaired tests are always found in steatorrhœa of pancreatic origin. The duodenal contents obtained in these tests are particularly suited to examination for exfoliated carcinoma cells in both biliary duct and pancreatic growths (Triple test (p. 929)).

Lundh Test.—The trypsin activity in the duodenum is measured after a test meal (consisting of corn oil 18 g, Casilan 15 g, glucose 40 g, syrup 15 g and hot water to 300 ml.). The duodenal juice is collected for 2 hours after the meal by syphonage or gentle suction through a carefully positioned tube. The tryptic *activity* is normally more than 9 μEq/min/ml, but it is less than 2 μEq/min/ml in pancreatic steatorrhœa (Lennard-Jones).

Glucose Tolerance Test.—With progressive pancreatitis, glycosuria appears and a diabetic type of blood sugar curve is obtained. This is in contradistinction to intestinal causes of malabsorption, e.g. idiopathic steatorrhœa, which give flat curves.

Occult blood in stools is usually absent in chronic pancreatitis, but may be present in carcinoma of the pancreas (p. 925).

Differential Diagnosis from Carcinoma of Pancreas.—It can be difficult to be certain about this: The duodenal intubation tests or E.R.C.P. give a diagnostic accuracy in the region of 90%. If a swelling found at laparotomy is confined to the pancreas alone, then it is still impossible to be certain. Biopsy is of limited value and it may be dangerous. Birnstingl recorded ten cases with obstructive jaundice declared on pancreatic biopsy to be chronic pancreatitis, yet all were dead with carcinoma of the pancreas within three years. Chronic pancreatitis predisposes to the development of carcinoma in the organ.

Prognosis.—A patient is unlikely to die of chronic pancreatitis, or even from one of the complications of this disease such as steatorrhœa, diabetes mellitus, or gastro-intestinal hæmorrhage, but is likely to succumb eventually to some unrelated disorder such as cerebrovascular disease or to cancer developing in the organ itself. In late onset diabetes cancer of the pancreas should always be suspected and the appropriate investigations undertaken.

Treatment

In general those with diabetes and malabsorption phenomena (i.e. chronic pancreatitis) are best treated conservatively and rarely need surgery. When, however, much pain or jaundice is present surgery is usually necessary.

All cases need a high-protein, high-calorie diet. Sustac (p. 916) should be tried. Alcohol is completely forbidden. A concentrated triple-strength

Göran Lundh, Contemporary. Department of Surgery, University of Lund, Lund, Sweden.
John Edward Lennard-Jones, Contemporary. Physician, London Hospital, London.
Martin Avigdor Birnstingl, Contemporary. Surgeon, St. Bartholomew's Hospital, London.

enteric-coated tablet of pancreatic enzyme is given with each meal, together with a multivitamin capsule. Anæmia should be corrected.

Operations for Pain.—This may be so severe that it leads to drug addiction. The variety of procedures recommended is an index of the unsatisfactory treatment of this condition.

Biliary Surgery.—*Pathology in the biliary tree* must be thoroughly eliminated.

Operative Pancreatography.—The planning of an appropriate operation depends upon the state of the main duct of Wirsung, as demonstrated by a contrast X-ray if this has not already been outlined by endoscopic cannulation (p. 929). Two ml. of 60% diatrizoate (Hypaque) are injected into the duct by a needle transduodenally. If the duct is dilated above a stricture at the ampulla a sphincterotomy is indicated. If the duct is stenosed over a distance, partial excision and drainage of the remnant into a Roux loop is done.

Transduodenal Sphincterotomy.—The second part of the duodenum and the head of the pancreas are mobilised and the region of the duodenal papilla is located by palpation. A transverse incision is then made through the duodenal wall exactly opposite the papilla. A grooved director is insinuated into the orifice and passed up into the common bile duct. The sphincter is now divided with the knife in the groove (at 11 o'clock). The full thickness of the duodenal wall should not be severed (see page 901).

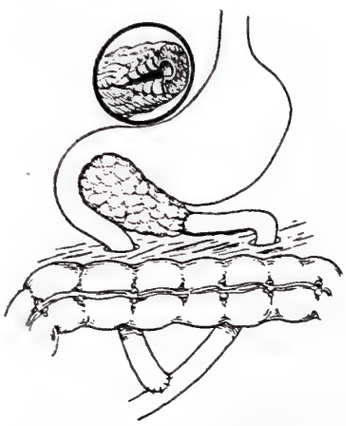

FIG. 1027.—Retrograde pancreatojejunostomy. (*After M. K. Du Val, Jnr.*)

Sphincterotomy performed in this way gives free access to the terminal portions of both the common bile duct and the duct of Wirsung. The duodenum is closed meticulously. The subhepatic space is drained.

Partial Excision and Drainage—Retrograde Pancreato-jejunostomy.—If the major pancreatic duct is strictured proximal to the sphincter the tail of the pancreas is mobilised and amputated obliquely. The duct is located and slit for a short distance, the cut edges being held apart by sutures. Any calculi are removed. The divided distal end of the jejunum is then brought over the stump of pancreas like the finger of a glove, and sutured into place. The operation is completed as shown in fig. 1027.

Where these changes are extensive the duct is dilated and contains multiple stones. The body can be 'filletted' and anastomosed to a Roux loop of jejunum (the Puestow operation).

Interruption of Nerve Pathways—Splanchnicectomy—Resection of 3 cm of the right great splanchnic nerve may be used in the treatment of intractable pain, but the long-term results are uncertain.

By and large, if any of these operations is undertaken, a good result may be expected in about half the cases. Splanchnic block may also, on occasion, prove useful.

(*b*) **For Jaundice.**—If this is the presenting feature, biliary drainage is essential.

Cholecyst-jejunostomy-en-Y (fig. 1028) is the oldest operation for this condition, and, for a patient in poor condition, is inferior to none, provided the gall-bladder is thin-walled and distended with bile (i.e. that there is no obstruction to the cystic duct). Simple cholecyst-jejunostomy with entero-enterostomy is equally efficacious. This stoma must be at least 3 cm.

FIG. 1028.—Cholecyst-jejunostomy-en-Y (Roux).

PANCREATIC CALCULI

These are intraductal and consist of calcium carbonate. The usual picture is one of multiple radio-opaque stones. Parathyroid disease should be excluded. They are the *result* of the disease and not the cause—but if surgery is performed on the pancreatic duct (see above), the stones should be removed. Surgery is *not* mandatory for stones alone.

PANCREATIC CYSTS { Pseudo-cyst 80%. / True 20%.

Charles B. Puestow, Contemporary. Professor of Surgery Emeritus, The Abraham Lincoln School of Medicine, University of Illinois, U.S.A.

Pseudo-cyst of the Pancreas.—This is essentially a collection of fluid in the lesser sac (fig. 1029) and occurs most frequently as a result of acute pancreatitis, or sometimes after injury. In order of frequency the pseudo-cyst projects (*a*) between the stomach and the transverse colon; (*b*) between the stomach and the liver; (*c*) behind or below the transverse colon.

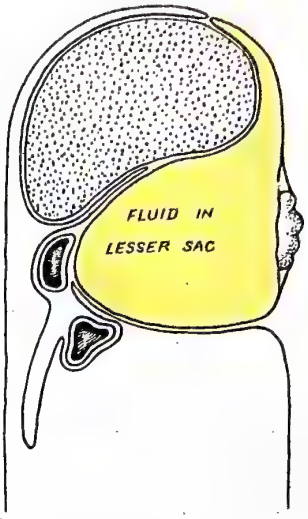

FIG. 1029.—Pseudo-pancreatic cyst.

Clinical Features.—An epigastric swelling appears during the conservative treatment of pancreatitis, or in traumatic cases during or after convalescence for an injury that did not merit laparotomy. Exceptionally the patient is admitted with a pseudo-cyst of the pancreas and gives a history of an attack of severe abdominal pain that occurred a week or more previously.

On examination there is a swelling, sometimes as large as a melon, placed centrally above the umbilicus: the swelling is fixed, and in many instances it is so tense that fluctuation cannot be elicited. As a rule, transmitted pulsation from the abdominal aorta is very noticeable and the diagnosis of an aneurysm may be considered, although in the latter case the pulsation is expansile and, in the knee-elbow position the pulsation is much diminished. Moreover, in the case of a pancreatic cyst, a bruit is absent and the swelling, which is the presenting feature, is much broader. Mesenteric cysts are rare and are very mobile. A barium meal shows projection of the cyst into hollow viscera, especially the stomach (fig. 1030). Every case of acute pancreatitis must be observed for the development of a pseudo-cyst. With this in mind, the width of the vertebro-gastric interval as seen on lateral X-ray should be assessed on about the tenth day of the disease. Ultrasound and E.M.I. scanning (fig. 1031) are proving valuable diagnostic advances. The earlier a pseudo-cyst appears the worse the prognosis.

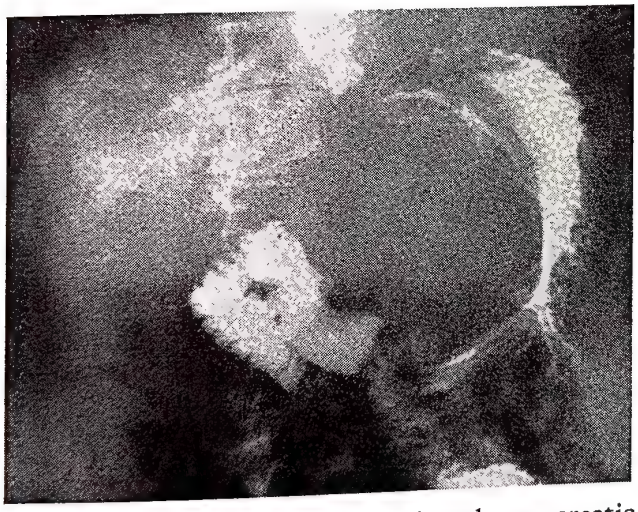

FIG. 1030.—Barium meal—Pseudo-pancreatic cyst displacing stomach. (*Rodney Smith, P.R.C.S., London, in* Trans. med. Soc. Lond.)

Treatment.—It is necessary to distinguish between acute and chronic pseudocyst formation. Acute pseudocysts commonly arise after severe attacks of pancreatitis. About 50% of these will resolve without treatment and so no action should be taken during the first weeks after they have been recognised unless there is clinical evidence that the cyst has become infected. Serial ultrasonic measurements will give a good indication of how the cyst is progressing and should show spontaneous resolution if this is occurring. Where, however, infection has supervened or when the cyst has clearly become chronic, operative treatment is indicated because of the risk to life from spontaneous rupture. The treatment is cysto-gastrostomy. The stomach is opened through its anterior wall and an incision of at least 6 cm made through the posterior wall into the cyst. Hæmostasis is secured with a circumferential running suture and the anterior wall of the stomach is closed (fig. 1032). The contents of the cyst then drain into the stomach. Convalescence is shortened thereby and the complications referred to are obviated. Curiously, food does not enter the sac, as might be expected. The opening must be large enough to allow for subsequent contraction. Bleeding from the incised edge may follow and this is the major post-operative hazard.

True Cysts of the Pancreas.—In 20 per cent. of cases a cyst of the pancreas is a true cyst, and falls into one of the following categories:

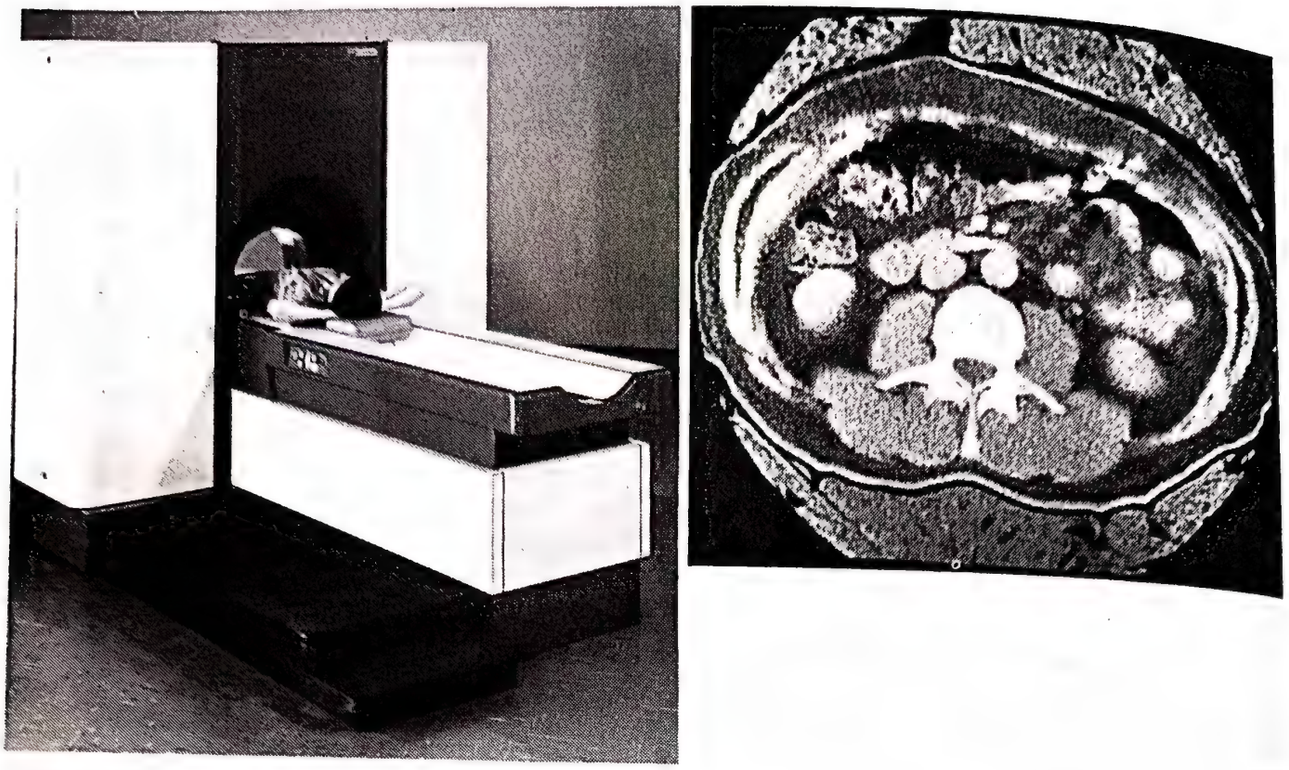

FIG. 1031.—EMI whole-body scanner[1]. This new general purpose whole-body diagnostic system operates on similar principles to those already fully proven on the original EMI-Scanner (p. 408). This entirely non-invasive system is designed to allow rapid x-ray examination of sections through the head or body, each 13 mm in thickness. A complete scan of a single ' slice ' is carried out in 20 seconds. Details of tissues invisible to conventional x-ray methods, e.g. brain, spleen, pancreas, and details of lung tissues are clearly and accurately visualised. The ' slice ' illustrated, viewed from a caudal aspect (right side on left of picture) shows a cross section of the abdomen in the region of the kidneys. The aorta, vena cava and pancreas are clearly visible.

(*a*) *Cyst-adenoma.*—Most true cysts belong to this group. Paradoxically these usually present as a solid swelling. The cysts are multiple and lie in an adenomatous mass. They may move on respiration and often have a narrow attachment to the pancreas. Removal is therefore accomplished without undue difficulty.

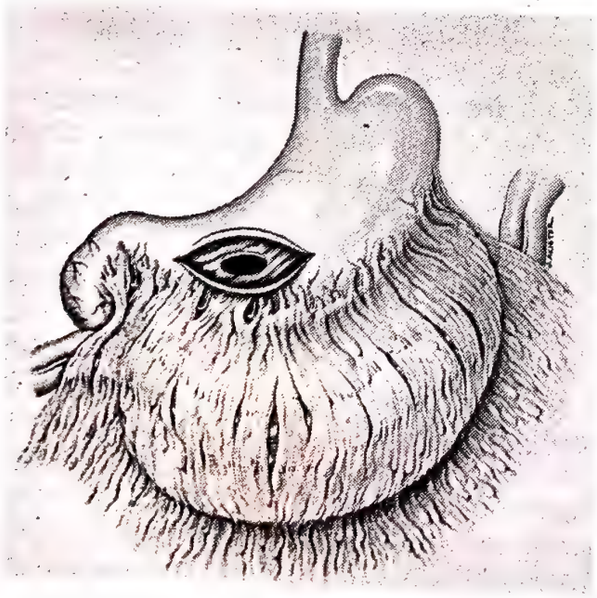

FIG. 1032.—Cysto-gastrostomy for pseudo-pancreatic cyst.

(*b*) *Mucoviscidosis of the Pancreas* (p. 910).

(*c*) *Congenital Cystic Disease.*—Possibly associated with polycystic disease of the kidneys and liver.

(*d*) *Retention Cyst.*—This is part of the pathological change in chronic pancreatitis and is due to ductal obstruction.

(*e*) *Hydatid Cyst.*—The ubiquitous hydatid completes the list.

Clinical Features. — Epigastric discomfort and the presence of a swelling are the usual reasons that cause the patient to seek advice. When the swelling arises in the tail of the pancreas it may be impossible to differentiate it from a renal lesion until pyelography has been performed. When the cyst arises in the head of the pancreas, the symptoms are identical with those of a choledochal cyst (p. 885).

Treatment.—A comparatively small cyst can be treated expectantly. A large cyst of the head of the pancreas is suitable for cystoduodenostomy. A similar cyst of the body of the organ can be treated by cysto-gastrostomy. When the cyst (or

[1] EMI-Scanner is manufactured by EMI Medical Ltd., 248 Blyth Road, Hayes, Middlesex, England.

cysts) are situated towards the tail of the pancreas (this is the site of election for cystadenoma) the affected portion of the pancreas can be amputated.

PANCREATIC FISTULA

This usually follows trauma to the gland either by closed external injury or operations for splenectomy or rarely gastrectomy or open biopsy. In most cases following operation, the injury was not suspected at the time.

Treatment.—The problems in the management of these fistulæ are:

(1) *Fluid and Electrolyte Loss.*—In the presence of a fistula the pancreas tends to hypersecretion and anything from a few ml. to 2 litres may be lost in twenty-four hours. Such a loss of fluid and electrolytes may constitute a menace to life; they must therefore be replaced either by mouth or intravenously. In large losses, daily fluid and electrolyte balance must be maintained. If there is much loss, pancreatic extract should be given by mouth. Pancreatic secretion can be partially suppressed by propantheline (p. 915). The diet should consist of high protein and low carbohydrate.

(2) *Autodigestion of the Parietes.*—The skin should be protected by an ointment composed of 1 per cent. HCl in zinc oxide cream.

(3) '*Pooling*' *of the discharge* deeply in the wound. If possible, completely *dependent* drainage must be instituted; if necessary, the patient must lie prone. If this is not possible, continuous motor suction sump drainage must be carried out (fig. 1033). In any case, the daily loss must be measured.

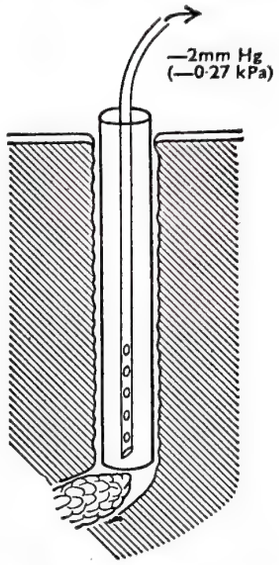

FIG. 1033.—Continuous suction sump drainage for pancreatic fistula.

Spontaneous closure occurs in 90 per cent. of cases, though this may take several months. Failure is usually due to inadequate dependent drainage.

If in spite of all these measures the fistula fails to close, it should be dissected to its source in the pancreas and drained into the stomach or into a Roux-en-Y jejunal loop.

ISLET-CELL TUMOURS OF THE PANCREAS

The islets of Langerhans contain three types of cells: alpha, beta, and gamma, and of these the beta-cell is most common.

Pathology.—The actual islet-cell lesion may be one of the following:

(1) Hyperfunction without morphological change; (2) generalised hyperplasia; (3) discrete adenomas; (4) generalised adenomatosis; (5) carcinomas. Two-thirds of islet lesions occur in the body or tail of the pancreas. Approximately in one-third of cases they are multiple and in one-third they are malignant.

Such lesions may be associated with similar states in other endocrine glands, especially the anterior pituitary, the parathyroids, and the adrenal cortex (multiple adenoma syndrome).

Clinically, in overt cases, there may be: (1) Hyperinsulinism. (2) Features of other endocrine lesions, e.g. enlarged sella turcica, altered phosphorus and calcium blood levels, and increased keto-steroids in the urine. (3) Peptic ulceration. If a patient has peptic ulceration and hyperinsulinism (see below), it is certain that he has a multiple adenoma syndrome. (4) Zollinger-Ellison syndrome (p. 925).

Of these it is only necessary here to discuss (1) and (4).

HYPERINSULINISM (BETA-CELL TUMOUR). INSULINOMA (fig. 1034)

Clinical features are not stereotyped, and unless the attending clinician is alive to the bizarre symptoms to which it gives rise, insulinoma of the pancreas, still somewhat of an enigma, will often continue to be displayed only at that final Court of Appeal—the post-mortem room, for so often the patient is diagnosed as psychoneurotic, epileptic, a malingerer, or a sufferer from organic nervous disease.

The attacks, due to hypoglycæmia, come on at irregular intervals and often with progressively increasing frequency and severity. Four stages are recognised, and in the beginning the attacks do not necessarily progress beyond the first or second stages.

Paul Langerhans, 1847–1888. Professor of Pathological Anatomy, Freiburg, Germany.

FIG. 1034.—Beta-cell islet tumour of the pancreas.

Stage 1.—Often the symptoms simulate duodenal ulcer, awakening the patient in the early hours of the morning with vague abdominal discomfort, relieved by carbohydrates. At other times nervous symptoms predominate. There is a vague feeling of being unwell, a disinclination for exertion, and possibly some disorientation.

Stage 2.—Trembling, sweating, dizziness, blurring of vision, and great hunger.

Stage 3.—Sluggish mind, inarticulate speech, incoordinated movements, diplopia, sometimes hallucinations.

Stage 4.—Fits indistinguishable from epilepsy[1] passing into semi-consciousness or coma, with dilated pupils and extreme spasticity. In course of time intellectual deterioration is liable to follow.

Usually the patient is an adult under forty years of age, but a few cases have occurred in children. Because eating relieves the symptoms, over-weight not infrequently results. Pain is not a feature of benign insulinoma, but is present in most cases where a malignant change has occurred.

In a few instances the tumour contains sufficient calcium to show in a radiograph.

Diagnosis.—The three criteria (Whipple's triad), which, if present, suggest the diagnosis, are:

1. An attack, as described above, occurs in the fasting state (i.e. in the morning) or with exercise.
2. During the height of the attack there is a hypoglycæmia below 45 mg per 100 ml (2·5 mmol/l) of blood.
3. The symptoms are relieved by glucose.

Confirmation depends on the identification of fasting hypoglycæmia (fig. 1035), associated with elevated human insulin levels as measured by radioimmunoassay. Further confirmation may be sought by more elaborate insulin stimulation and suppression tests.

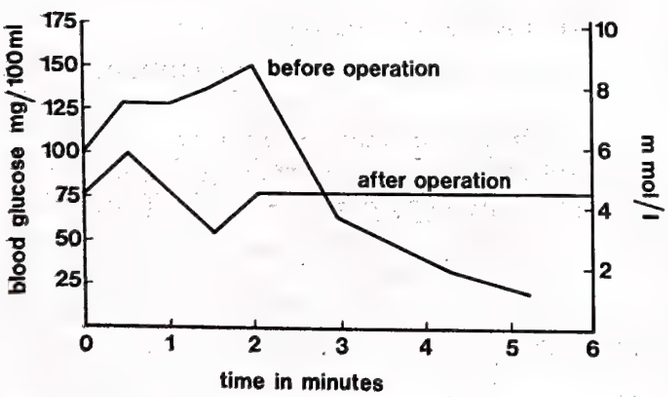

FIG. 1035. — The hypoglycæmia caused by the islet-cell tumour is cured by operation.

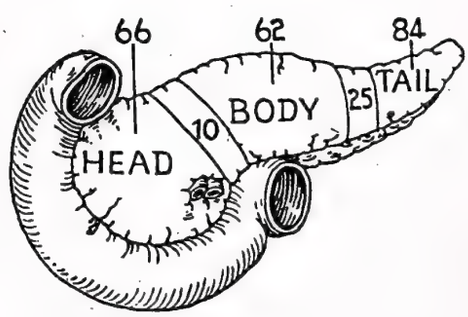

FIG. 1036.—Site of the insulin-secreting adenoma in 254 cases. Seven were situated in an ectopic pancreas. Twenty were overlooked at operation. (*J. M. Howard et al., Philadelphia.*)

Treatment.—The only curative treatment is extirpation of the tumour or tumours. An intravenous drip infusion of isotonic dextrose solution is started, laparotomy is performed and the pancreas is displayed. When the tumour (fig. 1036) is not located at once, the pancreas should be mobilised to enhance thorough palpation. In 12 per cent. of cases more than one tumour is present. Once found by palpation, an incision is made in the pancreas over the tumour. As a rule complete enucleation is possible. Drainage of the area is essential. Undue hardness of the tumour calls for partial pancreatectomy, but this measure is required most often because of failure to locate the tumour, in which event more than half the specimens removed reveal no abnormality. Consequently, the result in these instances is not always what is hoped

[1] The brain cannot store dextrose, which it requires in large amounts. Deprivation of this essential brings about a burst of nervous energy; the higher centres are affected first.

Allen Oldfather Whipple, 1881–1963. Valentine Mott Professor of Surgery, Columbia University College of Physicians and Surgeons, New York, U.S.A.

for. In cases where the tumour is removed, 87 per cent. of patients are cured; in 4 per cent. there is slight or no relief. The mortality is about 8 per cent.

Zollinger-Ellison Syndrome.—This diagnosis should be suspected in every case of recurrent peptic ulceration particularly where multiple ulcers are present or where they occur in unusual sites in the gastrointestinal tract. Two types are recognised—

Z.E.S. Type I (rare). These have antral G-cell hyperplasia, hypergastrinaemia and chronic peptic ulceration.

Z.E.S. Type II. This may be due to an ulcerogenic, non-β-islet-cell tumour[1], or sometimes to diffuse hyperplasia of the islet cells. The tumour secretes gastrin and is usually found in the tail of the pancreas. About half are malignant. There is (1) intractable peptic ulceration, often in the jejunum (2) hypergastrinaemia with massive acid hypersecretion of up to 500 ml per hour (3) diarrhœa and sometimes steatorrhœa or hypokalæmia.

Diagnosis.—Acid secretion studies (p. 786) and estimation of circulating gastrin (p. 787) will usually establish this. In Type I the plasma gastrin levels are further increased by meat extracts. In Type II calcium infusions may do the same.

Treatment.—Type I—partial gastrectomy to remove the G-cell bearing area.
Type II—total gastrectomy with removal of the tumour if present.

This classification is the subject of current dispute.

CARCINOMA OF THE PANCREAS

of the Head 70% — The head proper ($\frac{2}{3}$).
of the Head 70% — The periampullary region ($\frac{1}{3}$).
of the Body and Tail 30%.

Primary carcinoma of the pancreas accounts for some 4,000–5,000 deaths in England and Wales every year. Both here and in North America it is thought to be on the increase. Most of the patients are past the meridian of life, the average age being 57; sometimes this condition is seen in patients who are in their thirties. Contrary to general belief men are attacked only a little more than women.

Pathology.—Usually the lesion is scirrhous, almost gritty to the knife edge, and fibrous in appearance. Occasionally it is medullary; exceptionally it is a cystadenocarcinoma. It is thought to arise from the duct epithelium.

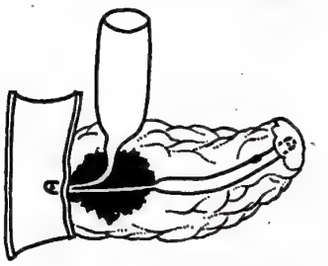

FIG. 1037.—Carcinoma of the head of the pancreas causing obstruction to the common bile duct and the duct of Wirsung.

(*a*) **Carcinoma of the head proper** is sometimes small in size (diameter 2–4 cm). The reason for this is that while still comparatively small it compresses the common bile duct (fig. 1037) and unless the obstruction is relieved, death from cholæmia results. As a small growth always lies deeply in the pancreas, obtaining a reliable specimen for biopsy is problematical (p. 933). This group includes a small number of carcinomas of the distal portion of the common bile duct which are much less invasive.

(*b*) **Periampullary Carcinoma.**—In less than one-third of cases of carcinoma of the head of the pancreas the neoplasm arises in the duodenal papilla, in the ampulla of Vater, or in the duodenal mucosa adjacent to the

[1] So-called because it is likely, but not absolutely certain, that alpha-cells are involved.

Robert Milton Zollinger, Contemporary. Professor of Surgery, Ohio State University, Columbus, Ohio, U.S.A.
Edwin Homer Ellison, Contemporary. Professor of Surgery, Marquette University, Milwaukee, Wisconsin, U.S.A.

papilla. When a specimen is examined at operation, it is often impossible to decide which of the three was the seat of origin—hence they are grouped together under the comprehensive term ' periampullary '.

(*c*) **Carcinoma of the body and tail** tends to attain a greater size than the foregoing varieties; it also metastasises more widely.

Spread: *Local Spread.*—Carcinomas belonging to categories (*a*) and (*c*) above tend to adhere to, and invade, adjacent structures, particularly the duodenum, occasionally the pyloric antrum, and the transverse mesocolon in the region of the superior mesenteric vessels.

Lymphatic spread from the head is first to the lymph nodes along the hepatic artery; that from the body and tail is to the gastric, cœliac, mesenteric, and para-aortic lymph nodes. The supraclavicular lymph nodes are involved less commonly than in cases of carcinoma of the stomach.

Spread by the blood-stream occurs somewhat later. Metastases are carried especially to the liver; usually the hepatic metastases are small and numerous.

Peritoneal implantation resulting in ascites occurs in 10% of cases.

Clinical Presentation

Primary carcinoma of the pancreas presents in two distinct ways:

(1) **As Painless progressive Obstructive Jaundice.**—This group includes the vast majority of cases, and pruritus due to bile salts in the blood coincides with the onset of jaundice and may be severe. The jaundice usually progresses steadily until the patient is almost green in colour.

An exception to this rule sometimes occurs in cases of periampullary carcinoma. After about a month of progressive (usually painless) jaundice, necrosis of a portion of the growth sometimes occurs, and pent-up bile escapes into the duodenum. Variations in the depth of the jaundice and pyrexia heighten the similarity of the symptoms caused by this neoplasm to those of obstruction of the common bile duct by a gall-stone.

Jaundice may occur when the growth is in the body and tail, but then it is due either to malignant lymph nodes in the portal fissure or metastases in the liver.

Pain.—This must be carefully enquired for, for though it is present in some of these patients it may not be a marked feature. It is usually a steady dull ache in the epigastrium radiating through to the back; it may be colicky and simulate gall-stone pain; sometimes it is paroxysmal radiating from the umbilicus and through to the back. *A distended gall-bladder* is palpable in 60% of cases (Courvoisier's law, p. 898).

Anorexia is present in about 65% of cases. It is usually not severe.

Diarrhœa may be troublesome, and foul smelling. The pale stools in the jaundiced patient with a periampullary tumour may take on a glistening watery appearance (like *aluminium or lead paint*)[1] due to the presence of small amounts of blood. Steatorrhœa from enzyme deficiency, is the explanation.

---

[1] Sir Heneage Ogilvie, 1887–1971. Surgeon, Guy's Hospital, London, described them as ' silvery stools '.

Loss of weight occurs in 90% of cases. Often the patient may not have noticed it. A feeling of profound weakness or depression is not uncommon.

Enlargement of the Liver.—The liver is palpably enlarged in 65% of cases of carcinoma of the head of the pancreas. As a rule this enlargement is due to biliary obstruction, but it may be due to hepatic metastases.

Acute cholecystitis and/or acute pancreatitis is occasionally the first indication of carcinoma of the pancreas, and in patients of the older age group this possibility should come to mind.

(2) **As Intractable Pain without Jaundice.**—It must be remembered that any middle-aged patient who complains of intractable pain in the back at the level of the lumbar vertebræ 1 and 2, and especially on the left side, may be suffering from carcinoma of the tail of the pancreas. The usual picture is that of a persistent epigastric or back pain with a normal barium series. The patient usually says that the pain is worse when he lies down and it tends to keep him awake at night. As with most cases of retroperitoneal inflammatory or neoplastic disease of the posterior abdominal wall, the pain is eased by sitting up and leaning forward in bed, and this is the position the patient usually adopts. The pain is not related to food, but a marked feature is that it persists, week in, week out. Unfortunately many of these cases are regarded as having a backache of functional origin. Weakness, loss of weight, anorexia, and diarrhœa are commonly present, and indeed, the disease may present in just this way.

Thrombophlebitis migrans may be an indication of the presence of pancreatic carcinoma of either type. The thrombophlebitis appears spontaneously in almost any superficial vein; it resolves, only to re-appear elsewhere. The explanation of this phenomenon is still obscure. It was first described by Trousseau and also occurs in other types of abdominal carcinoma and sometimes in chronic pancreatitis.

Diabetes and Carcinoma of the Pancreas.—(*a*) Diabetes mellitus is occasionally the first sign of carcinoma of the pancreas. Typical pain may be a pointer. The condition should be suspected when a middle-aged person develops diabetes and, in spite of adequate diabetic treatment, continues to lose weight. In these patients the carcinoma may run a galloping course.

(*b*) Carcinoma of the pancreas is about ten times more frequent in diabetics than in the population at large.

Calcinosis and Carcinoma of the Pancreas —While pancreatic calcinosis is relatively rare among patients with pancreatic carcinoma, carcinoma of the pancreas develops in patients with pancreatic calcinosis with such frequency as to warrant the assumption that pancreatic calcinosis is a pre-carcinomatous condition.

Investigations:

Radiography.—In the case of carcinoma of the head of the organ sometimes the ⊂ of the barium-filled duodenum is widened—the ' pad ' sign (so-called because it appears as if the ⊂ is crammed with padding) (fig. 1038). On infrequent occasions a periampullary carcinoma provides a filling defect which may give the duodenum the appearance of a reversed 3→Ɛ (the reversed Ɛ sign, fig. 1039). Coeliac

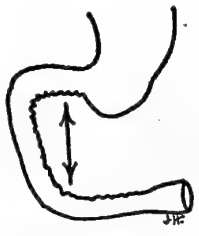

FIG. 1038.—The pad sign.

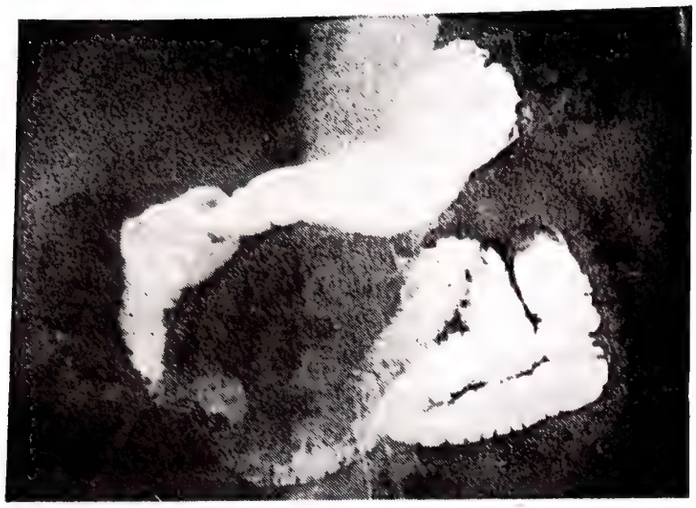

FIG. 1039.—Barium meal showing widened duodenal loop and the reversed 3 sign. (*Rodney Smith, P.R.C.S., London,* Trans. med. Soc. Lond.)

angiography may show an abnormal vascular pattern in the gland.

Hypotonic Duodenography.—A Dreiling double lumen tube is screened into the duodenum (fig. 1040) 20–40 ml. of liquid barium solution is then run in and 4 mg of oxyphenonium bromide (Antrenyl) given intravenously to render the bowel atonic. Air is then carefully insufflated to distend the duodenum. This gives a clear outline of the viscus (fig. 1041). Where carcinoma has invaded the duodenal wall spiculation or 'rose-thorn' distortion of the contour of the medial border may be seen (fig. 1042).

Chronic pancreatitis by contrast appears to straighten the medial duodenal wall. *Ampullary carcinomas* may be well shown as a filling defect (fig. 1043).

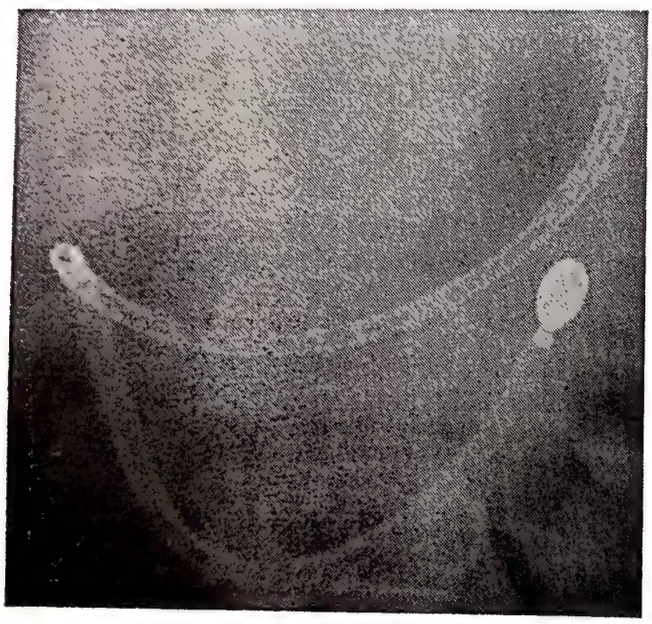

FIG. 1040.—Dreiling tube in duodenum.

FIG. 1041.—Normal hypotonic duodenogram.

FIG. 1042.—Carcinoma of head of pancreas. 'Rose thorning' of medial wall of duodenum.

FIG. 1043.—Carcinoma of ampulla. Filling defect in region of ampulla.

Laboratory Tests.—*The stercobilinogen content of the faeces* is often lower than that found in chronic pancreatitis—less than 10 mg. per day.

Occult blood in the stools is a valuable finding. It is especially frequent in cases of periampullary carcinoma (see aluminium paint stool, p. 926).

Pancreatic Function Tests

These may be combined with hypotonic duodenography and duodenal cell cytology studies in a useful *Triple Test.* In this, 1. the tube is inserted, pancreatic function tested (p. 918) and 2. some of the aspirate centrifuged as soon as possible, at 3,000 rev/min for 10 minutes. 3. The deposit is then fixed and stained by Papanicolaou's method. At the conclusion of this hypotonic duodenography is performed. In a recent series all but one of 29 carcinomas of the head of the pancreas and all ampullary tumours were diagnosed by this combination of tests. This method will not, however, show stones in the common bile duct or high bile duct carcinomas. It can be carried out with modest hospital facilities.

Endoscopic Retrograde Cholangio-Pancreatography (*E.R.C.P.*).—The ampulla of Vater (fig. 1044) can now be cannulated using a side-viewing fibre-

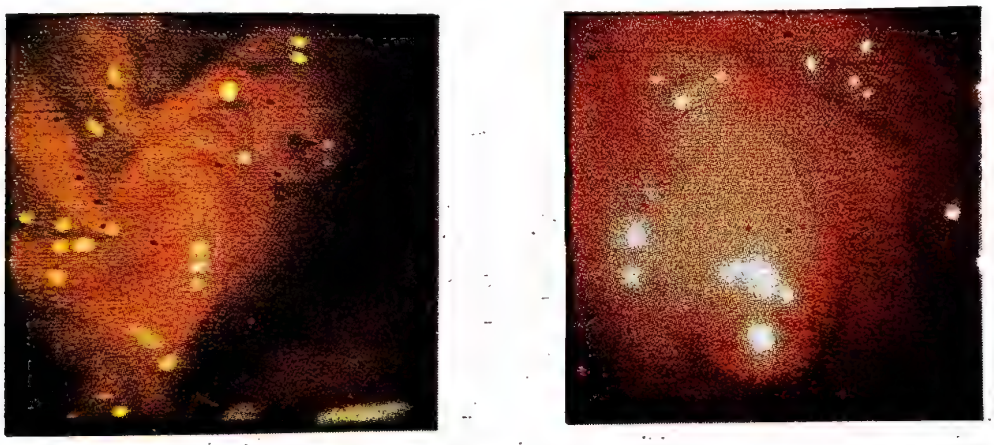

FIG. 1044.—Normal ampulla seen at duodenoscopy.

optic duodenoscope and the biliary and pancreatic ducts outlined with 65% Angiografin. This technique can be of value in confirming the presence or absence of a surgical cause of jaundice (figs. 1045 and 1046).

The retrograde pancreatogram will demonstrate the morphology of the pancreatic ducts. The normal anatomy is shown in fig. 1047. Changes seen in chronic pancreatitis include strictures, dilated main ducts with stones (figs. 1048 and 1049) and first order branches and pancreatic cysts (fig. 1050). The 'chain' of lakes appearance due to alternating strictures and duct sacculation is seen in fig. 1051. The technique is of great value in both the diagnosis of chronic pancreatitis and in determining whether surgical intervention is indicated and what therapeutic procedure should be used.

In pancreatic carcinoma the main pancreatic duct is narrowed or completely obstructed at the site of the tumour with dilatation upstream of the obstruction but with a normal duct system downstream of the obstruction (fig. 1052). In cases where the changes are difficult to distinguish from pancreatitis, cytological examination of pancreatic juice obtained directly

from the cannulated pancreas can confirm the radiological diagnosis (fig. 1053).

The investigation is not free of side effects; cholangitis, amylasæmia and acute pancreatitis have occasionally been encountered.

Although difficult to master, the technique has much to offer and seems less risky than liver biopsy or percutaneous transhepatic cholangiography (p. 905) in jaundiced cases where the diagnosis remains in doubt. The *triple test* by contrast requires no special equipment or skill but has the limitations mentioned above (p. 929).

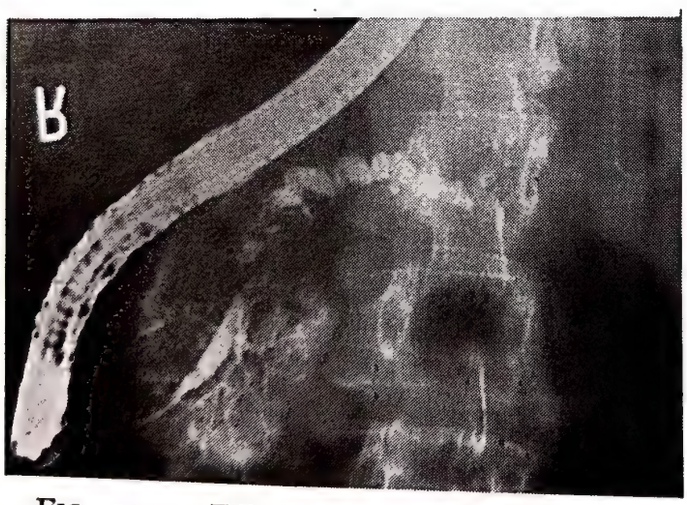

FIG. 1052.—E.R.C.P.: Pancreatic carcinoma. Irregular stricture of main pancreatic duct with dilatation upstream of obstruction.

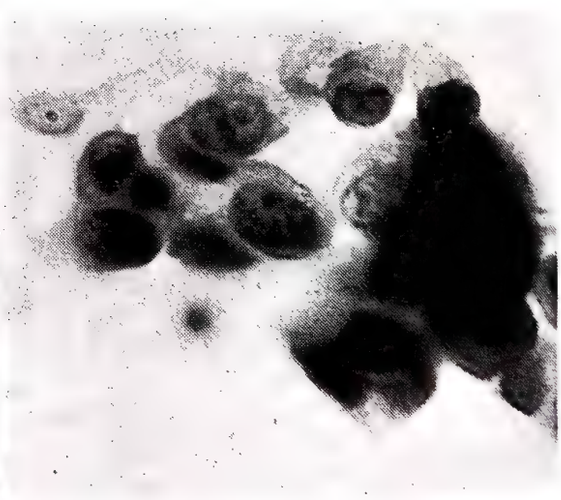

FIG. 1053.—Group of adenocarcinoma cells from the pancreatic juice, collected at the time of E.R.C.P. of the patient illustrated in fig. 1052.

Management:

Exploratory laparotomy is called for under the following circumstances: (1) Patients presenting with upper abdominal pain and loss of weight which might be pancreatic in origin, where none of the above special investigative

back-up is available, (2) where undiagnosed jaundice persists and the laboratory tests remain equivocal but not until at least three weeks have passed. In such cases preliminary vitamin K injections are necessary. If the serum bilirubin is over 15 mg/100 ml (255 mol/l) and rising or the blood urea is elevated Mannitol should be given at the start of the operation. If resection is judged to be feasible and there is no evidence of metastases or extra-pancreatic spread, histological evidence should, if possible, be obtained. Suction needle biopsy is emerging as the most safe technique for this but all methods are limited by histological dubieties. Ideally studies of pancreatic juice obtained with the Triple Test or with E.R.C.P. will already have shown malignant cells and this renders biopsy, which can be hazardous, unnecessary.

Operative Treatment.—The problem of obtaining histological evidence is now, however, of limited relevance. Many series from all over the world have shown that pancreaticoduodenectomy for growths in the head of the pancreas itself have given five-year survival rates which are no better than is achieved by palliative operations. These carry an immediate operative mortality rate which is much lower. In most centres resection is now advised only in cases where the tumour is likely to be slow growing, that is, in tumours of the distal bile duct, ampulla or duodenal papilla.

PANCREATICODUODENECTOMY

Procedure.—A long right paramedian incision is made. Explore the abdomen and the area thoroughly. Involved lymph nodes, fixity of the tumour, and liver secondaries rule out radical surgery.

Expose the duodenum by separating the right half of the transverse colon and the hepatic flexure from their peritoneal attachments and dissect out the common bile duct above the duodenum. Mobilise the duodenum by dividing the peritoneum along its right border so that it can be lifted off the inferior vena cava. Clear the superior mesenteric vessels and make sure that these and the portal vein are not involved in growth.

If the growth is operable the operation may proceed. Divide the common bile duct above the duodenum, mobilise the duodenum and pyloric antrum and ligate and divide the right gastric, right gastro-epiploic, and gastro-duodenal vessels. The duodenojejunal flexure is exposed and divided and the inferior pancreaticoduodenal vessels are ligated. The superior mesenteric vessels in the region of the uncinate process must be carefully exposed. The pancreatic venous radicles there are very short and tenuous. They may be torn easily. Reconstruction is now carried out as in fig. 1054. Alternatively, the pancreas may be anastomosed end-to-end with the jejunum and the bile duct end-to-side.

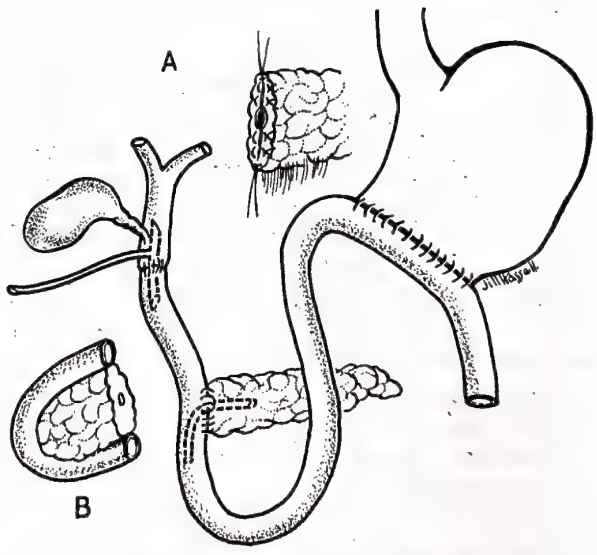

FIG. 1054.—Reconstruction after pancreatoduodenectomy. Inset A, the stump of the body of the pancreas prepared for anastomosis with the jejunum. Inset B, the portion removed. *(After H. A. Zintel.)*

The abdomen is now closed, but the areas of the biliary and pancreatic anastomoses must be drained.

Post-operative Treatment.—Transfusion of blood should be continued after the operation, as necessary, and vitamin K injections given for several days.

Mortality and Results.—The general mortality of this extensive procedure is about 20%. The complications are principally those of bleeding from numerous unidentified sources or leakage from the pancreatic or common bile duct anastomoses. The five-year survival rate of this operation is disappointingly low for carcinoma of the pancreas proper (4–6%); when performed for carcinoma of the ampulla the rate is much better (>30%).

PALLIATIVE OPERATION

In the presence of jaundice when resection is not indicated, cholecystjejunostomy (fig. 1055) is performed. This measure, by short-circuiting the obstruction of the common bile duct, relieves the jaundice and gives good palliation. It should be combined with gastroenterostomy if there is any danger of the tumour later obstructing the duodenum. Where the cystic duct is inserted low and may come to be occluded, the operation is unsuitable. Here choledocho-jejunostomy is indicated. Perhaps the major blessing it confers is relief from the intolerable itching. Back pain from continued infiltration of the growth is its most serious sequel. Operative mortality is 3–5%.

FIG. 1055.—Cholecystjejunostomy.

From time to time, to the astonishment of all concerned, the patient continues to improve and recovers completely, which shows how closely chronic pancreatitis of the head of the organ can mimic a neoplasm in this situation (fig 1056.).

Treatment of Carcinoma of the Body and Tail of the Pancreas.—When laparotomy is performed before a growth situated towards the tail of the organ has metastasised, it can be resected with comparative ease, and some lasting cures have been reported. The outlook in cases of papillary cystadenocarcinoma is particularly favourable.

Total pancreatectomy is a formidable procedure but has been successful for both carcinoma and chronic pancreatitis. The patients require insulin—30 to 70 units daily. Pancreatin, 10 to 12 g daily, is given to improve fat absorption.

Treatment of Papillary Carcinoma.—There is some evidence that transduodenal amputation of such lesions, with reimplantation of the bile and pancreatic ducts into the duodenum, may afford good palliation in debilitated subjects. The procedure should be combined with cholecystjejunostomy, to anticipate local recurrence. It should not be attempted without full mobilization of the duodenal loop.

FIG. 1056.—Obstructive jaundice with markedly distended gall-bladder (Courvoisier's sign, p. 864). ? carcinoma of pancreas. ? chronic pancreatitis.

Treatment of Intractable Back Pain.—Both Splanchnic Block and Percutaneous Cordotomy have been used successfully for this.

Chemotherapy 5-Alpha-Fluoro-Uracil (5 FU) reduces pancreatic secretion and may reduce the speed of growth of the tumour and relieve pain in some cases.

CHAPTER 46

THE PERITONEUM. OMENTUM. MESENTERY AND RETROPERITONEAL SPACE

THE peritoneum is conveniently divided into two parts—the *visceral* surrounding the viscera, the *parietal* lining the rest of the cavity. The parietal portion is richly supplied with nerves and, when irritated, causes severe pain accurately localised to the affected area. The visceral peritoneum, on the other hand, is poorly supplied with nerves and pain arising therefrom is vague and poorly localised (p. 960).

Surgical Physiology.—The peritoneal cavity is the largest cavity in the body, the surface area of its lining membrane being nearly equal to that of the skin. This veil-like serous membrane is composed of flattened polyhedral cells, one layer thick, resting upon a thin layer of fibro-elastic tissue, the two layers constituting the peritoneum. Beneath the peritoneum, supported by a small amount of areolar tissue, lies a network of lymphatic vessels and rich plexuses of capillary blood-vessels from which all absorption and exudation must occur. In health, only sufficient peritoneal fluid, which is a pale yellow, somewhat viscid fluid containing lymphocytes and leucocytes, is secreted to ensure that the more mobile viscera glide easily. The specific gravity of the intra-abdominal contents is approximately 1.000. Mobile gas-filled structures float upwards. It is not possible to measure pressure in a potential space but indirect evidence suggests that intraperitoneal pressure may be lower than atmospheric, and is unrelated to intravisceral pressure.

When free fluid is present in the peritoneal cavity, the pressure relationships are altered. Pressure is reduced in the upper abdomen compared with the lower abdomen. When air is introduced it rises, allowing all the abdominal contents to sink.

Under the influence of decreased intra-abdominal pressure, occasioned by the upward movement of the diaphragm during expiration, aided by capillary attraction, any secretion travels continuously in an upward direction to the subdiaphragmatic spaces, where experimental evidence shows that fine coloured particulate matter and bacteria are absorbed rapidly into the subperitoneal lymphatic network. In a matter of minutes these coloured particles reach the lymph nodes *above* the diaphragm.

When there is an outpouring of many ounces of peritoneal fluid, and, perhaps in addition, the contents of the stomach or duodenum escape into the peritoneal cavity through a perforation, it is extremely doubtful if the forces just described are powerful enough to counteract the law of gravity In all probability, excess of free fluid within the peritoneal cavity unobstructed by adhesions runs downwards.

When parietal peritoneal defects are created, healing occurs not from the edges, but by metamorphosis of *in situ* mesenchymal cells. Large defects heal as rapidly as small defects.

ACUTE PERITONITIS

Nearly all varieties of peritonitis are due to an invasion of the peritoneal cavity by bacteria. To such an extent is this true that when the term 'peritonitis' is used without qualification, bacterial peritonitis is implied.

Bacteriology

Bacteria from the Alimentary Canal.—Usually the infection is caused by two or more strains. The commonest invaders are *Escherichia coli*, aerobic and anaerobic streptococci, and the bacteroides. Less frequently the

Clostridium welchii is found; still less frequently staphylococci or *Klebsiella pneumoniæ* (Friedländer's bacillus), and so on. Many of the strains of *Esch. coli*, bacteroides, and *Cl. welchii* produce toxins which cause severe illness or death when they invade a large absorptive area (endotoxin shock, p. 78).

The Bacteroides.[1]—Only recently has the frequency and importance of the presence of bacteroides in the causation of peritonitis been realised. These Gram-negative, non-sporing organisms though predominant in the lower intestine often escape detection because they are strictly anaerobic, and slow to grow on culture media unless there is an adequate carbon-dioxide tension in the anäerobic apparatus (Gillespie). In many laboratories, the culture is discarded if there is no growth in forty-eight hours. These organisms are resistant to penicillin and streptomycin but sensitive to metronidazole, clindamycin and lincomycin.

Bacteria NOT *from the Alimentary Canal.*—Examples are peritonitis due to the gonococcus, beta-hæmolytic streptococcus, pneumococcus, and the *M. tuberculosis*. Since the advent of antibiotics hæmolytic streptococcal peritonitis has lost many of its dreaded lethal properties.

PATHS OF BACTERIAL INVASION

Direct infection	Via perforation of some part of the gastro-intestinal canal.
	Through a penetrating wound of the abdominal wall.
	Post-operative.
Local extension	From an inflamed organ, e.g. appendicitis, cholecystitis.
	Migration through gut wall, e.g. strangulated hernia.
	From or via the Fallopian tubes.
Blood-stream	Part of general septicæmia.

Even in non-bacterial peritonitis (e.g. intraperitoneal rupture of the bladder or a hæmoperitoneum) the peritoneum soon becomes infected by transmigration of organisms from the bowel, and it is not long (often a matter of hours) before chemical peritonitis becomes a peritonitis in the usual meaning of the term.

Factors which favour Localisation of Peritonitis. These factors are anatomical and pathological:—

Anatomical.—Excluding the subphrenic spaces (p. 941), the greater sac of the peritoneum is divided into (*a*) the pelvis, and (*b*) the peritoneal cavity proper. The latter is re-divided into a supracolic and an infracolic compartment by the transverse colon and transverse mesocolon, which deter the spread of infection from one to the other. When the supracolic compartment overflows, as is often the case when a gastric ulcer perforates, it does so over the colon into the infracolic compartment, or, by way of the right paracolic gutter to the right iliac fossa, and thence to the pelvis.

Pathological.—The clinical course is largely governed by the manner in which adhesions form around the affected organ. Inflamed peritoneum loses its glistening appearance and becomes reddened and velvety. Flakes of fibrin appear and cause coils of intestine to become adherent to one another and to the parietes. There is an outpouring of serous fluid rich in leucocytes and antibodies, that soon becomes turbid; if localisation occurs, the turbid fluid becomes frank pus. Peristalsis is retarded in affected coils,

[1] Bacteroides = bacteria with rounded ends.

Theodor Albrecht Edwin Klebs, 1834–1913. Professor of Bacteriology successively at Prague, Zurich and Rush Medical College, Chicago, Illinois, U.S.A.

William Alexander Gillespie, Contemporary. Professor of Clinical Bacteriology, University of Bristol.
Gabriele Falloppio (Fallopius), 1523–1563. Professor of Anatomy, Surgery and Botany, Padua, Italy.

and this helps in preventing distribution of the infection to other coils. The greater omentum, by enveloping and becoming adherent to inflamed structures, often forms a substantial barrier to the spread of infection.

Factors which tend to cause diffusion of peritonitis

(*a*) A prime factor in the spread of peritonitis is whether it develops rapidly or slowly. If an inflamed appendix (fig. 1057) or other hollow viscus perforates before localisation has taken place, there is a gush of intestinal contents into the peritoneal cavity which spreads over a large area almost instantaneously.

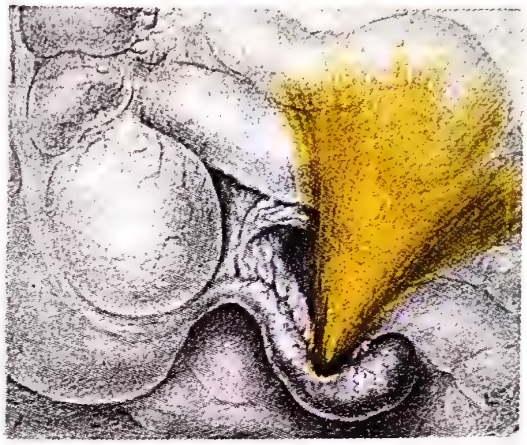

FIG. 1057. — Sudden perforation, especially if engendered by purgation, often results in an immediate widespread bacterial peritonitis.

(*b*) The ingestion of food, or even water, by stimulating peristaltic action, hinders localisation. Violent peristalsis occasioned by the administration of a purgative or an enema, causes a widespread distribution of an infection that would otherwise have remained localised.

(*c*) When the virulence of the infecting organism is so great as to render the localisation of the infection difficult or impossible.

(*d*) In children the omentum is small.

CLINICAL FEATURES

Localised peritonitis is bound up intimately with the causative lesion, and the initial symptoms and signs are those of that lesion. When the peritoneum becomes inflamed the temperature, and especially the pulse-rate, rise. The pain increases and usually there is repeated vomiting. The most important sign is rigidity of the abdominal wall over the area of the abdomen which is involved. If inflammation arises under the diaphragm, shoulder tip (referred) pain may be felt (p. 942). In cases of pelvic peritonitis arising from an inflamed appendix in the pelvic position or from salpingitis, the abdominal signs are often slight, deep tenderness of one or both lower quadrants alone being present, but a rectal or vaginal examination reveals tenderness, often exquisite, of the pelvic peritoneum. With appropriate treatment localised peritonitis usually resolves. In about 20% of cases an abscess follows. Infrequently, localised peritonitis becomes diffuse. Conversely, in favourable circumstances diffuse peritonitis can become localised, most frequently in the pelvis.

Diffuse (*syn.* **Generalised**) **Peritonitis.**—1. *Onset.*—Pain, which is 'sore', 'cutting', or 'burning', is made worse by moving or breathing. It is at first localised to the site of the original lesion, and spreads outwards from this point. Vomiting may occur. The patient usually lies still. Tenderness, guarding, and rigidity on palpation are typically found when the

peritonitis affects the anterior abdominal wall. Abdominal tenderness, guarding, and rigidity are diminished or absent if the anterior wall is unaffected, as in pelvic peritonitis or, rarely, peritonitis in the lesser sac. Patients with pelvic peritonitis may complain of urinary symptoms; they are tender on rectal or vaginal examination. Bowel sounds may still be heard for a few hours but they gradually cease with the onset of paralytic ileus. The pulse rises progressively, but if the peritoneum is deluged with irritant fluid, there is a sudden rise. The temperature changes are variable.

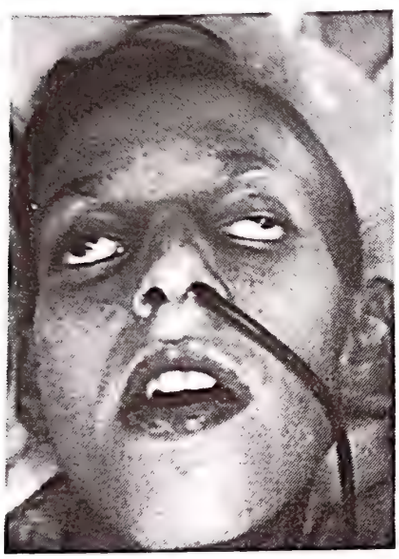

FIG. 1058.—The facies in terminal diffuse peritonitis.

2. *Intermediate.*—Peritonitis may resolve, so that the pulse slows, the pain and tenderness diminish, leaving a silent, soft, abdomen. (These are features that can easily mislead the observer.) The condition may localise, producing one or more abscesses, with overlying swelling and tenderness.

3. *Terminal.*—If resolution or localisation have not occurred, the abdomen remains silent, and increasingly distends. Circulatory failure ensures, with cold, clammy extremities, sunken eyes, dry tongue, drawn and anxious face (Hippocratic facies—fig. 1058). The patient finally lapses into unconsciousness. With adequate treatment, this condition is rarely seen in hospitals.

Diagnostic aids.—Investigations will not save the need for careful confirmation of the history and physical signs, which are tenderness, guarding and rigidity with a distending silent abdomen. It is unwise to rely slavishly on any single symptom or sign; not one is incontrovertible.

A battery of investigations *may* elucidate a doubtful diagnosis. More often, they only confuse it. Peritonitis usually, but not always, produces leucocytosis. *Peritoneal diagnostic aspiration* may be helpful but is usually unnecessary. After infiltrating the skin of the abdomen with local anæsthetic, the peritoneum is entered in each quadrant with a sterile needle attached to a syringe, into which is sucked any free fluid. Bile-stained fluid indicates perforated peptic ulcer, the presence of pus indicates bacterial peritonitis; blood is aspirated in a high proportion of patients with intraperitoneal bleeding. When aspiration fails, the introduction of a small quantity of sterile physiological saline, followed after a few minutes by peritoneal aspiration may produce fluid of diagnostic value.

An X-ray film of the abdomen may reveal free air, or confirm the presence of dilated gas-filled loops of bowel with multiple fluid levels.

Serum amylase estimation may uphold the diagnosis of pancreatitis, provided it is remembered that raised values are frequently found following other abdominal catastrophes, and operations.

Treatment

The essential principles in the treatment of peritonitis are: (1) Correction of circulating volume and any electrolyte imbalance. (2) Decompression. (3) Antibiotics. (4) Appropriate surgical treatment.

1. *Intravenous Fluids.*—These patients are frequently hypovolæmic with electrolyte disturbances. The plasma volume must be restored and the plasma electrolyte concentrations corrected. Plasma protein depletion may

Hippocrates, by common consent the Father of Medicine, was born on the Greek Island of Cos, off Turkey, about 460 B.C. and died in 375 B.C.

need correction—inflamed peritoneum leaks protein calamitously and continuously.

2. *A nasogastric tube* is passed into the stomach, which is aspirated. Intermittent aspiration is maintained until the paralytic ileus resulting from peritonitis has recovered. After operation, measured volumes of water are allowed by mouth, when only small amounts are being aspirated. If the abdomen is soft and not tender, and bowel sounds return, oral feeding may be progressively introduced. It is important not to prolong the ileus by missing this stage.

3. *Antibiotics.*—Administration of antibiotics prevents the multiplication of bacteria, and the release of endotoxins. Penicillin 500,000 units with streptomycin 0·5 g twice daily intramuscularly, or tetracycline 0·5 g twice daily by slow intravenous infusion in dextrose-saline, are justly popular.

4. *Surgical correction of the underlying cause* must not be delayed in appropriate cases, once the patient is fit for operation. At the same time the results of peritonitis are corrected—necrotic material and pus are removed from the peritoneal cavity (see Peritoneal Toilet, below).

Ancillary Care

5. *A fluid balance chart* must be started at once so that daily output by gastric aspiration and urine are known, losses from the lungs, skin, and in fæces are estimated, so that the intake requirements can be calculated and seen to have been administered. Throughout recovery, the hæmatocrit values, blood electrolytes, and urea must be checked.

6. *Intravenous fluids* are continued after operation until the patient can be fully maintained by oral feeding. If recovery is delayed, high caloric, vitamin-rich supplements must be added to the balanced electrolyte solutions.

7. The patient, nursed in the sitting-up position, must be relieved of pain before and after operation. Morphine may be given, and small doses continued for 48 hours. Freedom from pain allows early mobilisation and adequate physiotherapy in the post-operative period, to prevent basal collapse, deep-vein thrombosis and pulmonary embolism.

Treatment of the Cause.—If the condition is amenable to surgery, such as in perforated appendicitis, gangrenous cholecystitis, diverticulitis, peptic ulcer or rarely in perforation of the small bowel, operation must be carried out as soon as the patient is fit for anæsthesia. This is usually within a few hours. In peritonitis due to pancreatitis, salpingitis, or in cases of primary peritonitis of streptococcal or pneumoccoccal origin, conservative treatment is the procedure of choice (if the diagnosis can be made with certainty).

Peritoneal Toilet.—In surgery for general peritonitis it is essential that after the cause has been dealt with, the whole peritoneal cavity should be explored with the sucker and mopped dry, if necessary until all sero-purulent exudate is removed. It is inadvisable to put in any antibiotic or antiseptic; the peritoneal fluid which is secreted is one of nature's best defence mechanisms.

Prognosis.—With modern treatment diffuse peritonitis carries a mortality of about 10 per cent. The lethal factors are (*a*) bacterial toxæmia, (*b*) paralytic ileus, (*c*) bronchopneumonia, (*d*) electrolyte-imbalance.

COMPLICATIONS OF PERITONITIS

All the complications of a severe bacterial infection are possible, but the special complications of peritonitis are as follows:

(1) *Acute intestinal obstruction due to peritoneal adhesions* (p. 1017). This usually gives central colicky abdominal pain with evidence of gas and fluid levels confined to the upper portion of the small intestine on X-ray. It is essential to distinguish this from:

(2) *Paralytic ileus* where there is usually little pain and gas-filled loops with fluid levels are seen distributed throughout the small and large intestines on the X-ray film. In intestinal obstruction, bowel sounds are increased. In paralytic ileus bowel sounds are reduced or absent.

(3) *Residual abscesses.*—Abscess formation following local or diffuse peritonitis usually occupies one of the situations shown in fig. 1059. When palpable, an intraperitoneal abscess should be treated by marking out its limitations on the abdominal wall, and meticulous daily examination. In the majority of cases, with the aid of antibiotic treatment, the mass becomes smaller and smaller, and finally is impalpable. In others, the abscess fails to resolve, or becomes larger, in which event it must be opened. In many situations, by waiting a few days the abscess becomes adherent to the abdominal wall, so that it can be drained without opening the general peritoneal cavity.

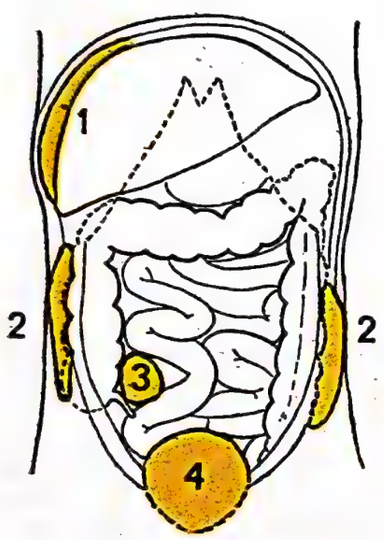

FIG. 1059. — Common situations for residual abscesses. 1. Subphrenic. 2. Paracolic. 3. Appendix. 4. Pelvic.

In the case of a laterally-placed abscess, the incision is made on the lateral side of the swelling. The layers of the abdominal wall are divided until the peritoneum is reached. With the finger, the extra peritoneal tissues are separated from the peritoneum until the abscess is opened. A drainage tube is inserted; if the path is tortuous, a Penrose drain (a thin tube of latex rubber containing a wick of gauze) is valuable.

PELVIC ABSCESS

The pelvis is the commonest site of an intraperitoneal abscess, because the vermiform appendix is often pelvic in position and also the Fallopian tubes are frequent foci of infection. A pelvic abscess can also occur as a sequel to any case of diffuse peritonitis. Pus can accumulate in this area without serious constitutional disturbance, and unless the patient is examined carefully from day to day, such abscesses may attain considerable proportions before being recognised. The most characteristic symptoms of a pelvic abscess are diarrhœa and the passage of mucus in the stools. It is no exaggeration to say that the *passage of mucus, occurring for the first time in a patient who has, or is recovering from, peritonitis, is pathognomonic of pelvic abscess.* Rectal examination reveals a bulging of the anterior rectal wall which, when the abscess is ripe, becomes softly cystic. Left to Nature, a proportion of these abscesses burst into the rectum, after which the patient nearly always recovers rapidly. If this

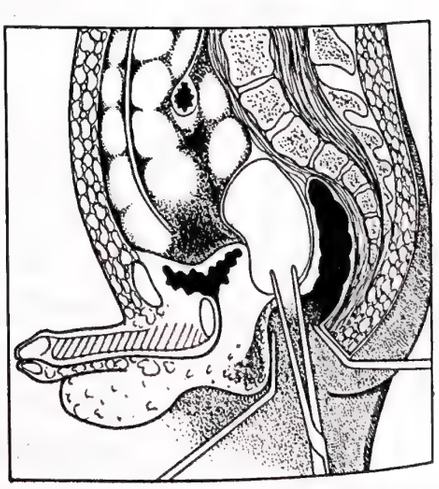

FIG. 1060.—Opening a pelvic abscess into the rectum.

Charles Bingham Penrose, 1862–1925. Professor of Gynæcology, University of Pennsylvania, Philadelphia, U.S.A.

possible happy termination does not readily occur, the abscess should be drained deliberately. In women vaginal drainage through the posterior fornix is often chosen. In other cases, where the abscess is definitely pointing into the rectum, rectal drainage (fig. 1060) is employed. If any uncertainty exists as to the presence of pus, an aspirating needle introduced through the rectal wall into the bulging swelling will settle the question. Occasionally, in the case of a large abscess which can be palpated above the pubes, after the bladder has been emptied by catheterisation, lower laparotomy should be undertaken in order to be quite certain of the diagnosis. Provided the abscess is shut off from the general peritoneal cavity, a point which can be ascertained undeniably when the abdomen has been opened, rectal drainage of a pelvic abscess is preferable to suprapubic drainage, which breaks down Nature's barriers and exposes the general peritoneal cavity to the dangers of spreading infection.

SUBPHRENIC ABSCESS

Anatomy.—The complicated arrangement of the peritoneum results in the formation of four intraperitoneal and three extraperitoneal spaces in which pus may collect. Three of these spaces are on either side of the body, and one approximately in the midline (fig. 1061).

Left Anterior intraperitoneal, bounded above by the diaphragm, behind by the left triangular ligament and left lobe of the liver, the gastro-hepatic omentum and anterior surface of the stomach. To the right is the falciform ligament, and to the left the spleen, gastrosplenic omentum, and diaphragm. The common cause of an abscess here is following operations on the stomach, the tail of the pancreas, the spleen or the splenic flexure of the colon or in diverticulitis.

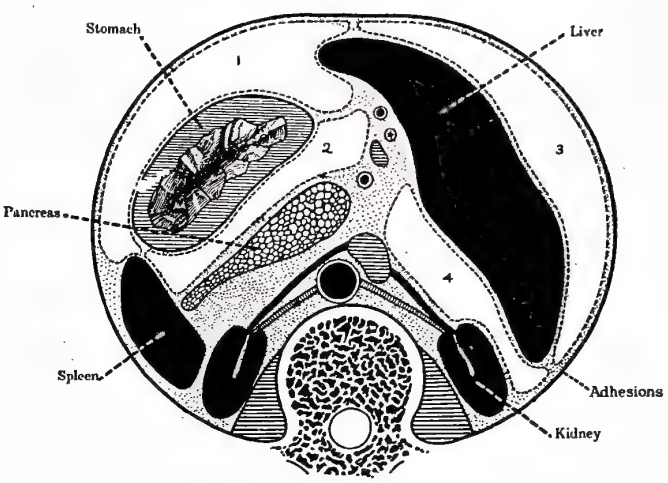

FIG. 1061.—Transverse section through the lesser sac of the peritoneum showing situations which extraperitoneal subphrenic abscesses may occupy. 1. left anterior space. 2. left posterior space (lesser sac). 3. right anterior space which becomes shut off by adhesions from 4, right posterior space.

Left Posterior intraperitoneal is another name for the 'lesser' sac. The commonest type of suppuration here is the pancreatic pseudo-cyst (p. 921). In practice perforated gastric ulcer rarely causes a collection here, because the potential space is obliterated by adhesions.

Right Anterior intraperitoneal, which lies between the right lobe of the liver and the diaphragm. It is limited posteriorly by the anterior layer of the coronary and the right triangular ligaments, and to the left by the falciform ligament. Common causes here are perforating cholecystitis, a perforated duodenal ulcer, a duodenal cap 'blow out' (p. 813) and appendicitis.

Right Posterior intraperitoneal (*syn.* Rutherford Morison's kidney pouch) lies transversely beneath the right lobe of the liver. It is bounded on the right by the right lobe of the liver and the diaphragm. To the left is situated the foramen of Winslow, and below this lies the duodenum. In front are the liver and gall-bladder, and behind, the upper part of the right kidney and diaphragm. The space is bounded above by the liver, and below by the transverse colon and hepatic flexure. It is the deepest space of the four and the commonest site of a subphrenic abscess which usually arises from appendicitis, cholecystitis, a perforated duodenal ulcer or following upper abdominal surgery.

Extraperitoneal.—There are three of these:

Right and Left extraperitoneal which are terms given to perinephric abscesses (Chap. 54).

Midline extraperitoneal which is another name for the 'bare' area of the liver which may develop an abscess in amœbic hepatitis (p. 856) (the commonest cause) or it may be a pyogenic liver abscess (p. 855).

James Rutherford Morison, 1853–1939. Professor of Surgery, Durham, England.
Jacob Benignus Winslow, 1669–1760. Professor of Anatomy, Physic and Surgery, Paris.

Clinical Features.—The symptoms and signs of subphrenic infection are frequently obscure, and it is well to remember the aphorism, " Pus somewhere, pus nowhere else, pus under diaphragm ".

Symptoms.—A common history is that when some infective focus in the abdominal cavity has been dealt with, the condition of the patient improves temporarily, but after an interval of a few days or weeks, symptoms of toxæmia reappear. The condition of the patient steadily, and often rapidly, deteriorates. Sweating, wasting, and anorexia are present. There is sometimes epigastric fullness and pain, or pain in the shoulder on the affected side, owing to irritation of sensory fibres in the phrenic nerve, referred along the descending branches of the cervical plexus. Persistent hiccup may be a presenting symptom.

FIG. 1062.—Radiograph in erect position showing subphrenic abscess containing gas.

Signs.—If the abscess is anterior, abdominal examination will reveal some tenderness, rigidity, or even a palpable swelling. Sometimes the liver is displaced downwards, but more often it is fixed by adhesions. Examination of the chest is important, and in the majority of cases collapse of the lung or evidence of effusion or empyema is to be found.

Accessory Investigations.—(i) *Blood Count.*—A relative and absolute leucocytosis is the rule.

(ii) *X-ray.*—A plain radiograph sometimes demonstrates the presence of gas (fig. 1062) or a pleural effusion. On screening, the diaphragm is often seen to be elevated (so-called ' tented ' diaphragm) and its movements impaired. A lateral film is also useful to show the position of the ' tented ' area ascertained. This helps in deciding on the surgical approach to the abscess.

Differential Diagnosis.—Pylephlebitis, tropical abscess, pulmonary collapse, and empyema give rise to most of the diagnostic difficulties.

Treatment.—The clinical course of suspected cases is watched, and blood and radiological examinations are made at suitable intervals. If suppuration seems probable, surgical intervention is indicated.

If a swelling can be detected in the subcostal region or in the loin, an incision is made over the site of maximum tenderness, or over any area where œdema or redness is discovered. The parietes usually form part of the abscess wall, so that contamination of the general peritoneal cavity is unlikely.

If no swelling is apparent, the subphrenic spaces should be explored either by an anterior sub-costal approach or from behind after removal of the *outer part* of the twelfth rib according to the position of abscess if indicated on a lateral X-ray film (see above). With the posterior approach the pleura must *not* be opened, and after the fibres of the diaphragm have been separated a finger is inserted beneath the diaphragm so as to explore the adjacent area.

Thus both approaches must be *extra-serous* to avoid dissemination of pus into the peritoneal or pleural cavities.

When the cavity is reached, all the fibrinous loculi must be broken down with the finger and one or two drains or drainage tubes must be fully inserted. These drains

are withdrawn gradually during the next ten days and the closure of the cavity checked by X-ray sino-grams.

The appropriate antibiotics are given in support.

Post-operative Peritonitis.—The patient is ill, with raised pulse and peripheral circulatory failure. Following post-operative leakage from a suture line, the general condition of a patient is far more grave than if the patient had suffered leakage from a perforated peptic ulcer with no preceding operation. Local symptoms and signs are less definite. Abdominal pain may not be prominent, tenderness may be masked by the presence of a recent wound. The patient's deterioration may be wrongly attributed to pulmonary collapse which is usually concomitant.

Peritonitis follows abdominal operations more frequently than is realised. The principles of treatment do not differ from those of peritonitis of other origin. Antibiotic therapy alone is inadequate; no antibiotic can stay the onslaught of bacterial peritonitis due to leakage from a suture line, which must be dealt with appropriately.

Peritonitis in Patients under Treatment with Steroids.—Pain is frequently slight or absent. Physical signs are similarly vague and misleading.

Peritonitis in Children.—The diagnosis is in some ways more difficult, in other ways more easy, than in adults. If a history can be taken it is plain and unembroidered. Any physical signs elicited by a gentle, patient, and sympathetic examiner are meaningful.

Peritonitis in Senile Patients.—These can be as fractious as children and unable to give a reliable history. Abdominal tenderness is usually well localised, but guarding and rigidity are less marked because the abdominal muscles are thin and weak.

Bile Peritonitis.—Unless there is reason to suspect that a bile duct was damaged at an operation in which drainage was not provided, it is improbable that bile as a cause of peritonitis will be thought of until the abdomen has been opened and bile is seen therein. The common causes of bile peritonitis are: (1) following biliary surgery—damage to the common bile duct, slipping of a ligature on the cystic duct, leakage from a divided accessory bile duct in the gall bladder bed or dislodgement of a T-tube drain in the early post-operative phase; (2) following perforation or gangrene of the gall-bladder or leakage from a choledochus cyst; and (3) following gastro-duodenal surgery, e.g. duodenal cap ' blow out ' (p. 813) or leakage from a suture line.

Unless the bile has extravasated slowly, and the collection becomes shut off from the general peritoneal cavity there are signs of diffuse peritonitis with a degree of shock. After a few hours a tinge of jaundice is not unusual. Local drainage, and when necessary suprapubic peritoneal drainage, is imperative, and if performed early enough, these measures will often save the patient's life. When bile is seen issuing from a perforation of some part of the biliary tree, a drainage tube should be passed through the opening and secured there. Infected bile is more lethal than sterile bile. The gall-bladder, if present, should be drained. A ruptured duodenum must be drained; it is too œdematous to repair.

Meconium Peritonitis.—Meconium is a sterile mixture of epithelial cells, mucin, salts, fats, and bile, and is formed when the fœtus commences to swallow amniotic fluid. By the third month of intra-uterine life the upper third of the small intestine has become filled with meconium; by the fourth month the accumulation has reached the ileo-caecal valve; during the remainder of intra-uterine life the colon becomes increasingly filled.

Meconium peritonitis is an aseptic peritonitis which develops late in intra-uterine life or during, or just after, delivery. Meconium enters the peritoneal cavity through an intestinal perforation, and in over 50 per cent. of cases the perforation is the result of some form of neonatal intestinal obstruction; in the remainder no cause for the perforation is discernible. When meconium, which is sterile, enters the peritoneal cavity an exudate is secreted that organises rapidly; matting of intestinal loops occurs, and in many cases in a matter of weeks the extruded meconium becomes calcified.

Meconium remains sterile until about three hours after birth; thereafter, unless the perforation has become sealed, sterile meconium peritonitis gives place to acute bacterial peritonitis which, unless treated promptly, is rapidly fatal.

Clinical Features.—Meconium peritonitis should always be considered when a baby is born with a tense abdomen. There is vomiting, and failure to discharge meconium. The differential diagnosis between neonatal intestinal obstruction and peritonitis is, in many cases, virtually impossible; indeed, in half the cases both are present. Free fluid in the peritoneal cavity is often sufficient to give a fluid thrill.

Radiography (fig. 1063).—Free air in the peritoneal cavity, an abundant quantity of abdominal fluid, fluid levels, calcification (often most distinct on the surface of the liver or the spleen, and most readily seen in a lateral view) are characteristic findings, all of which are unlikely to be present in every case. Meconium peritonitis has been diagnosed by radiography of the fœtus *in utero* two days before birth.

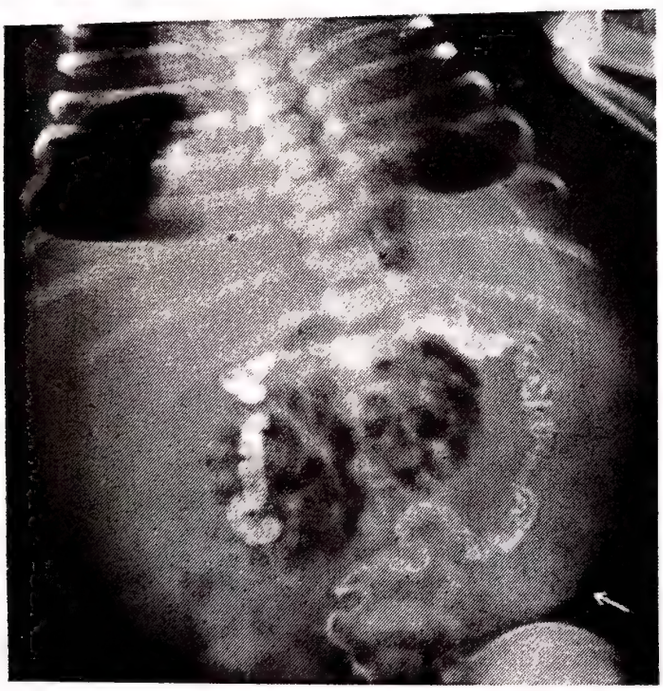

FIG. 1063.—Meconium peritonitis. Note: Free air and fluid in the peritoneal cavity; intra-abdominal calcification [↖] and on the spleen; air in the small intestine; microcolon shown by a barium enema. *(Dr. Jack Lester, Copenhagen.)*

Treatment.—The prognosis is bad, but recovery has followed prompt operation in some cases. The greatest chance of survival is in those patients who have an intestinal perforation but no intestinal obstruction, in which case closing the perforation and draining the peritoneal cavity is all-sufficient, and can be performed expeditiously.

Pneumococcal Peritonitis.—There are two forms of this disease:

1. Primary.
2. Secondary to pneumonia.

Primary pneumococcal peritonitis is much the more common. The patient is often an under-nourished girl between three and six years of age, and it is probable that the infection sometimes occurs via the vagina and Fallopian tubes, for pneumococci have been cultured from patients' vaginæ. At other times, and always in males, doubtless the infection is blood-borne from the upper respiratory tract or the middle ear. After the age of ten years pneumococcal peritonitis is most unusual. Children with nephritis are more liable to this condition than others. During the past thirty years the incidence of pneumococcal peritonitis has declined greatly and the condition is now rare. Perhaps this is on account of the greater cleanliness and higher standard of living of what was the poorer classes.

Clinical Features.—The onset is sudden, and the earliest symptom is pain localised to the lower half of the abdomen. The temperature is raised to 39·8° C or more, and there is usually frequent vomiting. After twenty-four to forty-eight hours profuse diarrhœa, occasionally blood-stained, is characteristic. There is usually increased frequency of micturition. The last two symptoms are due to severe pelvic peritonitis. Herpes on the lip or nostril is often present. In acute forms of the disease, even in cases where there is no involvement of a lung, there is a tinge of cyanosis of the lips and cheeks, and movement of the alæ nasi is often discernible. On examination rigidity is usually bilateral, but is less than in most cases of acute appendicitis with peritonitis.

Differential Diagnosis.—A leucocytosis of 30,000/mm^3 (30×10^9/l) or more with approximately 90 per cent. polymorphs speaks more for pneumococcal peritonitis than appendicitis. Even so, it is often impossible, especially in males, to exclude perforated appendicitis. The other condition which is extremely difficult to differentiate from primary peritonitis in its early stage is pneumonia. An unduly high respiratory rate and the absence of abdominal rigidity are the most important signs supporting the diagnosis of pneumonia, which is usually clarified by a radiograph of the thorax.

Treatment.—*Early operation* is always required. After correcting dehydration and electrolyte imbalance, a short paramedian incision is made over the right rectus abdominis. The peritoneum is incised. Should the exudate be odourless and sticky, the diagnosis of pneumococcal peritonitis is practically certain, but it is desirable to perform a routine laparotomy to exclude other lesions. Assuming that no other cause for the peritonitis is discovered, some of the exudate is removed with a syringe, and sent to the laboratory for culture and sensitivity tests. Thorough peritoneal toilet is carried out and the incision closed. The patient is returned to bed and antibiotic and fluid replacement therapy continued. Gastro-intestinal suction drainage is essential.

Primary streptococcal peritonitis of infants and children is rather more frequent than the foregoing but still uncommon. When a streptococcus is the infecting organism, the peritoneal exudate is thin, slightly cloudy, and contains flecks of fibrin. From the standpoints of clinical aspects and treatment, streptococcal peritonitis in infants and children does not differ from those detailed in the account of pneumococcal peritonitis (*vide supra*), but the mortality is higher.

Idiopathic streptococcal peritonitis in adults is fortunately rare, for prior to the antibiotic era it was nearly always fatal, and the mortality is still very high. Rightly, in early cases the abdomen is opened, usually on a diagnosis of acute appendicitis. In streptococcal peritonitis the peritoneal exudate is odourless, thin, contains small flecks of fibrin, and may be blood-stained. In these circumstances pus is removed by suction, the abdomen closed with suprapubic drainage, and the measures detailed in the conservative treatment of peritonitis carried out.

Peritonitis following Abortion Parturition.—The abortionist has usually pushed an instrument through the uterine vault and streptococcal peritonitis follows. When peritonitis follows puerperal infection, it is a notifiable disease. It is more common after first deliveries. Rigidity is seldom much in evidence; this, at any rate in part, is due to the stretched condition of the abdominal musculature. The lochia may be offensive but not necessarily so. Diarrhœa is common.

Treatment.—Provided the infection is limited strictly to the pelvis, the correct treatment is rest for the alimentary canal, intravenous fluids, the required antibiotic, and attention to electrolyte balance. Posterior colpotomy may be necessary if a pelvic abscess forms. If the peritonitis is generalised, the patient is usually extremely ill and drainage is advisable. This is best carried out by making a small

suprapubic incision under local anæsthesia and inserting a drain. This can be done with the patient in bed, if necessary.

In the pre-antibiotic era the mortality of general peritonitis following parturition or abortion was at least 50 per cent.; with antibiotic therapy and timely operation, the mortality has fallen to less than 10 per cent. (Brews).

Periodic peritonitis is characterised by abdominal pain and tenderness, mild pyrexia, polymorphonuclear leucocytosis, and occasionally pain in the thorax and joints. The duration of an attack is twenty-four to seventy-two hours, when it is followed by complete remission, but exacerbations recur at regular intervals. Most of the patients have undergone appendicectomy in childhood. The disease, often familial, is limited principally to Arabs, Armenians, and Jews; other peoples occasionally are affected. At laparotomy, which may be necessary to exclude other causes, the peritoneum—particularly in the vicinity of the spleen and the gall-bladder—is inflamed. There is no evidence that the interior of these organs is abnormal.

Differential Diagnosis.—Patients with abdominal epilepsy do not have positive physical signs or pyrexia, and their attacks are usually controlled by anti-convulsive medication.

The ætiology of periodic peritonitis is unknown, and no form of treatment has been found to be of the slightest avail.

Usually children are affected, but it is not rare for the disease to make its first appearance in early adult life, when females outnumber males by two to one. Exceptionally the disease becomes manifest in patients over forty years of age.

TUBERCULOUS PERITONITIS

Acute Tuberculous Peritonitis.—It is doubtful if tuberculous peritonitis is ever acute. However, tuberculous peritonitis sometimes has an onset that resembles so closely acute peritonitis that the abdomen is opened. Straw-coloured fluid escapes, and tubercles[1] are seen scattered over the peritoneum and greater omentum. Tubercles occasionally simulate fat necroses (p. 913) or the nodules of peritoneal carcinomatosis (p. 950). On opening the abdomen and finding tuberculous peritonitis, the fluid is evacuated, some being retained for bacteriological study, a portion of the diseased omentum is removed for histological confirmation of the diagnosis, and the wound closed without drainage.

At other times, although acute abdominal symptoms arise, the presence of ascites makes the diagnosis of acute tuberculous peritonitis reasonably evident.

Chronic Tuberculous Peritonitis.—Although the incidence of tuberculous peritonitis has declined in Britain, in many parts of the world where measures for eradicating tuberculosis (especially the disease in cows) are enforced less strictly, the condition still occurs.

FIG. 1064.—Tuberculous peritonitis, ascitic form. The patient has also left-sided tuberculous epididymitis. (*F. H. Roberts, F.R.C.S., Edinburgh.*)

Origin of the infection:

1. From tuberculous mesenteric lymph nodes.
2. From tuberculosis of the ileo-cæcal region.
3. From a tuberculous pyosalpinx.
4. Very occasionally it is due to a blood-borne infection from pulmonary tuberculosis.

There are four varieties of tuberculous peritonitis:

1. **Ascitic Form.**—The peritoneum is studded with tubercles, and the peritoneal cavity becomes filled with pale, straw-coloured fluid. The onset is insidious. There is loss of energy, facial pallor, and some loss of weight. The patient is usually brought

[1] Early tubercles are greyish and translucent. They soon undergo caseation, and appear white or yellow, and are then less difficult to distinguish from carcinoma.

Richard Alan Brews, 1902–1965. Obstetric and Gynæcological Surgeon, The London Hospital.

for advice because of enlargement of the abdomen (fig. 1064). Pain is often completely absent; in other cases there is considerable abdominal discomfort which may be associated with constipation or diarrhœa. On inspection dilated veins can be seen coursing beneath the skin of the abdominal wall. Shifting dullness can be elicited readily. In the male child congenital hydroceles sometimes appear, due to the patent processi vaginales becoming filled with ascitic fluid from the peritoneal cavity. Because of the increased intra-abdominal pressure, an umbilical hernia commonly occurs. On abdominal palpation a transverse solid mass can often be detected. This is rolled-up greater omentum infiltrated with tubercles.

The diagnosis is seldom difficult, except when it occurs in an acute form or when it first appears in an adult, in which case it has to be differentiated from other forms of ascites, especially from malignant secondary deposits (p. 950). A positive Mantoux test in a child with ascites strongly suggests, and a negative test is good evidence against, tuberculosis. In adults this test is of negligible value. The diagnosis of tuberculous peritonitis having been made, it is always important to look for tuberculous disease elsewhere, and in this respect the possibility of tuberculous salpingitis in females should be remembered.

The fluid is pale yellow, usually clear, and rich in lymphocytes. The specific gravity is comparatively high, often 1·020 or over. Even after centrifugation, rarely can the *mycobact. tuberculosis* be found, but its presence can be demonstrated by culture or by guinea-pig inoculation.

Treatment.—Sanatorium treatment is helpful.

Chemotherapy.—Streptomycin, P.A.S., isoniazid or other drugs are given as detailed on p. 32. If the general condition is good, the patient can return home and, if an adult, to light work, before the course of chemotherapy has been completed.

2. **Encysted** (*syn.* **Loculated**) **form** is similar to the above, but one part of the abdominal cavity alone is involved. Thus is produced a localised intra-abdominal swelling which gives rise to difficulty in diagnosis. In a female above the age of puberty, when the swelling is in the pelvis, an ovarian cyst will probably be diagnosed. In the case of a child it is sometimes difficult to distinguish the swelling from a mesenteric cyst. For these reasons laparotomy is often performed, and if an encapsulated collection of fluid is found, it is evacuated and the abdomen is closed. The general treatment already detailed is required, but the response to this treatment is more rapid. Late intestinal obstruction is a possible complication.

3. **Fibrous** (*syn.* **plastic**) **form** is characterised by the production of widespread adhesions, which cause coils of intestine, especially the ileum, to become matted together and distended. These distended coils act as a 'blind loop' (p. 965) and give rise to steatorrhœa, wasting and attacks of abdominal pain. On examination the adherent intestine with omentum attached, together with the thickened mesentery, may give rise to a palpable swelling or swellings. The first intimation of the disease may be subacute or acute intestinal obstruction. Sometimes the cause of the obstruction can be remedied easily by the division of bands. Lateral anastomosis between an obviously dilated loop and a collapsed loop of small intestine should not be done or the 'blind loop' syndrome (p. 965) is a certain outcome. If the adhesions are accompanied by fibrous strictures of the ileum as well, it is best to excise the affected bowel, provided not too much of the small intestine needs to be sacrificed. If adhesions only are present a Noble plication operation (p. 1024) or intestinal intubation should be done. This is a dangerous condition and the surgeon must adhere to strict

Charles Mantoux, 1877–1947. Physician, Le Cannet, Alpes Maritimes, France.

physiological principles in its treatment. Fortunately, chemotherapy after adequate surgery will rapidly bring it under control.

4. **Purulent form** is rare. When it occurs, usually it is secondary to tuberculous salpingitis. Amidst a mass of adherent intestine and omentum, tuberculous pus is present. Sizeable cold abscesses are wont to form, and point on the surface, commonly near the umbilicus, or burst into the bowel. In addition to prolonged general treatment, operative treatment may be necessary for the evacuation of cold abscesses and possibly for intestinal obstruction. If the patient survives long enough to overcome the infection, it may be possible to close a fæcal fistula, which otherwise usually persists because of obstruction distal to it. Closure must therefore be combined with some form of anastomosis between the segment of intestine above the fistula and an unobstructed area below. The prognosis of this variety of tuberculous peritonitis is relatively poor.

SCLEROSING PERITONITIS

Practolol, a β-adrenergic blocking agent used in the treatment of cardiovascular disorders, has been found to be associated with the late development of a sclerosing condition in the peritoneum which may cause intestinal obstruction. At laparotomy the condition resembles plastic tuberculous peritonitis. It may be confused with mesothelioma or carcinoid syndrome. Lysis of the adhesions is indicated. The condition may cause recurrent obstruction.

PERITONEAL BANDS AND ADHESIONS

Congenital bands and membranes occur in the peritoneum as described in textbooks of anatomy. None of them causes intestinal obstruction except an obliterated vitello-intestinal duct (p. 1099).

Peritoneal adhesions are discussed on p. 1017.

Talc Granuloma.—Talc (silicate of magnesium) should never be used as a lubricant for rubber gloves for it is a cause of peritoneal adhesions and granulomas in the Fallopian tubes. Potassium bitartrate, which is completely soluble, is free from these serious objections. *Starch peritonitis* (see p. 950).

ASCITES

Ascites, an excess of serous fluid within the peritoneal cavity, can be recognised clinically only when the amount of fluid present exceeds 1,500 ml.; in the obese a greater quantity than this is necessary before there is clear evidence of the presence of intraperitoneal fluid.

Mechanism of Ascites.—The balanced effects of plasma and peritoneal colloid osmotic pressures and hydrostatic pressures determine the exchange of fluid between the capillaries and the peritoneal fluid. Normal intraperitoneal pressure and normal peritoneal fluid colloid osmotic pressure cannot be measured. Protein-rich fluid enters the peritoneal cavity when capillary permeability to protein is increased, as in peritonitis and carcinomatosis peritonei. Capillary pressure may be increased because of generalised water retention, cardiac failure, constrictive pericarditis, or vena caval obstruction. Capillary pressure is raised selectively in the portal venous system in the Budd-Chiari syndrome (p. 863), portal cirrhosis, or extrahepatic venous obstruction.

Plasma colloid osmotic pressure may be lowered in patients with reduced intake, diminished absorption, abnormal losses, or defective protein synthesis as occurs in cirrhosis.

Clinical Features.—The abdomen is distended evenly, with fullness of the flanks, which are dull to percussion. Usually shifting dullness is present, but when there is a very large accumulation of fluid, this sign is absent. In such cases, on flicking the abdominal wall, a characteristic fluid thrill is transmitted from one side to the other. In the female, ascites must be differentiated from an enormous ovarian cyst.

Type 1. *Due to Congestive Heart Failure.*—This, the commonest cause of ascites, is due to chronic venous stasis in the thoracic segment of the inferior vena cava, and consequent obstruction to the venous outflow from the liver. There is stasis also in the superior vena cava, as evinced by engorgement of the veins of the neck—a striking sign in this condition. The ascitic fluid is light yellow serum of low specific gravity, about 1·010.

Type 2. *Due to Hepatic Cirrhosis.*—In cirrhosis of the liver there is obstruction to the venous outflow of the liver due to obliterative fibrosis of the intrahepatic venous bed (p. 864). Lymph flow may be increased.

Type 3. *Due to Tuberculous Peritonitis* (p. 946).

Type 4. *Secondary Carcinoma of the Peritoneum.*—Again the ascites is due to excessive outpouring, due to lymphatic blockage. The fluid is dark yellow and frequently blood-stained. The specific gravity is high—1·020 or over. Microscopical examination often reveals cancer cells.

Type 5. *Chronic Constrictive Pericarditis* (syn. *Pick's Disease*).—In addition to the peritoneal effusion, effusions occur into the pleural cavity. These effusions are due to engorgement of the venæ cavæ consequent upon diminished capacity of the right side of the heart.

Type 6. *Due to depletion of blood protein* consequent upon albuminuria or starvation. The ascites in this instance is due to alterations in the osmotic pressure of the capillary blood.

Type 7. *Meigs' Syndrome.*—This is ascites and pleural effusion associated with solid fibroma of the ovary. The effusions disappear when the tumour is excised.

Treatment.—Ascites may be tapped (paracentesis abdominis) but unless other measures are taken, the fluid soon re-accumulates and repeated tappings remove valuable protein. Dietary sodium restriction to 200 mg per day is frequently successful. Diuretics may be effective in selected patients.

If portal venous pressure is raised, it may be possible to lower it by treatment of the primary condition. (See Chapter 43).

Paracentesis Abdominis.—The bladder having been emptied by a catheter, under local anæsthesia puncture of the peritoneum is carried out with a moderate-sized trocar and cannula at one of the points shown in fig. 1065. In cases where the effusion is due to cardiac failure the fluid must be evacuated slowly. In other circumstances this precaution is unnecessary. If the cannula becomes blocked with fibrin, it is cleared with a stylet.

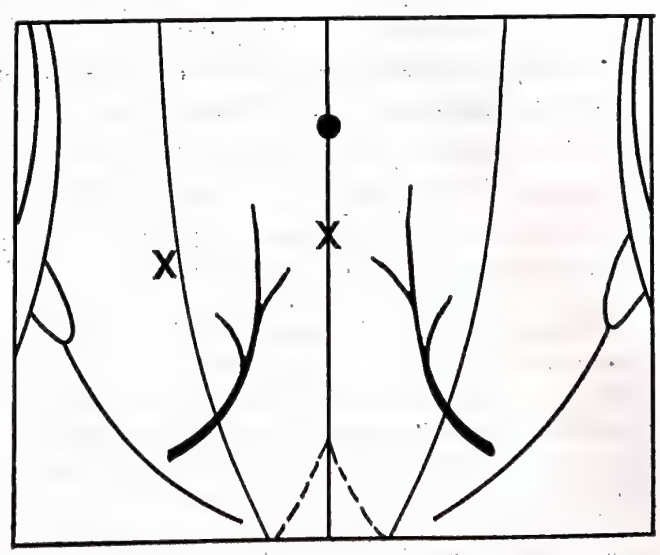

FIG. 1065.—Usual points of puncture for tapping ascites. The bladder must be emptied by a catheter before the puncture is made. Note the relationship of the sites of puncture to the inferior epigastric artery. (*Drs. V. C. and V. V. Shah, Jamnagar, India.*)

Friedel Pick, 1876–1926. Professor of Laryngology, Prague, Czechoslovakia. (*See footnote, p. 741.*)
Joe Vincent Meigs, 1892–1964. Gynæcological Surgeon, Massachusetts General Hospital, Boston, Mass., U.S.A.

After the fluid has been evacuated the puncture is sealed, and a tight binder is applied to the abdomen.

Permanent Drainage of Ascitic Fluid.—In rare cases where ascites accumulates rapidly after paracentesis, and the patient is otherwise fit, permanent drainage of the ascitic fluid renders the patient more comfortable. A number of procedures have been described, the best of which is probably the operation of ileoentectropy (segmental eversion of the ileum). A 40-cm loop of isolated terminal ileum is opened along its anti-mesenteric border, turned inside out and sutured with catgut in the triangular area of posterior abdominal wall between the root of the mesentery and the right colon. The ileal mucosa then absorbs the ascitic fluid (Neumann). To prevent its adhesion to the ileal mucosa, the greater omentum should be removed.

STARCH PERITONITIS

Like talc (p. 948), starch powder has found disfavour as a surgical glove lubricant. In a few starch-sensitive patients it causes a painful ascites, fortunately of limited duration. Should laparotomy be performed, any small granulomas in, say, the omentum, will be found to contain birefringent starch particles.

PERITONEAL LOOSE BODIES (Peritoneal mice)

Peritoneal loose bodies almost never cause symptoms. One or more may be found in a hernial sac or in the pouch of Douglas. The loose body may come from an appendix epiploica that has undergone axial rotation, followed by necrosis of its pedicle, and detachment, but they are also found in those who suffer from subacute attacks of pancreatitis. These hyaline bodies attain the size of a pea or bean, and contain saponified fat surrounded by fibrin.

NEOPLASMS OF THE PERITONEUM

Carcinoma peritonei is a common terminal event in many cases of carcinoma of the stomach, colon, ovary, or other intraperitoneal organ and also of the breast. The peritoneum, both parietal and visceral, is studded with secondary growths, and the peritoneal cavity becomes filled with clear, straw-coloured, or blood-stained ascitic fluid.

The main forms of peritoneal metastases are:

1. Discrete nodules. This is by far the most common variety.
2. Plaques varying in size and colour.
3. Diffuse adhesions. This form occurs at a late stage of the disease, and gives rise, sometimes, to a ' frozen pelvis '.

Gravity probably determines the distribution of free malignant cells within the peritoneal cavity. Cells not caught in peritoneal folds along the attachments of mesenteries gravitate into the pelvic pouches or into a hernial sac, enlargement of which is occasionally the first indication of the condition. Implantation occurs also on the greater omentum, the appendices epiploicæ, and the inferior surface of the diaphragm.

Differential Diagnosis.—Early discrete tubercles common in tuberculous peritonitis are greyish and translucent, and closely resemble the discrete nodules of peritoneal carcinomatosis, but the latter feel hard when rolled between the finger and the thumb, making the differential diagnosis tolerably simple. Fat necroses usually can be distinguished from carcinomatous nodules by their opacity. Peritoneal hydatids can also simulate malignant disease after rupture of a hydatid cyst.

It is remarkable how often patients riddled with intraperitoneal carcinoma preserve their nutrition, and look and feel comparatively well until the terminal stage.

Treatment.—Ascites due to carcinomatosis of the peritoneum can be considerably ameliorated by instillations of radio-active gold.

Charles G. Neumann, Contemporary. Associate Professor of Clinical Surgery, New York University, U.S.A.
James Douglas, 1675–1742. Anatomist and Obstetrician, London.

Radio-active gold (^{198}Au) has a half-life of two and a half days, and is supplied as a purple colloidal solution. One hundred millicuries or more of the solution are introduced into the peritoneal cavity after paracentesis. To improve distribution the foot of the bed is raised; then the patient lies on one side and then on the other, and finally prone, each for fifteen minutes. There follows a period of nausea, but approximately half the patients so treated are benefited for a time. The treatment is of no avail if, after paracentesis, the secondary deposits can be palpated, as the isotope can penetrate only to a depth of 1 millimetre.

Radio-active chromic phosphate (^{32}P) is also supplied as a colloidal solution, and is as effective as gold. Not only is it less expensive, but this solution requires none of the troublesome precautions connected with the protection of personnel. It emanates pure beta radiation, and has a longer half-life, viz. 14·3 days. In its administration rubber gloves are the only protection needed.

Pseudomyxoma Peritonei.—This rare condition occurs more frequently in females. The abdomen is filled with a yellow jelly, large quantities of which are often more or less encysted. The condition arises in one of two ways: more often from rupture of a pseudomucinous cyst of the ovary, less often from rupture of a mucocele of the appendix. It is painless, and there is no impairment of general health for a long time. When the condition arises from the appendix the mass is often more localised, but in cases of ovarian origin the whole peritoneal cavity is involved. Although an abdomen distended with what seems to be fluid that cannot be made to shift should suggest the possibility, it is highly improbable that a correct pre-operative diagnosis will be made. At laparotomy masses of jelly are scooped out, and the primary focus, if it can be found, is removed. Unfortunately, recurrence is usual. When pseudomyxoma peritonei arises from a mucocele of the appendix, repeated recurrence is less common. Pseudomyxoma peritonei is locally malignant but does not give rise to metastases. Occasionally the condition responds to radio-active isotopes, which certainly should be employed in recurrent cases.

Mesothelioma.—As in the pleural cavity this highly malignant tumour may arise. It has a predilection for the pelvic peritoneum and may mimic pubo-prostatic carcinoma, clinically. As in the pleura, asbestos is a recognised cause. It is not radio-sensitive.

PERITONEOSCOPY (LAPAROSCOPY)

The peritoneoscope resembles a cystoscope. Preferably under general anæsthesia, a midline incision 6 mm. long is made close to the umbilicus. A trocar and cannula are pushed into the peritoneal cavity and the requisite amount of air (1 to 1½ litres) is introduced with a pneumoperitoneum apparatus. The patient is tilted so that the air will rise into the upper abdomen or the pelvis, as required. The telescope is inserted via a special cannula and the organs inspected. Biopsy of a particular area of the liver is possible, but hæmorrhage from it is not infrequent. Air embolism is another possible danger.

THE GREATER OMENTUM

Rutherford Morison called the greater omentum 'the abdominal policeman.'[1] Relatively larger and structurally more substantial in the adult than in the child, the discharge of its life-saving constabulary duties becomes more effective after puberty, and remains unabated throughout life. The greater omentum attempts, often successfully, to limit intraperitoneal infective and other noxious processes (fig. 1066). For instance, an acutely inflamed appendix is often found wrapped in omentum, and this saves many a patient from developing diffuse peritonitis. Some sufferers from herniæ are also greatly indebted to this structure, for it often plugs the neck of a hernial sac and prevents a coil of intestine from becoming strangulated.

[1] But it has not any feet, i.e. it does not move across the abdomen of its own volition, but passively due to peristalsis, and it may be pushed by the movements of the abdominal wall into an area of immobility (rigidity) where there is local peritoneal irritation.

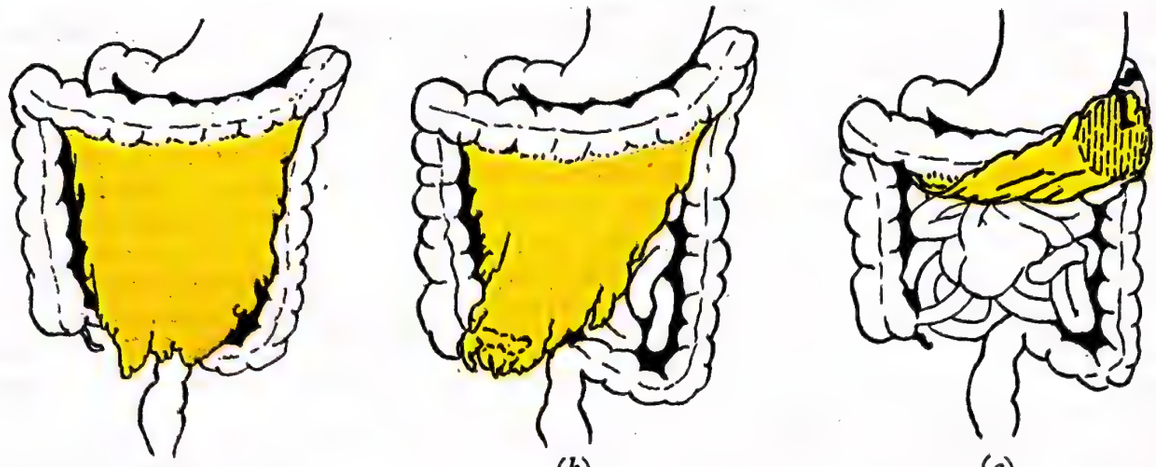

FIG. 1066.—The greater omentum. (*a*) Normal. (*b*) In appendicitis. (*c*) In a (comparatively small) laceration of the spleen.

Apart from a small portion of it becoming gangrenous while performing the last-mentioned duty (strangulated omentocele), this good Samaritan[1] of the peritoneal cavity seldom itself becomes diseased; when it does become overwhelmed, as in tuberculous peritonitis and carcinomatosis peritonei, it becomes rolled like a scroll.

FIG. 1067.—Torsion of the greater omentum. Specimen removed by operation. Actual size. (*Archibald Ronald, F.R.C.S., Barrow-in-Furness.*)

Torsion of the Omentum.—Torsion of the omentum (fig. 1067) is a rare emergency, and consequently is seldom diagnosed correctly. It is usually mistaken for appendicitis with somewhat abnormal signs. It may be primary or secondary to an adhesion of the omentum, to an old focus on infection, or to a hernia. Successive herniations of a portion of the omentum into a hernial sac of irregular bore are credited with giving the necessary stimulus to omental torsion.

The patient is most frequently a middle-aged, obese male. A tender lump may be present in the abdomen. The blood supply having been jeopardised, the twisted mass sometimes becomes gangrenous, in which case bacterial peritonitis soon follows.

Treatment.—The abdomen having been opened, the pedicle above the twist is ligated securely and the mass removed.

Omental Cyst (p. 957).

THE MESENTERY

A wound of the mesentery can follow a severe abdominal contusion,[2] and is a cause of hæmoperitoneum. In about 60% of cases the mesenteric laceration is associated with a rupture of the intestine. If the tear is a large one, and especially if it is transverse (fig. 1068), the blood supply to the

[1] Samaritan, an inhabitant of Samaria, Jordan. The parable of the Good Samaritan is told in the Bible, *Luke* x, 30–37.

[2] *Seat Belt Syndrome.*—If a car accident occurs when a seat belt is worn, sudden deceleration can result in a torn mesentery. This possibility should be borne in mind particularly as multiple injuries may distract attention from this injury. If there is any bruising of the abdominal wall, or even marks of clothing impressed into the skin, laparotomy is indicated.

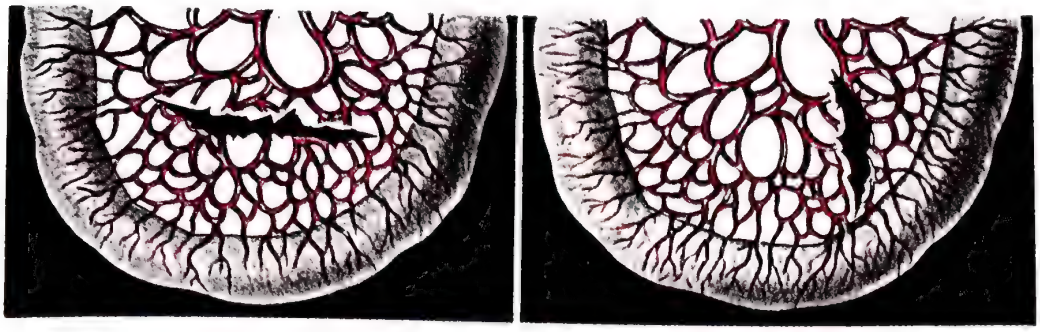

FIG. 1068 FIG. 1069

Laceration of the mesentery, a common injury in car accidents. A transverse tear (fig. 1068) often imperils the blood supply of a segment of intestine, making resection necessary. A longitudinal tear (fig. 1069) can be closed by suture.

neighbouring intestine is cut off, and a limited resection of gut is imperative. Small wounds and wounds in the long axis (fig. 1069) should be sutured.

Torsion of the Mesentery (see Volvulus Neonatorum, p. 1010, and Volvulus of the Small Intestine, p. 1015).

Embolism and Thrombosis of the Mesenteric Vessels (p. 1021).

ACUTE NON-SPECIFIC ILEO-CÆCAL MESENTERIC ADENITIS

Ætiology.—Non-specific mesenteric adenitis was so named to distinguish it from specific (tuberculous) mesenteric adenitis. It is now very much commoner than the tuberculous variety. Despite much investigation, the ætiology remains unknown. As so often happens in other inflammatory diseases when no causative bacterium can be found, an unidentified virus is blamed. In about 25% of cases a respiratory infection precedes an attack of acute non-specific mesenteric adenitis. In spite of the fact that the vermiform appendix is not diseased in this condition, which is definitely recurrent, appendicectomy does reduce the incidence of further attacks, perhaps by removing what is sometimes known as ' the abdominal tonsil '. This self-limiting disease is never fatal.

Living Pathology.—There is a small increase in the amount of peritoneal fluid. As seen and felt between the leaves of the mesentery, the ileo-cæcal mesenteric lymph nodes are enlarged, being firmly elastic and usually about the size of a haricot bean. In very acute cases they are distinctly red, and many of them are the size of a walnut. The nodes nearest the attachment of the mesentery are the largest. They are not adherent to their peritoneal coats, and if a small incision is made through the overlying peritoneum, a node is extruded easily.

Clinical Features.—During childhood, acute non-specific mesenteric adenitis is a common condition, the ratio of acute appendicitis to acute non-specific adenitis being about 10:1. It is unusual after puberty, but is sometimes seen in teenage girls (nurses syndrome). The typical history is one of short attacks of central abdominal pain lasting from 10–30 minutes, and associated with circum-oral pallor. They tend to come on when the patient is tired. Vomiting is usual, but there is no alteration of bowel habit.

On Examination.—There are spasms of general abdominal colic, usually referred to the umbilicus, with intervals of complete freedom, which never

appertains in obstructive appendicitis. The patient seldom looks ill. In more than half the cases the temperature is elevated; in severe examples it exceeds 38·3°C. Abdominal tenderness is greatest along the line of the mesentery. When present, shifting tenderness is a valuable sign for differentiating the condition from appendicitis. After laying the patient on the left side for a few minutes, the maximum tenderness moves to the left of the original site.

The pelvic peritoneum is tender to rectal palpation in 30% of cases. The neck, axillæ, and groins should be palpated for enlarged lymph nodes—if these nodes are enlarged, brucellosis[1] should come to mind (p. 955).

Leucocyte Count.—There is often a leucocytosis of 10–12,000/mm^3 (10—12^9/l) or more on the first day of the attack, but this falls on the second day.

Treatment.—When the diagnosis can be made with assurance, bed rest for a few days is the only treatment necessary. If at a second examination, an hour or two after confinement to bed, acute appendicitis cannot be excluded, it is safer to perform appendicectomy.

FIG. 1070.—Massive tuberculosis of the lymph nodes of the mesentery.

TUBERCULOSIS OF THE MESENTERIC LYMPH NODES

Tuberculous mesenteric lymphadenitis is considerably less common than acute non-specific lymphadenitis, and it has become increasingly less frequent in Britain during the past thirty years. Tubercle bacilli, usually but not necessarily bovine, are ingested, and enter the mesenteric lymph nodes by way of Peyer's patches. It is possible for one draught of raw milk to start the infection; it is equally possible that a toddler can become infected with human tubercle bacilli by placing one dust-covered small object in its mouth. Sometimes only one lymph node is infected; usually there are several; occasionally massive involvement occurs (fig. 1070).

Presentation:

1. **Demonstrated Radiologically.**—The shadows cast by one or more calcified tuberculous lymph nodes are seen frequently in a plain radiograph of the abdomen (fig. 1071). Often the shadow cast by such a lymph node or nodes is situated in the ileo-cæcal region, but nearly as many are displayed along the line of attachment of the mesentery. Usually the radiological characteristics are unmistakable. Each node is round or oval, not homogenous, but mottled, and its outline is not regular, but bosselated like a black-

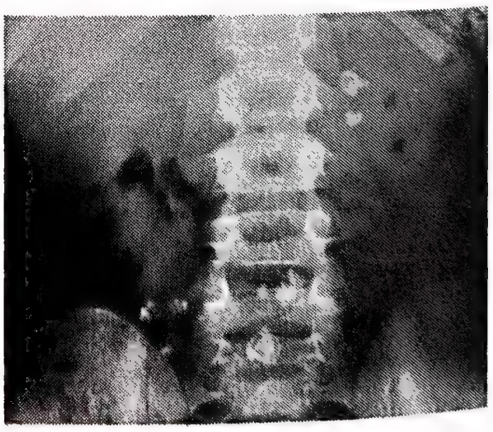

FIG. 1071.—Radiograph showing calcified tuberculous lymph nodes of the mesentery. (*Dr. H. R. E. Wallis, Bath.*)

[1] Sir David Bruce described Malta Fever in 1887.

Sir David Bruce, 1855–1931. Major-General, Royal Army Medical Service.
Johann Conrad Peyer, 1653–1712. Professor of Logic, Rhetoric and Medicine, Schaffhausen, Switzerland.

berry. Calcification of these lymph nodes occurs at the earliest in eighteen months. It is often assumed that because a tuberculous lymph node is calcified, the infection is necessarily defunct. Especially in children, this assumption may not be valid. Firstly, radio-opaque lymph nodes (fig. 1071) do not become white in a single night,[1] and secondly, calcification does not eliminate the presence of uncalcified tuberculous sister lymph nodes.

2. **As a Cause of General Symptoms.**—Less frequently the tuberculous process is more active, and gives rise to general symptoms. The patient, usually a child under ten years of age, loses appetite, looks pale, and there is some loss of weight ; sometimes evening pyrexia occurs. In children with these symptoms, especially those who live in the country, if the Mantoux test is negative, brucellosis, the ' disease of mistakes,' should be thought of, and an intradermal test with brucellin performed.

3. **As a Cause of Abdominal Pain.**—Sometimes abdominal pain is the cause of the patient being brought for advice; usually this pain is central, not severe, but rather a discomfort, and is often constant. On examination the abdomen is somewhat protuberant and there is tenderness on deep pressure to the right of the umbilicus. In these circumstances the condition resembles acute non-specific mesenteric lymphadenitis. On deep palpation inflamed mesenteric lymph nodes are sometimes palpable as firm, discrete, tender bean-like objects most frequently to the right of and near the umbilicus. In both conditions a normal leucocyte count favours tuberculosis, and in a child a positive Mantoux test is confirmatory evidence of tuberculosis.

4. **Symptoms Indistinguishable from those of Appendicitis.**—On occasions the abdominal pain is acute and may be accompanied by vomiting. This, combined with tenderness and some rigidity in the right iliac fossa, makes the diagnosis from subacute appendicitis almost impossible. When, as is sometimes the case, the tuberculous infection of the mesenteric lymph nodes becomes reactivated in adolescent or adult life, the diagnostic difficulties are even greater. A radiograph may show calcified lymph nodes, but as such a condition can co-exist with appendicitis, in some cases laparotomy for appendicectomy and visualisation of the lymph nodes is necessary. If the mesentery is found to be in an inflamed state with caseation of some of the lymph nodes, the diagnosis of active tuberculosis of the nodes is confirmed.

Treatment is similar to that of other surgical tuberculosis (p. 581).

Most cases subside, but from time to time a local abscess forms, usually in the right iliac fossa, when the tuberculous pus should be evacuated and the abdomen closed without drainage (see Pseudo-mesenteric Cyst, p. 956).

Tuberculous Mesenteric Lymph Nodes as a Cause of Intestinal Obstruction.—Remote, rather than recent, tuberculous mesenteric adenitis can be the cause of intestinal obstruction. For instance, a coil of small intestine becomes adherent to a caseating node, and is thereby angulated

[1] My hair is grey, but not with years,
Nor grew it white
In a single night,
As men's have grown from sudden fears:
Byron, *The Prisoner of Chillon.*

(fig. 1072), or a free coil may become imprisoned in the tunnel beneath the site of adherence and the mesentery.

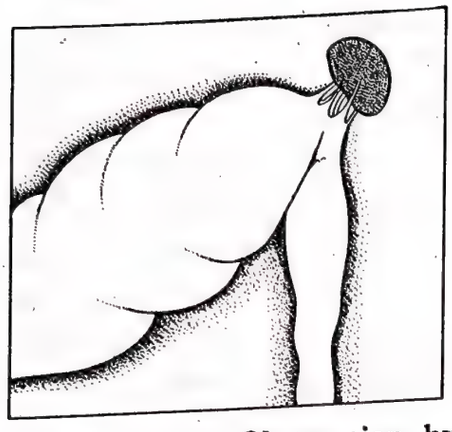

FIG. 1072. — Obstruction by angulation. The gut has become adherent to a tuberculous lymph node.

As a Cause of Pseudo-mesenteric Cyst. —When tuberculous mesenteric lymph nodes break down, the tuberculous pus may remain confined between the leaves of the mesentery, and a cystic swelling having the characteristics of a mesenteric cyst is found. When such a condition is confirmed at operation the tuberculous pus should be aspirated without soiling the peritoneal cavity, the wound closed, the sensitivity of the organism should be sought and specific treatment continued until the infection has been overcome.

Calcifying Mesenteric Lymph Nodes as a Confusing X-ray Shadow.—Sometimes the shadow cast by a calcified mesenteric lymph node or nodes simulates that of a ureteric or renal calculus. A change of posture often causes a lymph-node shadow to alter in position. Pyelography clarifies the diagnosis in doubtful cases.

Carcinoid Tumour of the Ileum (p. 986) may give rise to yellowish enlarged glands in the ileo-cæcal mesentery. The diagnosis is usually only made at laparotomy.

MESENTERIC CYSTS

Classification
- Chylolymphatic.
- Enterogenous.
- Urogenital remnant.
- Dermoid (teratomatous cyst).

Chylolymphatic cyst, the commonest variety of mesenteric cyst, probably arises in congenitally misplaced lymphatic tissue that has no efferent communication with the lymphatic system: it arises most frequently in the mesentery of the ileum. The thin wall of the cyst, which is composed of connective tissue lined by flat endothelium, is filled with clear lymph or, less frequently, with chyle varying in consistency from watered milk to cream. Occasionally the cyst attains a great size (fig. 1073). More often unilocular than multilocular, a chylolymphatic cyst is almost invariably solitary, although there is an extremely rare variety in which myriads of cysts are found in the various mesenteries of the abdomen. A chylolymphatic cyst has a blood supply independent of that of the adjacent intestine, thereby enucleation is possible without the necessity of resection of gut.

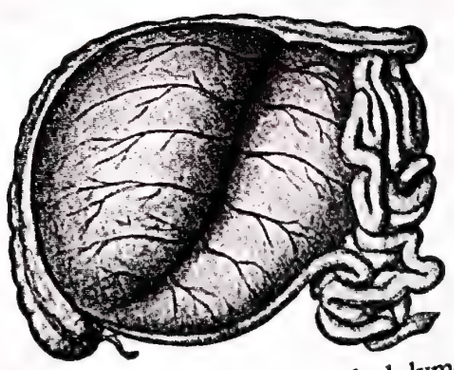

FIG. 1073.—A large chylolymphatic mesenteric cyst. (*Higgins and Lloyd.*)

Enterogenous cyst is believed to be derived either from a diverticulum of the mesenteric border of the intestine which has become sequestrated from the intestinal canal during embryonic life, or from a duplication of the intestine. An enterogenous cyst has a thicker wall than a chylolymphatic cyst, and it is lined by mucous membrane, sometimes ciliated. The content is mucinous, and is either colourless or yellowish-brown from bygone hæmorrhage into the cyst. As can be seen at operation, the muscle

in the wall of an enterogenous cyst and the bowel with which it is in contact have a common blood supply; consequently removal of the cyst always entails resection of the related portion of intestine.

Clinical Features of a Mesenteric Cyst.—A mesenteric cyst is encountered most frequently in the second decade of life, less often between the ages of one and ten years, and exceptionally in infants under one year.

The patient presents on account of:

(*a*) *A painless abdominal swelling.*—A cyst of the mesentery presents characteristic physical signs.

1. There is a fluctuant swelling near the umbilicus.

2. The swelling moves freely in a plane at right angles to the attachment of the mesentery (fig. 1074).

3. There is a zone of resonance around and, classically, a belt of resonance across the cyst.

(*b*) *Recurrent attacks of abdominal pain* with or without vomiting. The pain results from recurring temporary impaction of a food bolus in a segmentof bowel narrowed by the cyst, or possibly from torsion of the mesentery.

(*c*) *An acute abdominal catastrophe* arises as a result of (1) torsion of that portion of the mesentery containing the cyst; (2) rupture of the cyst, often due to a comparatively trivial accident; (3) hæmorrhage into the cyst; (4) infection.

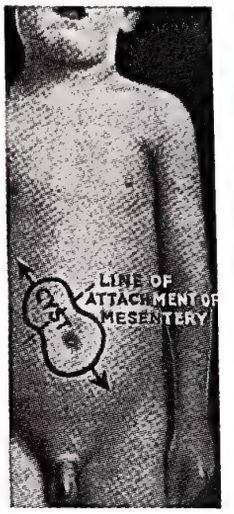

FIG. 1074.—A mesenteric cyst moves freely in the direction of the arrows, i.e. at right angles to the attachment of the mesentery.

Radiography.—In most instances the patient should be submitted to X-ray after a barium meal. The hollow viscera will be found to be displaced around the cyst, and not infrequently some portion of the lumen of the small intestine will be narrowed. In order to exclude or confirm the diagnosis of a hydronephrosis an excretory pyelogram should not be omitted. In cases of painless enlargement of the abdomen this examination should be undertaken first.

Treatment.—As has been indicated already, many chylolymphatic cysts can be enucleated *in toto.*

When, after aspiration of about half the contents of the cyst, the major portion of the cyst has been dissected free but one portion abutting on the intestine or a major blood-vessel seems too dangerous to remove, this portion can be left attached and its lining destroyed by careful diathermy.

In the case of an enterogenous cyst, enucleation must not be attempted. If a comparatively short segment of the intestine is involved, resection of the cyst with the adherent portion of the intestine, followed by intestinal anastomosis, is the correct course. Should a very large segment of small intestine be implicated, an anastomosis should be made between the apex of the coil of small intestine and the cyst wall which, in this instance, holds sutures well.

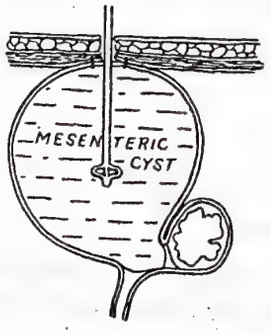

FIG. 1075.—Method of treating a large mesenteric cyst by marsupialisation.

The older treatment of marsupialisation of a mesenteric cyst has little to recommend it, for a fistula or recurrence sometimes results. Occasionally, however, on account of its simplicity, it is advisable in a poor-risk subject (fig. 1075).

Omental cyst occurs nearly as frequently as a mesenteric cyst. Preoperative differentiation is possible because a lateral radiograph shows the cyst in front of the intestines. Treatment is omentectomy.

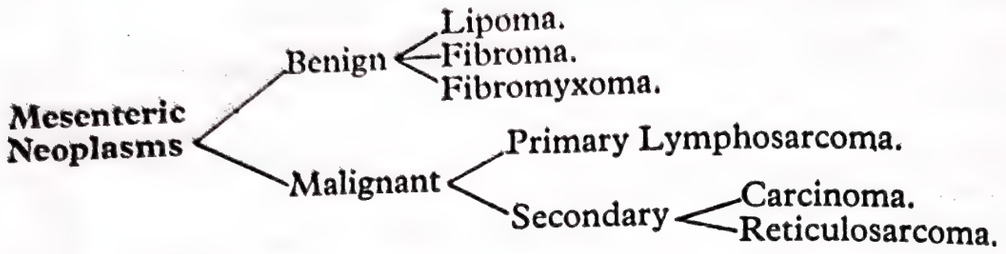
Cyst of the mesocolon is uncommon, and it is differentiated from a mesenteric cyst only at operation. The treatment is similar.

Cysts arising from a urogenital (Wolffian or Müllerian) remnant are essentially retroperitoneal, but they are included in the classification because it is not impossible for such a cyst to project forward into the mesentery.

The following, while not being mesenteric cysts in the meaning of the term, give rise to the same physical signs, and, in practice they *are* mesenteric cysts: *Serosanguineous cyst* is probably traumatic in origin, but a history of an accident is seldom obtained. *Tuberculous abscess of the mesentery.* *Hydatid cyst of the mesentery.*

NEOPLASMS OF THE MESENTERY

Tumours situated in the mesentery give rise to physical signs similar to those of a mesenteric cyst, the sole exception being that they sometimes feel solid.



A benign tumour of the mesentery is excised in the same way as an enterogenous mesenteric cyst, i.e. with resection of the adjacent intestine. When possible, a malignant tumour of the mesentery is subjected to the same treatment. In inoperable cases radiotherapy can be employed if the biopsy specimen reveals that the growth is probably radio-sensitive.

THE RETROPERITONEAL SPACE

Pus or blood in the retroperitoneal space tends to track to the corresponding iliac fossa. If a retroperitoneal abscess develops, it should be evacuated by an incision through the abdominal wall, meticulously avoiding opening the peritoneum. Should the retroperitoneal collection be found at laparotomy, it must be drained by a counter-incision in the flank. Retroperitoneal hæmatoma may be caused by fractured spine (p. 452), a leaking abdominal aneurysm (p. 138), or acute pancreatitis (p. 912).

Retroperitoneal Cyst.—A cyst developing in the retroperitoneal space often attains very large dimensions, and has at first to be distinguished from a hydronephrosis. Even after the latter condition has been eliminated by pyelography, a retroperitoneal cyst can seldom be diagnosed with certainty from a retroperitoneal tumour, until displayed at operation. The cyst may be unilocular or multilocular. Many of these cysts are believed to be derived from a remnant of the Wolffian duct, in which case they are filled with clear fluid. Others are teratomatous, and are filled with sebaceous material.

Excision of these and other retroperitoneal swellings is best performed through a transperitoneal incision (see p. 959).

Idiopathic Retroperitoneal Fibrosis.—See Chapter 54.

PRIMARY RETROPERITONEAL NEOPLASMS

Although *neuroblastomas* and *ganglioneuromas* of the adrenal gland are retroperitoneal tumours, they have now been segregated as clinical entities, and have been dealt with on p. 630.

Retroperitoneal lipoma, in the first instance, is usually mistaken for a hydronephrosis, a diagnosis which is ruled out by pyelography. Women are more often affected. These swellings sometimes reach an immense size. We have removed such a tumour weighing 2·5 kg, and much larger specimens have been recorded. A

Kasper Friedrich Wolff, 1733–1794. Professor of Anatomy and Physiology, St. Petersburg (now Leningrad, U.S.S.R.).

Johannes Peter Müller, 1801–1858. Professor of Anatomy and Physiology, Berlin.

retroperitoneal lipoma sometimes undergoes myxomatous degeneration, a complication which does not occur in a lipoma in any other part of the body. Moreover, a retroperitoneal lipoma sometimes becomes malignant (liposarcoma) (fig. 1076).

Retroperitoneal sarcoma presents signs similar to a retroperitoneal lipoma. The patient may seek advice on account of a swelling or because of indefinite abdominal pain. On other occasions the tumour, by pressure on the colon, causes symptoms of subacute intestinal obstruction. On examination a smooth fixed mass, which is not tender, is palpated. The most probable original diagnosis is that of a neoplasm of the kidney. This is ruled out by pyelography. The ureter, however, is liable to become displaced by the tumour. Exploratory laparotomy should be performed, and when possible the tumour is removed. Often it is found widely disseminated in the retroperitoneal space, rendering complete removal impossible, in which case a portion is excised for microscopy. Even when excised at a comparatively early stage, recurrence always takes place, and these tumours must be looked upon as being necessarily fatal. Deep X-ray therapy sometimes keeps recurrences in abeyance for a time.

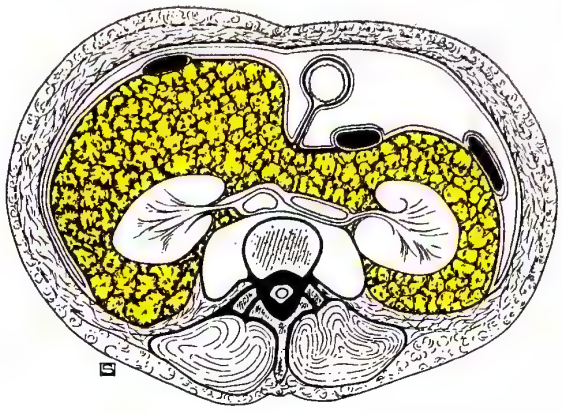


FIG. 1076.—Rapidly growing retroperitoneal liposarcoma.

Removal of a Retroperitoneal Cyst or Neoplasm.—After the anterior abdominal wall has been opened and the diagnosis of a retroperitoneal tumour has been confirmed, the incision is extended as necessary. The small intestine is packed away in the upper abdomen, and the cæcum and the sigmoid are relegated to their respective fossæ. The posterior peritoneum is then incised throughout its length over the area to be exposed, the incision parallel to the left border of the aorta. The peritoneum is dissected from the tumour which is removed as completely as possible, the intestines being kept out of the way with packs or exteriorised temporarily, depending on which manœuvre is the more useful.

CHAPTER 47

THE INTESTINES

Abdominal Pain arising from the Alimentary Canal is of two types:

1. *Visceral Pain.*—The alimentary tract is primarily a midline structure with a bilateral nerve supply. Although rotation about the midline occurs during development, nevertheless true visceral pain is referred to the midline as illustrated in fig. 1077. It is dull and poorly localised. The presence of a bilateral nerve supply may account for contralateral pain from some diseased structures as with left sided pain in cholecystitis.

2. *Peritoneal Pain* however is of the somatic type—and is much more precise, more severe and localised to site of origin. These components account for the changes in character and site of pain which occurs in appendicitis (p. 1030).

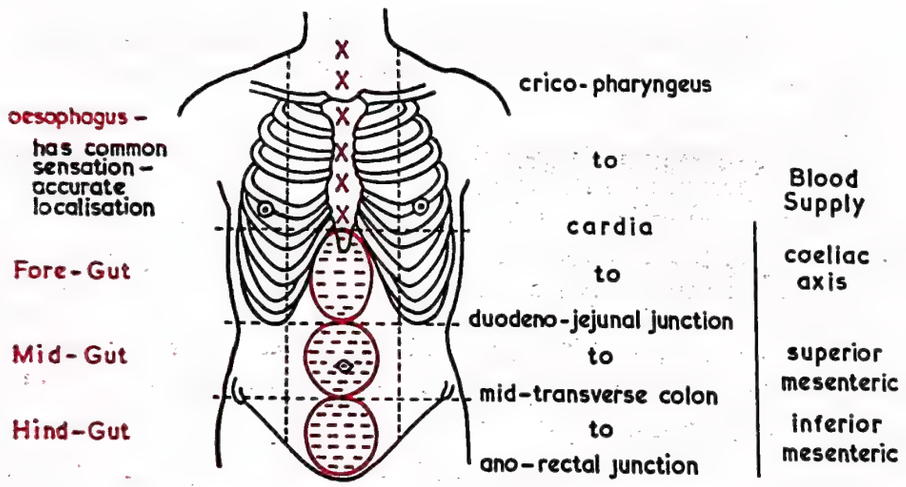

FIG. 1077.—Sites of origin of visceral pain.

Surgical Anatomy.—It is of great practical importance to be able:

1. To distinguish various portions of the intestinal canal at sight.
2. To know in which part of the abdomen the upper coils, as opposed to the lower coils, of the small intestine lie in relationship to the anterior abdominal wall.
3. To be able to decide which is the proximal and which the distal end of any coil under consideration.
4. To distinguish irrefutably large from small intestine.

For practical purposes these problems are settled as follows:

(*a*) The mesentery of the jejunum has only two series of arches of blood-vessels, whereas the lower ileum has several series of arches.

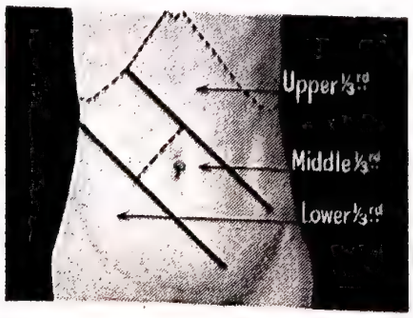

FIG. 1078.—Monks's method of localising the small intestine upon the surface.

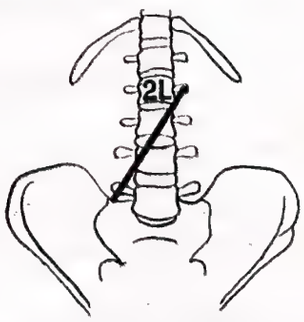

FIG. 1079.—The attachment of the mesentery.

(*b*) Monks's method of intestinal localisation roughly indicates the disposition of the upper, middle, and lower thirds of the small intestine (fig. 1078).

(*c*) The mesentery, after being made taut, is examined. As the mesenteric attachment runs from left to right (fig. 1079), if palpation reveals that the mesentery is not twisted, then the upper end of the bowel in the wound is the proximal end. Such a test is useful, but not as easy to perform in the living as in the dissecting-room subject.

(*d*) As the 'small' intestine is sometimes found enormously distended and the 'large' intestine entirely collapsed, size is no criterion. The large intestine is characterised by its tæniæ coli and appendices epiploicæ.

CONGENITAL MALFORMATIONS OF THE INTESTINES

Congenital Atresia of the Duodenum (p. 1008).
Congenital Atresia of the Small Intestine (p. 1009).
Volvulus Neonatorum (p. 1010).

Failure of Descent of the Cæcum.—The cæcum remains under the right lobe of the liver—a normal situation of the structure in the mangabey monkey. This anomaly is associated with displacement of the vermiform appendix.

MEGACOLON

There are two varieties of this relatively uncommon condition (1) *primary* or true megacolon (*syn.* Hirschsprung's disease, congenital aganglionic megacolon) and (2) *secondary* or acquired megacolon (fig. 1080).

Primary Megacolon.—Hirschsprung's disease:

Pathology.—This disease is characterised by enormous dilatation and hypertrophy of the pelvic colon, sometimes extending into the descending colon but rarely involving the more proximal parts of the large intestine. The pelvic mesocolon is elongated and thickened and its blood-vessels are large and prominent. All coats of the dilated intestine show gross pathological changes. The mucous lining is chronically inflamed and frequently ulcerated. There is a terminal constricted, non-hypertrophied segment of bowel involving the anal canal, the rectum, and a variable part of the large intestine. In nine out of ten cases the upper limit of the contracted segment is the pelvi-rectal junction; occasionally the deficiency extends to a higher level (fig. 1081). It is in this contracted segment that physiological obstruction lies[1], and the dilatation hypertrophy of the colon above is due to absence of peristalsis in the spastic segment.

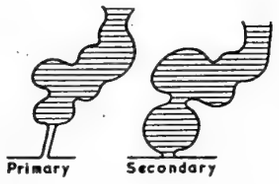

FIG. 1080.—Barium enema findings in primary and secondary megacolon.

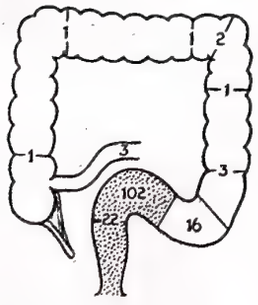

FIG. 1081.—The extent of the aganglionic segment in 152 cases of Hirschsprung's disease treated by operation at the Hospital for Sick Children, Great Ormond Street. (*After G. G. Wyllie.*)

On histological examination the cause of the immotility of the spastic segment is evident; there is a complete absence of parasympathetic ganglion cells, and this ganglion deficiency

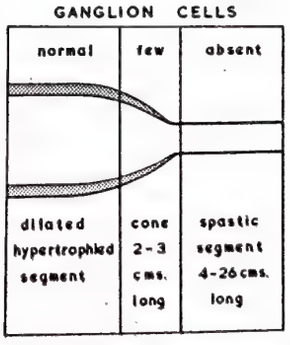

FIG. 1082.—Showing the essential pathological histology in congenital Hirschsprung's disease. (*After M. Bodian, London.*)

[1] In 1898 Treves attributed Hirschsprung's disease to congenital spasm of the distal segment, thus preceding the re-discovery of this concept by fifty years.

George H. Monks, 1853–1933. Surgeon-in-Chief, City Hospital, Boston, U.S.A.
Harald Hirschsprung, 1830–1916. Physician, Queen Louise Hospital for Children, Copenhagen.
Sir Frederick Treves, 1853–1923. Surgeon, The London Hospital.

extends for a distance of 1 to 5 cm into a transitional zone or cone (fig. 1082) between the terminal spastic segment and the hypertrophied portion (Bodian). Above the transitional zone, parasympathetic ganglion cells are present as in normal intestine.

Clinical Features.—Hirschsprung's disease shows a familial tendency. It is much more common in males than females. In 90 per cent. of cases symptoms appear within three days following birth.

FIG. 1083.—Hirschsprung's disease showing enormous colonic dilatation and a wave of visible peristalsis. *(The late Sir Denis Browne, F.R.C.S., London.)*

Constipation.[1]—The infant fails to pass meconium during the first two or three days of life, and then only after the insertion of a little finger or a tube into the rectum. Subsequently motions are tooth-paste-like, and inadequate in amount; straining is in evidence during their passage.

Abdominal distension is usually unmistakable by the third day. In a proportion of cases the abdominal distension progresses, and sometimes it is evident that the colon is obstructed (fig. 1083); in others it is impossible clinically to differentiate large from small intestinal obstruction. Loud borborygmi and visible peristalsis are much in evidence.

Rectal Examination.—The anus is free from fissures and excoriation and there is no perianal soiling. The rectum is empty and *grips the examining finger.*

Complete intestinal obstruction occurs quite frequently within a few days of birth and may be fatal. As a rule, the attacks are recurring and relief is given by a small enema, by passing a greased examining finger or by the spontaneous passage of a large stool sometimes followed by diarrhœa. Owing to the enormous abdominal distension, chest infection may supervene. In any case, if the child survives, malnutrition and stunted growth are obvious features together with enormous abdominal distension.

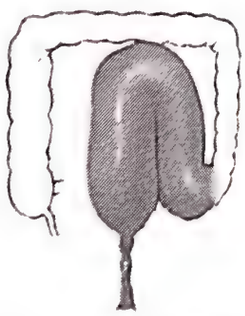

FIG. 1084.—Radiological appearances in Hirschsprung's disease; coning, as well as dilatation, is diagnostic. *(After B. C. H. Ward, London.)*

Radiography (p. 991). *Barium Enema.*—When the clinical findings are atypical a barium enema is often helpful in confirming the diagnosis. The objective is to demonstrate the contracted aganglionic segment, if such be present, and to this end preliminary wash-outs are withheld. For reasons explained below, the barium should be admixed with normal saline solution, not tap-water. By using only a little dilute barium emulsion—just sufficient to run over the fæcal masses—a good outline of the bowel can be obtained (fig. 1084).

Biopsy of the ano-rectal wall is employed in order to prove or disprove the presence of ganglia. A piece of rectal mucosa 1 cm^2 is removed and searched for ganglia in the sub-mucosa (Meissner's plexus).

[1] *Diarrhœa.* It cannot be emphasised too strongly that these infants sometimes present with diarrhœa and abdominal distension, and unless a rectal tube is passed, the patient may rapidly succumb to what is mistakenly thought to be simple gastroenteritis.

Martin Bodian, 1910–1963. Morbid Anatomist, Hospital for Sick Children, Great Ormond Street, London.
Georg Meissner, 1829–1905. Professor of Physiology, Göttingen, Germany.

Laparotomy to establish the diagnosis is required when the patient has acute-on-chronic intestinal obstruction, and other causes cannot be eliminated. If the case proves to be one of Hirschsprung's disease it is advisable to establish a temporary transverse colostomy or, in the rare event of the whole colon being spastic, an ileostomy.

Pre-operative Treatment.—Colonic lavage in Hirshsprung's disease is dangerous, because the use of tap-water in the enemas in this condition may cause water intoxication. The megacolon absorbs water much more rapidly than does a normal colon, and the disturbance of electrolytic balance, especially of sodium, may prove fatal. Provided the general condition is good, normal saline solution can be used with safety. In patients with impaired cardiac or renal reserve, 7 per cent. gelatine solution should be substituted. Unless measurements show that distension is increasing, four weeks' pre-operative preparation is desirable (Svenson). During the last five pre-operative days, Sulfasuxidine is given for bowel sterilisation.

Treatment.—The only curative treatment of Hirschsprung's disease is excision of the entire aganglionic segment. No reparative operation should be done till the child is 8·2 kg in weight and thriving (Brown).

Operation.—The patient is placed in a semi-lithotomy position, to give good access to the abdomen and the peri-anal region. Through a suitable incision the rectum, the contracted part of the adjoining colon, and the commencement of the hypertrophied portion are freed from their attachments as far downwards as possible towards the anal canal. In contrast to excision for carcinoma of the rectum, the dissection must be kept immediately outside the fascia propria. In this way the seminal vesicles and the autonomic nerve trunks to the bladder are protected. Should doubt exist as to whether the aganglionic segment has been encompassed, frozen section biopsy will provide the answer. The intestine is then transected at an indubitably motile level, and the distal end is closed with a purse-string suture. The mobilised aganglionic segment is then everted through the anus (fig. 1085(*a*) and (*b*)). The mucosa thus exposed is painted with antiseptic solution, and dried. The anterior half of the junction of the inverted rectum with the anal canal is opened transversely, and the

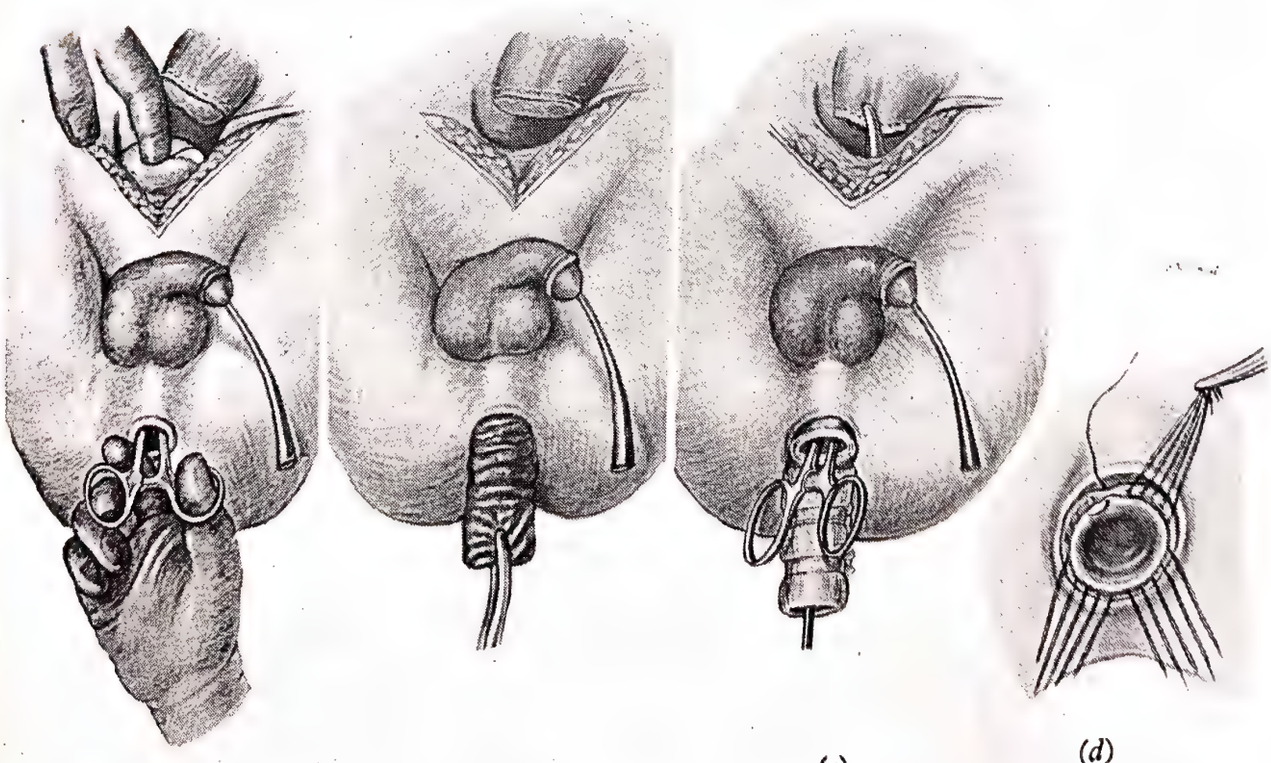

FIG. 1085. (*a*) Long hæmostat introduced through the anus so that the top of the closed bowel can be grasped. (*b*) Mobilised segment is everted through the anus. (*c*) Long hæmostat introduced through the incision in the rectal wall to grasp the proximal end of the divided colon. (*d*) Anastomosis of the colon to the anal canal. (*After O. Svenson.*)

Orvar Svenson, Contemporary. Professor of Surgery, Northwestern University, Chicago, Illinois, U.S.A.
James Johnston Mason Brown, 1908–1964. Surgeon-in-Charge, Royal Hospital for Sick Children, Edinburgh.

proximal colon is pulled through the opening (fig. 1085(*c*)). End-to-end anastomosis between the colon and the anal canal is carried out (fig. 1085(*d*)) as the everted aganglionic segment is excised. The union having been completed, it is reduced into the anal canal. Gloves having been changed, the abdominal incision is repaired. By two teams working simultaneously, one abdominally and one perineally, the operation can be performed expeditiously. Cases of Hirschsprung's disease involving the entire colon have been treated successfully by total colectomy and ileoproctostomy.

Modified Duhamel Operation.—This operation is devised to preserve rectal sensation. Preliminary colostomy and bowel preparation is carried out as above. The aganglionic segment is removed down to the level of the peritoneal reflection over the rectum. At this point the rectum is divided, turned in, and closed over. The sacral hollow is then opened up and the normal colon brought down to the posterior aspect of the rectal stump. The anus is now widely stretched and a transverse incision is made in the posterior wall just above the sphincter. Through this opening the colon lying behind the rectum is seized and brought down to present at the anus. The colon is then fixed to the rectum by a few catgut stitches to make a somewhat loose colo-rectal anastomosis. A special crushing clamp is now introduced to crush the spur between the rectum and the colon. It is left in position till the spur separates, when the clamp becomes loose and can be removed. The colostomy is closed a few weeks later.

ACQUIRED OR SECONDARY MEGACOLON

Dilatation and hypertrophy of an otherwise normal large bowel extends to the anal canal. The obstruction is due to fæcal impaction. Characteristically, there is a fissured anus, a spastic sphincter and much perianal soiling. As a rule, faulty bowel care and training are the sources of the trouble, and usually they can be traced to infancy; the onset, however, is never from birth.

Rectal Examination.—This is usually painful and the finger encounters a scybalous mass just inside the anus, which is contrary to the findings in Hirschsprung's disease.

FIG. 1086.—Radiological appearances of acquired megacolon. (*After B. C. H. Ward, London.*)

Radiography.—In all cases of acquired megacolon the dilatation as shown by a barium enema ends at the anal canal (fig. 1086).

Biopsy of the Ano-rectal Wall.—When acquired megacolon cannot be differentiated from Hirschsprung's disease by clinical and radiological means, biopsy is required. The presence of ganglion cells in the submucosa is the signal for conservative treatment.

Conservative Treatment.—Should an anal stricture or a fissure-in-ano be present, these lesions must be treated appropriately. The essential feature is bowel training so that a regular habit is established. It is wise to start with regular enemas and Senokot until the bowel is clean. The family environment must be thoroughly investigated. Upset of bowel habit in a child is a not uncommon result of domestic upheaval or emotional deprivation.

Redundant Colon.—Some constipated patients (usually female) are found on investigation by barium enema X-ray to have an elongated sigmoid colon (dolichocolon). Volvulus formation is a theoretical risk, but the wise surgeon avoids removing the redundant bowel for these patients may be neurotic, and will plague him after the operation with the same or other symptoms.

TRAUMATIC RUPTURE OF THE INTESTINE

The intestine can be ruptured with or without an external wound. The most frequent cause of the latter is a blow on the abdomen which crushes

Bernard Duhamel, Contemporary. Chief-Surgeon, Hôpital Saint-Denis, Saint-Denis, France.

the bowel against the promontory of the sacrum (see also seat belt syndrome in traffic accidents p. 952). Rupture is particularly liable to occur in the presence of an irreducible inguinal hernia (John). Rupture typically occurs where a fixed part of the alimentary tract joins a mobile one, such as the duodenojejunal flexure, in which case the damage may be retroperitoneal and easily overlooked; this type of lesion is usually due to runover accidents.

In small perforations the mucosa prolapses and tends partially to seal the rent (fig. 1087); consequently the early signs are misleading. In general the signs simulate closely those of a perforated peptic ulcer.

Laceration of the mesentery (p. 952) is a frequent operative finding in the type of injury under consideration.

FIG. 1087.—Traumatic rupture of the ileum. Note the prolapse of the mucous membrane.

Traumatic rupture of the large intestine is much less frequent. Compressed-air rupture of the colon is sometimes the result of a damnable form of practical joke, whereby a hose, carrying air under considerable pressure, is turned on near the victim's anus.

Blast injuries of the abdomen sustained during air-raids resulted in a number of cases of traumatic rupture of the intestine. The pelvic colon was found to be injured more frequently than other segments of the intestine. Rupture of the upper reaches of the rectum is not unknown during sigmoidoscopy. In ulcerative lesions the air insufflation has been sufficient to perforate the intestinal wall.

FIG. 1088.—Laceration of the mesentery resulting in gangrene of the associated portion of gut.

Treatment.—In all cases of suspected rupture of the intestine immediate laparotomy must be performed. In many instances, simple closure of the perforation is all that is required. In others, e.g. where the mesentery is lacerated, resection may be necessary (fig. 1088). In the case of the large intestine, exteriorisation is the procedure of choice; if this is not feasible, the perforation is closed and proximal colostomy is performed.

THE BLIND LOOP SYNDROME

It has been shown in dogs that if a blind loop of the small intestine is made (fig. 1089*A*) defects of absorption will appear. If this occurs in the upper intestine the defect is chiefly of fat absorption; if in the lower intestine there is vitamin B_{12} deficiency. This has been found to occur in humans and is referred to as the blind loop syndrome, or the 'stenosis-anastomosis loop' syndrome (Witts).

Essentially, the stasis produces an abnormal bacterial flora, which fouls the main intestinal pathway. Sometimes the only manifestation is anæmia, due to Vitamin B_{12} deficiency, but if steatorrhœa appears, other serious malabsorption features follow. In general, high loops produce steatorrhœa, etc., whereas low loops tend to produce anæmia.

Temporary improvement will follow the use of antibiotics to destroy the

bacteria causing the trouble, but the main treatment is surgical extirpation of the cause of the stasis.

ALIMENTARY DIVERTICULA[1]

Diverticula occur from the stomach to the recto-sigmoid junction. There are two varieties:—

(*a*) *Congenital.*—All three coats of the bowel are present in the wall of the diverticulum, e.g. Meckel's.

(*b*) *Acquired.*—The wall of the diverticulum lacks a muscular coat. In spite of the absence of demonstrably increased intraluminal pressure, most alimentary diverticula are thought to be acquired (Edwards).

DIVERTICULA OF THE SMALL INTESTINE

The belief that a diverticulum of the small intestine originates as a mucosal herniation through a point of entrance of blood-vessels is based on the fact that most of these diverticula arise from the mesenteric side of the bowel (fig. 1089).

Duodenal Diverticulum.—There are two types.

1. *Primary.*—Mostly in older patients on the inner wall of the second and third parts, they are found incidentally on barium meal and usually do not cause symptoms.

2. *Secondary*, of the duodenal cap resulting from long standing duodenal ulceration.

Jejunal diverticula vary in size, are sometimes single (fig. 1089A). More often several are present (figs. 1089*D* and 1092). Clinically they may (*a*) be symptomless (*b*) give rise to abdominal pain, flatulence and borborygmi or (*c*) produce a malabsorption syndrome. This latter consists of anæmia steatorrhœa, hypoproteinæmia and avitaminosis. They are, in fact, examples of the blind loop

FIG. 1090.—Primary diverticula of second and third parts of duodenum.

FIG. 1091.—Secondary diverticula of duodenal cap.

[1] Literally, a diverticulum means a wayside house of ill-fame, and these wayside houses certainly live up to their evil reputation.

Johann Friedrich Meckel (The Younger), 1781–1833. Professor of Anatomy and Surgery, Halle, Germany.
Harold Clifford Edwards, Contemporary. Consulting Surgeon, King's College Hospital, London.

syndrome (p. 965). If the length of affected bowel is not too extensive, resection and end-to-end anastomosis give excellent results.

FIG. 1092.—Jejunal diverticula.

Meckel's diverticulum is present in 2 per cent. of the human race; it is situated upon the antimesenteric border of the small intestine, 60 cm from the ileo-cæcal valve, and it is usually 5 cm long. Many variations occur.

In nearly 90 per cent. of cases the diverticulum arises from the anti-mesenteric border of the ileum, and, being congenital, it possesses all three coats of the intestinal wall. It will be noted in figs. 1093 and 1094 that it has its own blood supply (like the appendix) and this makes it vulnerable to infection and obstruction. In 20 per cent. of cases the mucosa contains heterotopic epithelium, viz. gastric, colonic, or sometimes pancreatic tissue. When present, heterotopic tissue lines the greater part of the proximal end of the pouch, and not infrequently extends for a short distance into the nearby ileum. Although Meckel's diverticulum occurs with equal frequency in both sexes, symptomatic cases, due almost entirely to the epithelium contained in the diverticulum, are predominant in males. In order of frequency, these symptoms are as follows:

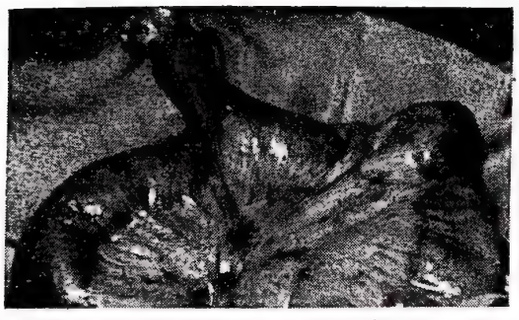

FIG. 1093.—Meckel's diverticulum.

1. **Severe hæmorrhage per rectum**, due to peptic ulceration. The blood passed is maroon in colour. Although the patient frequently vomits, the vomitus contains no blood. Seldom is the hæmorrhage preceded by pain; sometimes bleeding precedes perforation. When operation is required for serious progressive hæmorrhage per rectum and no lesion in the stomach or duodenum is found, the next step should be the examination of the terminal 150 cm of ileum.

2. **Intussusception.**—In the majority of cases the apex of the intussusception is swollen, inflamed, heterotopic epithelium at the mouth of the diverticulum—not inversion of the diverticulum, as is commonly stated. Intussusception due to Meckel's diverticulum is discussed on p. 1011.

3. **Meckelian diverticulitis** with or without perforation is usually due to lodgement of coarse food residue or a sharp foreign body. The symptoms of Meckelian diverticulitis without perforation are those of acute appendicitis, and unless the appendix has been removed the diagnosis is impossible before operation. When a diverticulum perforates, so rapid is the onset of peritonitis that the symptoms simulate those of a perforated duodenal ulcer. Whether or not the diverticulum has perforated, urgent operation is required. In non-perforated cases an inflamed diverticulum should be sought as soon as it has been ascertained that the vermiform appendix (and, in the case of a female, the Fallopian tubes) is not at fault.

4. **Chronic Peptic Ulceration.**—Because the diverticulum is part of the midgut, the pain, though related to meals, is felt around the umbilicus.

Gabriele Falloppio, 1523–1562. *(See footnote, p 144.)*

5. **Intestinal Obstruction.**—The presence of a band between the apex of the diverticulum and the umbilicus may cause obstruction either by the band itself or to a volvulus around it.

Radiography.—In cases of Meckel's diverticulum giving rise to symptoms, failure to visualise the diverticulum by radiography after a barium meal, which is very common, is of no significance, because so often the entrance of the diverticulum is blocked by œdema.

'Silent' Meckel's Diverticulum.—A Meckel's diverticulum usually remains symptomless throughout life, and be found only at necropsy. When a silent Meckel's diverticulum is encountered in the course of an abdominal operation, and can be excised without appreciable additional risk, this should be done in order to exclude the possibility of subsequent complications.

Exceptionally a Meckel's diverticulum is found in an inguinal or femoral hernial sac, when it is known as a Littre's hernia (p. 1105).

Meckelian Diverticulectomy.—A Meckel's diverticulum should not be amputated at its base and invaginated in the same way as a vermiform appendix, because of the risk of a stricture. Moreover, it does not remove heterotopic epithelium

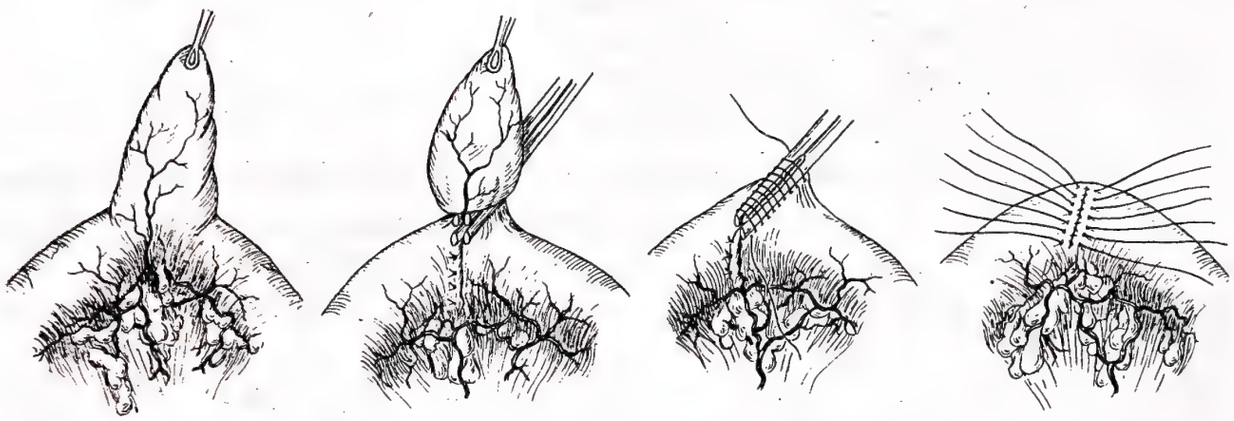

FIG. 1094.—Steps in the performance of Meckelian diverticulectomy.

completely, if such be present. The steps of diverticulectomy are displayed in fig. 1094. Should there be considerable induration of the base of the diverticulum, and particularly when such induration extends into the neighbouring ileum, it is advisable to resect a short segment of the ileum containing the diverticulum, and to restore the continuity of the bowel by anastomosis.

DIVERTICULAR DISEASE OF THE COLON

Diverticula of the colon are acquired herniations of colonic mucosa, protruding through the circular muscle at the points where the blood vessels penetrate the colonic wall (fig. 1095). Thus they tend to occur in rows in between the strips of longitudinal muscle (tænia coli) (fig. 1096). The condition may be localised to one part of the colon, usually the sigmoid, but sometimes the entire large bowel is involved from the cæcum to the rectosigmoid junction. The rectum with its complete muscle layers is not affected. In 90% of cases the sigmoid colon is involved and becomes almost always the site of inflammation, i.e. diverticulitis. Some 5% of patients have associated gallstones and hiatus hernia (Saint's triad, p. 889).

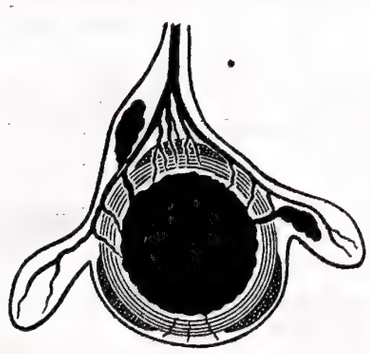

FIG. 1095.—The usual sites of diverticulation of the colon. (*After Hamilton Drummond.*)

Diverticular disease is rare in Africans and Asiatics who eat a diet which contains natural fibre. In Western countries, where the roughage has been removed from flour and sugar, diverticula are

Alexis Littre, 1658–1726. Surgeon and Anatomist, Paris.

found in 5% of barium enemas over the age of 40, and the incidence increases with age.

Diverticulosis, the primary stage of the disease, is caused by muscular inco-ordination and hypertrophy resulting in increased segmentation and intraluminal pressure (fig. 1097 *a*, *b*, and *c*). This may lead to diverticulum

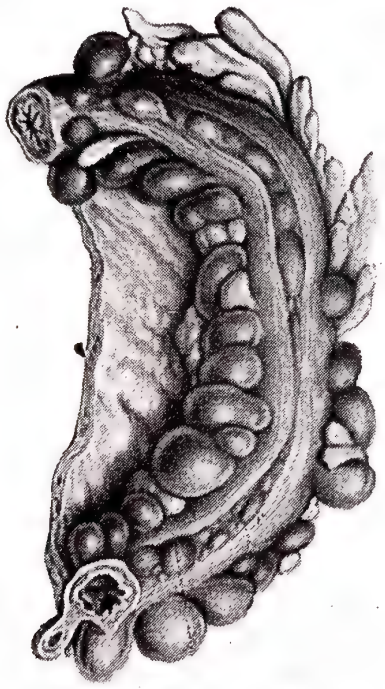

FIG. 1096.—Pelvic colon with multiple diverticula.

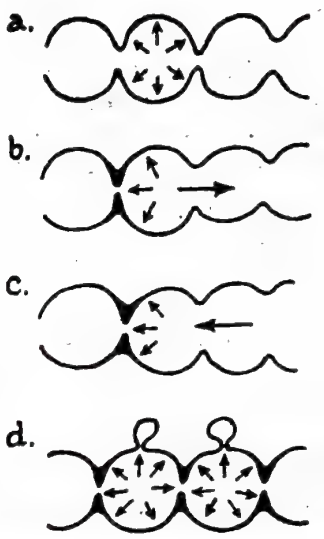

FIG. 1097.—Segmentation of the colon.

formation (fig. 1097*d*). Segmentation plays an important part in colonic physiology. Emotion and drugs like morphine and prostigmine[1] increase segmentation and intra-colonic pressure (see treatment).

Diverticulitis is the secondary state and is due to inflammation of one or more diverticula, usually with some pericolitis. Episodes of diverticulitis may be followed by years free of symptoms, but the condition is essentially progressive—the longer the duration, the worse are the symptoms and the greater the risk of complications. Diverticulitis is not a precancerous condition, but cancer may coexist.

The Complications are:

1. Recurrent periodic inflammation and pain.
2. Perforation leading to general peritonitis or local (pericolic) abscess formation.
3. Intestinal obstruction, due to progressive fibrosis leading to stenosis.
4. Hæmorrhage: diverticulitis may present with *profuse* colonic hæmorrhage in about 17% of cases, often requiring blood transfusion.
5. Fistula formation (vesico-colic, vagino-colic, entero-colic, colo-cutaneous) occurs in about 5% of cases.

Clinical Features.—Diverticulosis may be asymptomatic, but the disordered colonic function may cause symptoms of distension, flatulence and

[1] Muscle relaxants of the curare type usually require the use of prostigmine at the end of an operation. This use of prostigmine may prejudice the safety of a colonic anastomosis.

a sensation of heaviness in the lower abdomen. Excessive colonic segmentation can cause severe colic pain in the left iliac fossa. This pain waxes and wanes too fast to be compatible with the onset and resolution of inflammation. Indeed, the sigmoid colon may only have thickened muscle (Morson). This condition is called *Painful Diverticular Disease* and is, in fact, due to functional obstruction of the colon (Painter).

Diverticulitis.—More persistent lower abdominal pain, usually in the left iliac fossa, or evidence of peritonitis, should always bring the diagnosis to mind in patients of either sex over the age of 40. Fever, malaise, and a leucocytosis help to differentiate diverticulitis from painful diverticular disease. The patient may pass loose stools or may be constipated. Abdominal distension may be relieved by flatus. The lower abdomen is tender especially on the left, occasionally in the right, iliac fossa. The sigmoid colon may be palpable, tender and thickened. Rectal examination may reveal a tender mass. The condition has been likened to left-sided appendicitis. Any urinary symptoms may herald the formation of a vesico-colic fistula, which leads to pneumaturia (flatus in the urine), and even fæces in the urine.

Diagnosis

Radiology.—Diverticulosis must never be blamed for symptoms unless all other diseases of the gastrointestinal tract have been excluded by barium meal, barium enema and by sigmoidoscopy. The diagnosis of acute diverticulitis is made on clinical grounds and is confirmed by barium enema and sigmoidoscopy *only when any acute inflammation has subsided* as any enema given in an acute attack may cause perforation and peritonitis. Diverticula may be revealed by a barium meal followed through the gut, but a barium enema must also be done to exclude a carcinoma and to assess the extent of the disease. Barium enema may show diverticula and the typical narrowed sigmoid but sometimes no diverticula are seen but only the 'saw tooth' appearance of the 'pre-diverticular state' (fig. 1098). Such strictures are sometimes relaxed by Probanthine and this may help to differentiate them from a neoplasm.

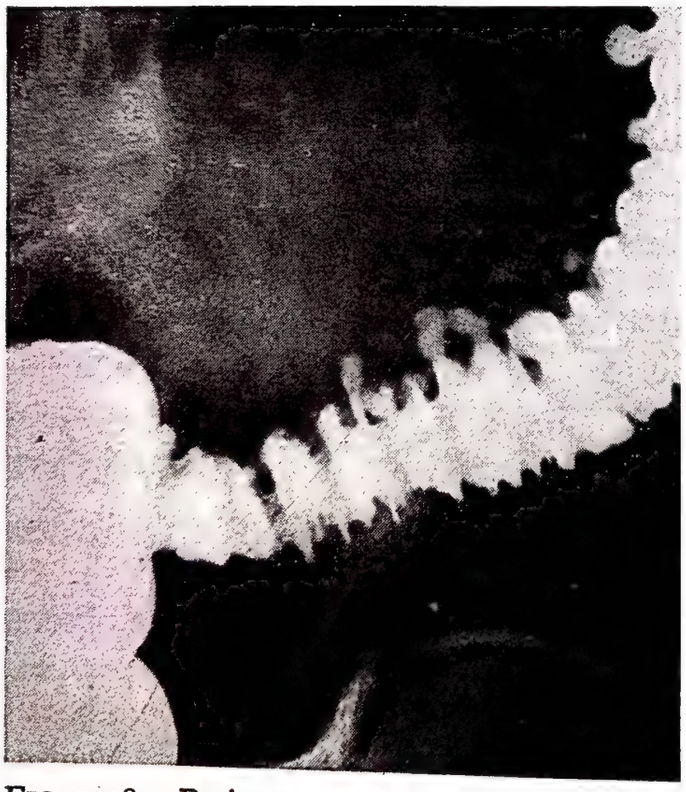

FIG. 1098.—Barium enema showing diverticular disease—'saw teeth' and diverticula.

Sigmoidoscopy.—The mucosa may be normal. In acute attacks, sigmoidoscopy may be painful and the mucosa inflamed. The bowel may be

Basil Clifford Morson, Contemporary. Pathologist, St. Mark's Hospital, London.
Neil Stamford Painter, Contemporary. Surgeon, Manor House Hospital, London.

rigid, narrow and acutely angled at about 15 cm. so that the instrument cannot be passed further. The necks of diverticula are seldom seen. Sigmoidoscopy excludes a neoplasm but diverticula must be diagnosed by barium enema.

Management

Diverticulosis should be treated with a high residue diet containing roughage in the form of wholemeal bread and flour, fruit and vegetables. Bulk formers such as bran, Celevac, Isogel, may be given until the stools are soft. Painful diverticular disease may require bed rest and antispasmodic drugs. Habitual liquid paraffin and purgative-taking should be avoided.

Acute diverticulitis is treated by bed rest, warmth to the abdomen, antispasmodic drugs and a 7–10 day course of broad-spectrum antibiotics (e.g. tetracycline) and/or non-absorbable sulphonamides (e.g. phthalylsulphathiazole). Morphine and enemas are contraindicated. Probanthine rests the bowel but in large doses may cause ileus and retention of urine. After the acute attack has subsided the diagnosis must be confirmed by radiology and a carcinoma must be excluded.

Operative Procedures for Diverticular Disease.—About 10% of the patients require operation, either for recurrent attacks which make life a misery or for the complications (p. 969):

1. *The ideal operation*, done as an interval procedure after careful preparation of the gut (p. 992), is a *One Stage Resection.* This involves removal of the affected segment—10 to 20 cm long, and restoration of continuity by end-to-end anastomosis.

At operation the sigmoid loop is often found adherent in the pouch of Douglas. Patient yet persistent dissection, taking care to preserve the rectum in the retroperitoneal area, is rewarded by exposure of normal rectum and greater mobility.

2. *BUT, if there is obstruction, inflammatory œdema and adhesions or the bowel is loaded with fæces*, a preliminary transverse colostomy must be done as a first stage; the second stage of resection is performed after 3 weeks or when the inflammation has subsided. The colostomy is closed after a further 2 weeks.

3. *In acute perforation*, peritonitis which soon becomes general is usually purulent with a mortality of about 15%. Fæcal peritonitis carries a 50% mortality. Pneumoperitoneum is present, but in this acute emergency often a diagnosis of peritonitis calling for urgent laparotomy is the only diagnosis which can be made. There is a choice of procedures:

(a) *Proximal colostomy* with suture of perforation.

(b) *Exteriorisation* of the affected bowel which is then opened as a colostomy.

(c) *Primary resection* of the inflamed bowel with immediate anastomosis in experienced hands. Primary resection removes the toxic tissues and may lower the mortality of this desperate emergency. Permanent colostomy with closure of bowel below the disease is safer.

All the above procedures must be accompanied by drainage of the abdomen. Simple drainage alone should be reserved for a localised pericolic abscess.

4. *Fistulas* can only be cured by resection of the diseased bowel and closure of the fistula. Ideally these procedures are done at the same operation but a

staged procedure with a preliminary colostomy is often necessary. Diverticular disease is a benign condition so the surgeon plays for safety even if it means staged procedures.

5. *Sigmoid Myotomy (Reilly).*—Resection of the thickened sigmoid colon may be avoided by sigmoid myotomy. The operation consists of a longitudinal incision through one tænia extending over the length of the affected colon. The incision is deepened until the mucosa bulges as in a Heller (p. 773) or Ramstedt's (p. 790) operation. This restores the colonic lumen and lowers the intracolonic pressures. The operation must never be used in acute diverticulitis. There is a risk of leakage post-operatively.

DIFFERENTIATION OF DIVERTICULITIS FROM CARCINOMA OF THE COLON

These conditions co-exist in 12 per cent of cases

	Diverticulitis	*Carcinoma*
History	Long	Short
Pain	More common	
Mass	25 per cent. have tenderness	25 per cent. painless
Bleeding	17 per cent. often profuse, periodic	65 per cent.—usually small amounts persistently
X-ray	Diffuse change	Localised: no relaxation with Probanthine
Sigmoidoscopy	Inflammatory change over an area	No inflammation until ulcer reached

Exploration may be necessary, but even then, differentiation may be difficult until histology is available. Weight loss, falling hæmoglobin, and a persistently positive occult blood test are sinister features.

Solitary diverticulum of the cæcum and ascending colon, is rare, and it is congenital for it has a complete muscular coat. It is usually situated just above the ileocæcal valve, viz.: ⟶

Inflammation of such a diverticulum is indistinguishable from acute appendicitis. Recurrent diverticulitis may cause the formation of a mass whose nature can only be ascertained after resection of the cæcum. An uninflamed cæcal diverticulum found casually at laparotomy should be invaginated with a purse-string suture.

ULCERATIVE COLITIS

Ætiology.—The cause is unknown. In spite of intensive bacteriological studies, no organisms or group of organisms can be incriminated. Probably the disease is linked with emotional stress. It may be related to the auto-immune diseases but this is by no means certain. Some cases are allergic to milk protein. In cases of extensive ulceration secondary infection plays a large part. In some families there is a strong tendency for the disease to occur in successive generations: either a genetic predisposition is inherent in the members of these families, or an unidentified environmental factor is present. The disease has been rare in Eastern populations, but is now being reported more commonly, suggesting an environmental cause that has developed as a result of increasing 'Westernisation' of diet and/or social habits.

Pathology.—In 95 per cent. of cases the disease starts in the rectum and spreads proximally. When the ileocæcal valve is incompetent, retrograde ileitis involving the last foot (30 cm) of the ileum is liable to occur.

Michael Charles Tempest Reilly, Contemporary. Surgeon, Plymouth General Hospital, Plymouth, England.

The disease is characterised by the appearance of multiple minute ulcers—sometimes the ulcers are discrete, in others there is a sea of ulceration. Microscopical evidence nearly always proves that the ulceration is more severe and extensive than the gross appearance indicates (Cuthbert Dukes). As time goes on the small ulcers are apt to coalesce to form larger ones, mainly due to the crypts of Lieberkühn becoming distended with pus and bursting into the bowel. When the ulceration extends into the submucosa it causes reflex muscle spasm, and the appearance of a stricture. In long-standing cases there is always considerable intramural fibrosis, causing the affected part of the colon to become permanently contracted. In addition, attempts at healing may produce epithelial thickening between the ulcers—the so-called pseudopolyposis.

Clinical Features.—Women are attacked somewhat more often than men. The onset of the disease is in the 3rd, 4th, and 2nd decade, in that order ; exceptionally it is encountered in childhood. The first symptom is watery diarrhœa occurring day and night, in a person of previously normal bowel habit. A rectal discharge of mucus, sometimes blood-stained and sometimes purulent is very common. Pain as an early symptom is unusual. In the majority of cases, the disease is chronic, characterised by relapses and remissions. In general, a bad prognosis is indicated by (1) a severe initial attack; (2) disease involving the whole colon; (3) increasing age, especially after sixty years. If the disease remains confined to the left colon, the outlook is better.

Two types are encountered :

Fulminating type (5 per cent.) is ushered in with a temperature of 38·9° to 39·4° C and incessant diarrhœa containing blood, mucus, and pus; the patient looks and feels very ill. There may be abdominal distension due to toxic paresis of the colon. In such circumstances the condition must be differentiated from dysentery and typhoid. These infections are eliminated by bacteriological examinations of the stools, blood culture, and a Widal reaction.

Chronic Type (95 per cent.).—As a rule the initial attack is of moderate severity, but exacerbations occur at intervals of weeks, months or, in mild cases, years. As the disease progresses the patient becomes wasted from diarrhœa, and severely anæmic from loss of blood (fig. 1099). Often during the attacks there are ten to twenty stools a day, accompanied by tenesmus. The frequency of the motions and the degree of invalidism go hand in hand, and are proportional to the extent of the involvement of the colon. Lesions of limited length are commonly found in milder cases. Sometimes the disease is confined entirely to the right hemi-colon. When the

FIG. 1099.—Emaciation and dehydration in ulcerative colitis. (*Dr. Peter Hansell, London.*)

Cuthbert Esquire Dukes, 1890–1977. Pathologist, St. Mark's Hospital, London.
Johann Nathaniel Lieberkühn, 1711–1756. Anatomist, Berlin. He demonstrated his anatomical preparations in London, and was awarded the F.R.S.
Fernand Widal, 1862–1929. Professor of Pathology and Physician, Hôpital Cochin, Paris.

whole colon is involved the patient may be so weak as to be partially or wholly bed-ridden.

Radiology after a barium enema shows one of the following:
(1) The earliest sign is loss of haustration, especially in the distal colon. Established disease will show:
(2) A narrow contracted (pipe stem) colon (fig. 1100).
(3) Undermining of the mucosa.
(4) Pseudopolyposis (fig. 1101) in 10 per cent. of cases.

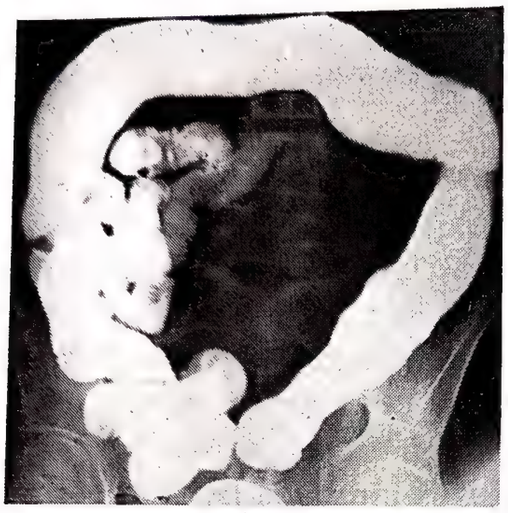

FIG. 1100.—Advanced ulcerative colitis. Showing tubular contraction and shortening of the colon. *(W. B. Gabriel, F.R.C.S., London.)*

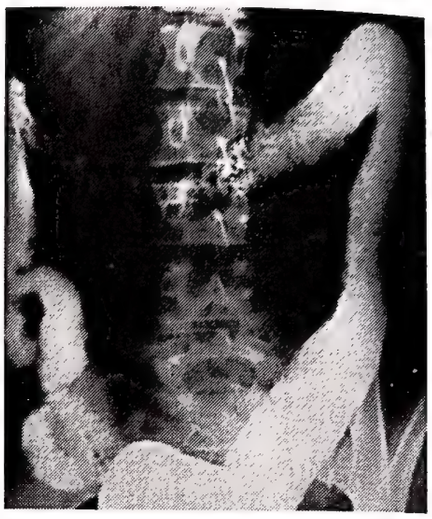

FIG. 1101.—Ulcerative colitis showing pseudopolyposis ('stippled' area in descending colon). *(Dr. Clifford Hawkins, Birmingham.)*

Sigmoidoscopy is indispensable in the diagnosis of early cases and in mild cases when the pathological effects of the disease are insufficient to alter the barium shadow. The initial findings are those of proctitis (p. 1073)—the mucosa is hyperæmic, bleeds on touch and there is considerable exudate. Later, tiny ulcers may be seen and appear to coalesce (fig. 1102). This is very different from the picture seen in amœbic dysentery, where there are large deep ulcerations with the intervening mucosa comparatively healthy. As the disease progresses, the ulceration may become so severe that practically no normal mucous membrane remains.

FIG. 1102.—Ulcerative colitis. The granular inflamed appearance of the mucosa is characteristic. *(After the late J. P. Lockhart-Mummery, F.R.C.S., London.)*

A barium enema and sigmoidoscopy should be avoided during the fulminating phase. Rectal biopsy is valuable not only in establishing the diagnosis, but also as an index of the effect of therapy.

Local Complications

Pseudopolyposis 15 per cent. (see above).

Carcinoma.—Although this is an important complication, it must be seen in its true perspective. The overall risk is about 3·5 per cent.; this risk is much less in early cases but increases with the duration of the disease. Thus, after twenty years of the dis-

ease, the risk may be as much as 12 per cent. Carcinoma is more liable to occur where the whole colon is involved and where the disease started in early life. Carcinomatous change may occur at many sites at once and these, often, are atypical. The colon is involved rather than the rectum and maximal incidence is during the 4th decade (Truelove). The golden rule is that after the disease has been present for more than ten years, regular radiological and sigmoidoscope checks must be done, even though the disease seems to be quiescent. It has been shown that the presence in a rectal biopsy of severe epithelial dysplasia denotes a pre-malignant potential, and may be the only sign that a carcinoma has already developed. At least an annual biopsy of all long-term cases of total colitis is indicated to enable this mucosal change to be detected (Morson and Pang). This precaution is also necessary after operations that have conserved the rectal stump.

Fibrous Stricture occurs in 6 per cent. of cases. The common sites are the recto-sigmoid junction and the anal canal. Although they usually respond to simple dilatation where the disease is confined to the distal colon, surgery may be advisable if the whole colon is involved.

Perforation (3 per cent.) occurs in the fulminating type of the disease. It is often preceded by toxic dilatation of the colon. Excessive steroid therapy may be a factor. Frequently the only sign that perforation has occurred is abdominal distension. This is a cardinal sign of impending doom.

Massive Hæmorrhage (3 per cent.) usually arises from the rectum rather than the colon.

Recto-vaginal Fistulæ[1] (3 per cent.), **Fistula in Ano** (4 per cent.), **Ischio-rectal Abscess** (4 per cent.), **Ileus and Toxic Megacolon** (1·5 per cent.) and **Hæmorrhoids** (20 per cent). also occur (Truelove).

General Complications

Liver Changes (7 per cent.) sometimes resulting in cirrhosis, may occur as the result of heavy protein loss and portal toxic absorption.

Skin Lesions (18·5 per cent.) including Pyodermia Gangrenosum (0·5 per cent.) and Erythema Nodosum (2 per cent.).

Arthritis (5 per cent.) usually of small joints, may occur at any stage of the disease.

Iritis (7 per cent.), **Ankylosing Spondylitis** (2 per cent.), **Stomatitis** (10 per cent.), **Renal Disease** (5 per cent.) and **Anæmia** (20 per cent.) are also important complications.

Treatment

There is no specific therapy—there are several agents which may induce a remission but it is difficult to predict the outcome in individual cases. The main *general principles* are:

(1) Maintenance of fluid and electrolyte balance.

(2) Anæmia must be speedily corrected.

(3) Adequate nutrition—at least 3,000 C (12560 kJ) per day—with high protein, carbohydrate and vitamin content and low fat.

(4) Phenobarbitone, belladonna and codeine phosphate are useful drugs.

(5) Antibiotics for febrile toxic cases (in short courses to prevent the onset of moniliasis). Salazopyrin (4 to 6 g daily) for seven days is specially valuable.

All are agreed on the above measures. All surgeons, however, are not agreed about the use of:

(6) Cortisone therapy. The M.R.C. trial (1950–58) showed that those receiving cortisone fared better than those receiving an inert substance and that first attacks did better than relapses. Its effect is far from permanent and is often negligible in the established disease. Topical steroids are of real

[1] Recto-vaginal and Anal Fistulæ usually mean that the underlying condition is Crohn's disease (p. 980) and not ulcerative colitis.

Sidney Charles Truelove, Contemporary. Physician, Radcliffe Infirmary, Oxford, England.
Basil Clifford Morson, Contemporary. Pathologist and Director of Research, St. Mark's Hospital for Diseases of the Rectum and Colon, London.
Lillian Shu Chao Pang, Contemporary. Histopathologist in Charge, Tumour Reference Collection, Imperial Cancer Research Fund, London.

value in the distal type of disease. In a moderately severe case it is probably best to try: (*a*) Salazopyrin for seven days. (*b*) Topical steroids—retention enemata of prednisolone phosphate 20 mg. in 100 ml. daily for seven days. If no response then: (*c*) Oral steroids—prednisolone 20 mg daily for two to three weeks.

Dangers of Prolonged Cortisone Therapy.—1. Not only is there an increased risk of massive hæmorrhage and of free perforation into the peritoneal cavity, but in patients who have not responded to a course of cortisone or similar steroid over a period of four to six weeks, the colonic wall becomes excessively friable and in some areas disintegrates, its place being taken by the parietes or adjacent viscera, usually the small bowel. In such cases the surgeon may then be unable either to remove the colon or even to perform ileostomy (Brooke).

2. Cortisone therapy renders the patient more susceptible to pyogenic infection.

The chief indication for the exhibition of steroid therapy is in fulminating cases, as an alternative to ileostomy performed during the ultra-acute phase (Crile Jnr.).

Indications for Surgery

(1) To save life—fulminating cases, severe hæmorrhage, perforation.

(2) Local complications (p. 974).

(3) General complications (p. 975).

(4) Risk of neoplastic change—especially in pseudo-polyposis and colitis of long standing.

(5) Onset in children or adolescents.

(6) Chronic invalidism.

Between 15 and 20 per cent. of sufferers are recommended for surgical treatment by their physicians.

When surgical treatment is advised, about six days' intensive pre-operative preparation by the methods already enumerated is carried out.

Operations

(i) The ideal procedure is *a one-stage total procto-colectomy with ileostomy*. If the disease is acute, it is wise to leave the rectal stump and either close it or bring it out as a midline colostomy or mucous fistula. The rectum can be removed about eight weeks later.

(ii) Some surgeons advocate *total colectomy* with immediate or subsequent *ileo-rectal anastomosis*—this can only be done satisfactorily in about 5 per cent. of cases where the rectum is not involved. Some surgeons have reported a much greater degree of success, and use total colectomy with ileo-rectal anastomosis in the majority of their cases (Aylett). If the degree of rectal inflammation makes the ileo-rectal anastomosis unsound, a temporary loop ileostomy proximal to the anastomosis is employed. After the operation a physiological bowel frequency of three to five actions a day is to be expected. It should not be performed if peri-anal complications are present. Should ileo-rectal anastomosis fail and the disease recur in the rectal stump, an ileostomy can be performed.

(iii) *Ileostomy alone* may sometimes be indicated for a gravely ill patient with fulminating disease and localised abscess around a perforation.

Colectomy is not a difficult operation when it is performed on an emaciated individual whose peritoneal cavity is free from adhesions. After a successful

Bryan Nicholas Brooke, Contemporary. Formerly Professor of Surgery, St. George's Hospital, London.

Stanley Aylett, Contemporary. Surgeon, Westminster Group Hospitals, and the Gordon Hospital, London.

ileostomy both these desiderata are absent; firstly, the patient has gained weight and, secondly, adhesions are bound to be present, especially in the right iliac fossa.

Ileostomy

As the ileostomy is nearly always permanent, the success of the operation lies in scrupulous attention to the details of technique in siting and fashioning the ideal 'spout'. It is best to arrange the position of the stoma beforehand with the patient (fig. 1103).

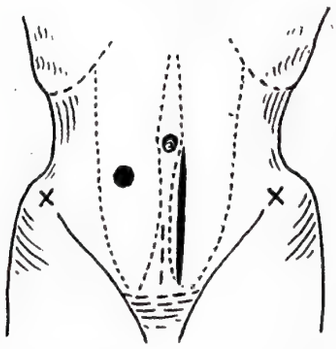

FIG. 1103.—Site of the ileostomy. The 'trephine' wound should be at least 5 cm. from all scars and bony points.

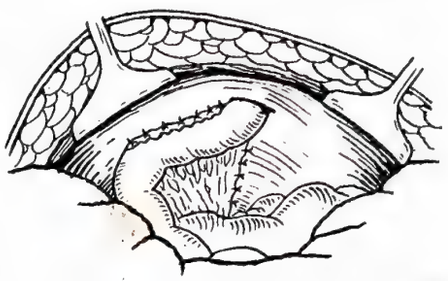

FIG. 1104.—Suture of the mesentery to the parietal peritoneum, to prevent prolapse. *(After J. C. Goligher, F.R.C.S., Leeds.)*

A disc of skin not more than 3 cm. in diameter is removed at least 5 cm. lateral to the umbilicus (fig. 1103). The abdomen is opened by a left paramedian incision and the ileum is divided near its termination, together with its mesentery. It may be necessary to divide the ileum more proximally if the terminal ileum is diseased also.

Important steps in the performance of ileostomy are (*a*) to close the peritoneal space on the external side of the ileostomy (otherwise a tunnel exists which invites intestinal obstruction), and (*b*) to anchor the anterior edge of the mesentery to the parietal peritoneum (fig. 1104). The latter prevents prolapse of the mucous membrane. The ileostomy opening must be prepared meticulously. A disc of tissue equal to the size of the skin disc should be removed from the anterior and posterior rectus sheath so that no stricture will occur in the parieties. The peritoneum is opened by a cruciform incision. About 7·5 cm. of the divided ileum (closed temporarily with a noncrushing clamp) is brought through the opening and its periphery is stitched to the skin edges by interrupted catgut in such a way that it is everted to form a 'spout' projecting 4 cm. from the skin surface. The greatest care must be taken in the construction of this projection (fig. 1105). A proctocolectomy is carried out and the abdomen is closed. A disposable plastic ileostomy bag (fig. 1106) is cut so that it exactly fits the skin at the muco-cutaneous junction and is fixed in position by latex rubber adhesive.

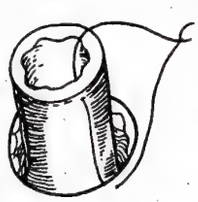

FIG. 1105.—Suturing the free extremity of the proximal ileum to the skin edges.

Care of Ileostomy. — During the first few post-operative days the fluid electrolyte balance must be adjusted with great care. For permanent use it is wise to fit a Chiron-type bag which has a firm rubber flange to be attached around the ileostomy spout. It is supported both by a waist strap and also made adherent to the skin by special double-sided adhesive plaster. The bag is attached to and detached from the flange which remains adherent to the skin for as long as is convenient. Great care must be taken that the lower rim of the bag does not press on and penetrate the lower margin of the ileostomy 'spout'. If soreness and excoriation of the skin occur as a result, a paste of aluminium 10 parts and zinc oxide 90 parts is helpful.

FIG. 1106.—Disposable ileostomy bag. *(Bryan N. Brooke, F.R.C.S., London.)*

Also a paste of Karaya gum (Goligher) acts as an adhesive and protective. The stools thicken in a few weeks and are semi-solid in a few months. A thin discharge from the stoma may indicate bolus obstruction and stenosis ; digital dilatation will help to relieve this.

Continent Ileostomy (Koch).—Professor Nils Koch has recently developed an ileostomy with a ' reservoir ' in the terminal ileum that opens to the surface by a one-way valve that prevents any escape of ileal effluent until a catheter is passed through the valve-spout to empty the ileal pouch. This type of ileostomy requires no bags or appliances and can be emptied at will by the patient. The ileostomy is called ' continent ' for this reason. The continent ileostomy is not easy to construct, and has a considerable morbidity: even the occasional death has been reported. It should not be used routinely at present.

Procto-colectomy requires no special description. The cæcum and colon are detached from their mesenteries and when the rectum is reached the procedure is exactly as for a combined abdomino-perineal resection (p. 1090). If the patient is too ill to stand the perineal dissection, the rectum is freed as far as the pelvic diaphragm and is transected at this point. The large intestine is removed, the upper end of the rectum closed and the pelvic peritoneum united over it. Alternatively, the lower bowel can be brought out as a colostomy through the paramedian incision.

INTESTINAL AMŒBIASIS

Amœbiasis denotes an infestation with *Entamœba histolytica*. Contrary to general belief, *E. histolytica* is not strictly a tropical parasite: *it has a world-wide distribution*, and is found in Great Britain particularly in the Southern counties. It is surprisingly common in overcrowded institutions. The reason why in some cases it becomes pathogenic is unknown.

Life History of the Parasite.—The active form of the parasite or trophozoite lives in the intestinal mucous membrane, where it ingests red blood corpuscles and other cells, and multiplies by mitosis. Should the parasite become pathogenic, it makes its way into the follicles of Lieberkühn, and by dissolving interglandular tissue by cytolysins, submucous loculi are produced. Some of these burst through the mucous membrane to become amœbic ulcers. While the trophozoites continue their activities in the base of the ulcer, others cease to feed, migrate towards the surface, and become transformed into cysts (fig. 935), which pass into the outer world with the fæces. Amœbiasis is transmitted mainly in drinking water.

Pathology.—The ulcers, which have been described as ' bottle-necked ' because of their considerably undermined edges, have a yellow necrotic floor, from which blood and pus exude. While on rare occasions the ulcers are scattered throughout the large intestine, in 75 per cent. they are confined to the lower sigmoid and the upper rectum.

Biopsy material is obtained by scraping the suspected area of mucosa with a long-handled Volkmann's spoon; this removes a thin slice of the diseased mucosa, which must be examined immediately. It should be noted particularly that the finding of *Entamœba histolytica* is not conclusive evidence that the symptoms are due to amœbiasis. On numerous occasions a positive slide examination has caused the clinician to assume that the diagnosis has been established when there has been a proximal carcinoma of the colon and the *Entamœbae histolyticae* have been non-pathogenic and incidental.

Clinical Features.—Dysentery is only one manifestation of the disease. In various guises amœbiasis obtrudes itself into the surgeon's diagnostic arena:

Appendicitis or Amœbic Typhlitis[1] *?*—In tropical countries where amœbiasis is endemic, this is a constantly recurring problem. To operate upon a patient with amœbic dysentery without the precautions subsequently described is to invite an exacerbation of amœbiasis that may prove fatal. Especially in cases where a palpable mass is present, the bowel is friable and satisfactory closure of the appendix stump becomes difficult or impossible. The death-rate from peritonitis and wound infection in the

[1] Typhlitis = inflammation of the cæcum.

John Cedric Goligher, Contemporary. Professor of Surgery, Leeds, England.
Professor Nils Koch, Contemporary. Professor of Surgery, Malmo, Sweden.
Richard von Volkmann, 1830–1889. Professor of Surgery, Halle, Germany.

notorious Chicago epidemic of amœbiasis in 1933 was appalling, which emphasises that surgeons in temperate climates should be familiar with the condition. In the case of amœbic typhlitis there is rarely rigidity, and pain commences in the right iliac fossa. In amœbic typhlitis there are two characteristics and localised zones of tenderness on deep palpation—one over the cæcum and one over the sigmoid. The latter is sharply defined, and being comparable to McBurney's point on the right side, it has been aptly named '*the amœbic point*' by Sir Philip Manson-Bahr. Routine sigmoidoscopy is of great value. If doubt still exists, 60 mg of emetine hydrochloride in 20 ml. of normal saline solution given intravenously very slowly is likely to ameliorate the symptoms within two hours (Andreasen).

Perforation.—The most common sites are the cæcum and recto-sigmoid. Usually perforation occurs into a confined space where adhesions have previously formed, and a pericolic abscess results, which eventually needs draining. When there is sudden fæcal flooding of the general peritoneal cavity, drainage of the region of the perforation, gastro-intestinal aspiration, intravenous fluid replacement, antibiotic therapy, and a full course of emetine are sometimes successful.

Severe rectal hæmorrhage due to the separation of sloughs is liable to occur.

Granuloma.—Progressive amœbic invasion of the wall of the rectum or colon, with secondary inflammation, may produce a granulomatous mass indistinguishable from a carcinoma. The exhibition of emetine as a therapeutic test will prevent mistakes in diagnosis. Amœbiasis and carcinoma occasionally co-exist (Naunton Morgan).

Fibrous stricture may follow the healing of extensive amœbic ulcers.

Intestinal obstruction is a common complication of amœbiasis, and the obstruction is due to the adhesions associated with pericolitis and a large granuloma.

Paracolic abscess, ischio-rectal abscess, and fistula occur from perforation by amœbæ of the intestinal wall followed by secondary infection.

Ulcerative colitis.—A search for amœbæ should always be made in the stools of patients believed to be suffering from ulcerative colitis.

Treatment.—Metronidazole (Flagyl) is the first line drug, 800 mg t.d.s. for 7–10 days. The patient must avoid taking alcohol. Emetine hydrochloride, 60 mg daily s.c. for 4 days, is the alternative if metronidazole cannot be taken by mouth. The patient must be kept in bed during and for one day after the course of emetine. Diloxanide furoate 500 mg t.d.s. for 10 days is another intra-lumenal drug. Intestinal antibiotics, e.g. tetracycline, improve results in the chronic stages, probably by coping with superadded infection.

THE SURGICAL COMPLICATIONS OF TYPHOID AND PARATYPHOID

Chloromycetin exerts a rapidly curative effect on typhoid and paratyphoid infections; consequently complications are uncommon. When complications of typhoid arise, chloromycetin should be given in addition to other necessary treatment, not forgetting that this antibiotic destroys the organisms responsible for the production of vitamin B complex which must be replaced.

1. *Paralytic ileus* is the commonest complication of typhoid (p. 1022).

2. *Intestinal hæmorrhage* may be the leading symptom. The condition must be distinguished from purpura with intestinal symptoms, and intussusception. A Widal reaction should be employed and, if negative, repeated in suspected cases. Urgent blood transfusion will be required.

3. *Perforation.*—Perforation of a typhoid ulcer usually occurs during the third week; occasionally it is the first intimation of the disease (ambulatory typhoid). The ulcer is parallel to the long axis of the gut (fig. 1107), and is situated in the lower

FIG. 1107A.—A typhoid ulcer is longitudinal (Peyer's patch necrosis).

FIG. 1107B.—A tuberculous ulcer is transverse (because it follows the lymphatics).

ileum. In paratyphoid B, perforation of the large intestine sometimes occurs. The former treatment was to perform laparotomy under local anæsthesia, and to close the perforation. The results were so poor that the conservative treatment of peritonitis plus chloromycetin yields better results.

Charles McBurney, 1845–1913. Surgeon, Roosevelt Hospital, New York, U.S.A.
Sir Philip Manson-Bahr, 1881–1966. Physician to the Hospital for Tropical Diseases, London.
Anthony Turner Andreasen, Contemporary. *(See footnote p. 803.)*
Sir Clifford Naunton Morgan, Contemporary. Consulting Surgeon, St. Bartholomew's Hospital, London.

4. *Cholecystitis.*—Acute typhoid cholecystitis is not uncommon and perforation can occur (p. 892). Gallstones occasionally contain typhoid bacilli. Chronic typhoid cholecystitis can result in the patient becoming a typhoid carrier.

5. *Phlebitis.*—Venous thrombosis, particularly of the left common iliac vein, is an occasional complication of typhoid fever.

6. *Genito-urinary Complications.*—Typhoid cystitis, pyelitis, bacilluria, and epididymo-orchitis all occur.

7. *Joints.*—All degrees of arthritis, from a mild effusion to suppuration, occur as a complication of this disease.

8. *Bone.*—Typhoid osteomyelitis and typhoid spine.

9. *Larynx.*—Typhoid perichondritis is met with occasionally, and typhoid laryngitis has been known to obstruct the airway.

REGIONAL ILEITIS (*syn.* CROHN'S DISEASE)

Ætiology.—No causative organism has been found in the lesion or in the stools. Dogs receiving finely powdered silicates admixed with their food for long periods develop an identical condition, and it has been suggested that the ingestion of fine, insoluble particulate matter such as toothpaste is a possible cause of regional ileitis. A disease similar to regional ileitis occurs in swine. Electron microscope studies have shown that in Crohn's disease fæcal bacteria enter the colonic wall. Whether it is these or something ingested or a metabolic product which acts as the hapten is not known, but granulomas develop (Aluwihare). There is evidence that heredity is a factor. Possibly Crohn's disease develops in patients with a relatively complete genotype. Ulcerative colitis is common in relatives of patients with Crohn's disease, but the converse is not common, suggesting that people with ulcerative colitis may have fewer of these genes. As with ulcerative colitis it is now believed that Crohn's disease is a pre-cancerous condition.

Pathology.—Regional ileitis is essentially a cicatrising inflammation with ulceration of the mucosa. It usually commences at or near the ileo-cæcal valve, and extends upwards along the ileum for about 30 cm, but as little as 5 cm, and, more often, as much as 1·2 metres may be implicated. In acute cases the affected intestine is seen to be swollen, bright pink in colour, and with a fibrinous exudate on its peritoneal surface; in chronic cases hyperæmia is less in evidence. On palpation the intestinal wall feels like a hose-pipe. The mesentery of the involved intestine is exceedingly thickened, œdematous, and contains enlarged and fleshy lymph nodes. Unlike tuberculosis, the affected lymph nodes neither break down nor calcify. Tracing the diseased ileum upwards, it terminates abruptly in normal intestine. Above this there is commonly another (short) area of diseased intestine; this is a so-called 'skip' lesion. Doubtless a comparatively inconspicuous additional lesion is sometimes overlooked, and is one cause of recurrence after resection. In 6 per cent. of cases there is an extension into the cæcum and at times the ascending colon is implicated in the interrupted manner referred to. Examples of primary Crohn's disease of the colon, jejunum, duodenum, and even of the stomach and anus have been reported, which justifies the newer term, regional enteritis.

Pathological Histology.—A characteristic finding is granulomatous infiltration of lymphatics of the submucosa with the presence of non-caseating giant-celled systems. In the late stages of the disease fibrosis extends into and obliterates the submucosa, but usually giant-celled systems can be found in the related mesenteric lymph nodes. An experienced histologist can easily distinguish the condition from tuberculosis.

Clinical Features.—The disease, which is independent of age, sex, social and economic conditions, or geographical location, is increasing in frequency. To some extent it is familial.

Acute regional ileitis occurs only in 5 per cent. of cases. The symptoms and signs resemble those of acute appendicitis, with one exception, viz. diarrhœa almost invariably precedes the acute attack. Exceptionally, perforation of the intestine, resulting in local or diffuse peritonitis, occurs.

Burrill Bernard Crohn, Contemporary. Gastroenterologist, Mount Sinai Hospital, New York. First described this disease in 1932.
A. P. R. Aluwihare, Contemporary. Surgeon, Sri Lanka.

Chronic regional ileitis is the usual form of the disease. It can be divided into three stages, but sometimes the second stage is lacking.

First Stage.—There is a history of mild diarrhœa extending over months or years, occurring continuously or in bouts accompanied by intestinal colic, relieved by defæcation. Intermittent pyrexia, seldom more than (37·2° C) is usual, but some patients are afebrile throughout. As a rule a tender mass can be felt in the right iliac fossa, and frequently by a pelvic examination also. There is often a moderate secondary anæmia. Occult blood and some mucus is present in the stools; two-thirds of the patients have some degree of steatorrhœa. *A perianal abscess* is a frequent accompaniment of early Crohn's disease. The cause is probably an infected anal crypt associated with the concomitant diarrhœa. The high incidence and diagnostic significance of perianal and perirectal abscesses and fistulæ in patients with regional ileitis is generally accepted.

Second stage is characterised by symptoms of acute or chronic intestinal obstruction. Cicatrisation of the granulomatous area has progressed to such

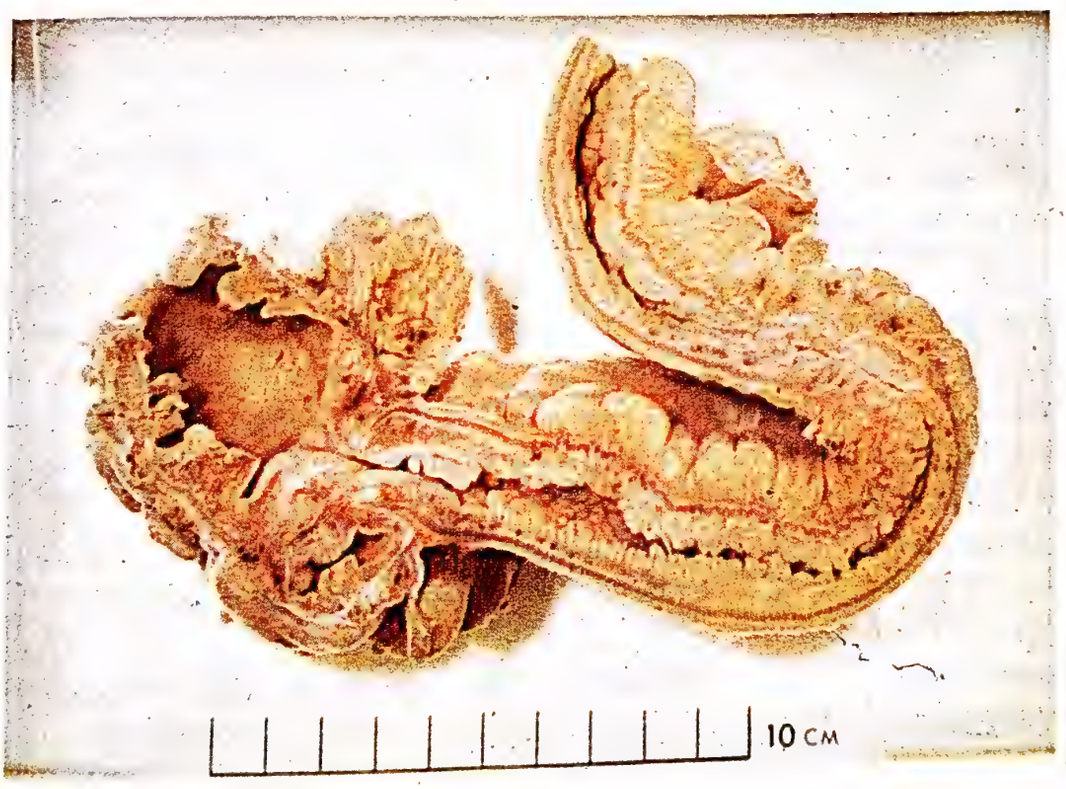

FIG. 1108.—Crohn's disease. Stage of cicatricial contracture.
(From the R.C.S. Museum, Professor G. Cunningham.)

an extent that the lumen of the affected portion of the intestine is narrowed (fig. 1108).

Third stage is that of adhesions sometimes accompanied by slow perforation of the intestinal wall. Adhesions are dense, abscess formation is common, and fistulous tracts are wont to develop:—

(*a*) *Internally* into neighbouring hollow viscera, e.g. a redundant pelvic colon, or occasionally into the right side of the bladder. In all cases of enterocolic and vesico-intestinal fistulæ the possibility of regional ileitis should be considered.

(*b*) *Externally*, nearly always through the scar of a previous operation for the condition, e.g. appendicectomy.

Radiological Diagnosis.—X-ray examination after a barium meal often shows lack of segmentation and feeble or absent peristalsis in the affected portion of the intestine, the lumen of which remains constant in diameter. Radiologically, cases can be divided into stenosing and non-stenosing. In the non-stenosing phase straightening of the valvulæ conniventes is characteristic. When ulceration has occurred multiple defects (cobblestone reticulation) can be seen after the barium has been evacuated from the segment in question. When cicatrisation has occurred the radiograph is particularly characteristic; sometimes the terminal ileum is so constricted that the 'string' sign of Kantor (fig. 1109) is seen.

FIG. 1109.—The 'string' sign of Kantor.

Treatment:

Medical Treatment.—In the early stages medical treatment is given an extended trial. It consists of rest in bed, a high protein diet with vitamin supplementation. Iron or blood transfusion may be required. Antibiotics—sulphaphthalidine is best—salazopyrine or steroids (e.g. prednisone or A.C.T.H. depot) are used with caution. In the acute form of the disease, particularly acute colitis, azathioprine has proved effective and may make colectomy unnecessary. It may also reduce fistula formation if operation is required. The drug may also have a place in the treatment of recurrences but not where obstruction is present. The response is less where the disease is chronic.

Indications for Surgery.—These are: (1) failure to arrest the course of the disease by adequate medical treatment; (2) intestinal obstruction; (3) the presence of fistulæ.

Operation.—Should the abdomen be opened on the mistaken diagnosis of acute appendicitis and acute regional ileitis is found, the one thing *not* to do is to remove the appendix. Appendicectomy frequently determines the development of an external fistula. The correct procedure is to close the abdomen forthwith. Occasionally the condition resolves completely; more often chronic ileitis supervenes.

Surgeons differ as to whether the affected bowel should be resected or by-passed. Probably a by-pass operation is best for young people, especially if the disease is in a florid state, and resection for older patients with firm strictures and where the main trouble is in the cæcum and colon.

On the whole, unless circumstances, such as an enterocolic fistula, leave no other alternative, more and more surgeons are following the advice of Crohn and his surgical colleagues, who for many years have recommended the conservative by-pass type of operation. The mortality is almost zero,

John Leonard Kantor, 1890–1947. Gastroenterologist, Presbyterian Hospital, New York, U.S.A.

and the results are at least as good as those following resection. In the cases that do not improve as a result of a short circuit, resection can still be undertaken.

TUBERCULOSIS OF THE INTESTINE

In countries where the Public Health control of tuberculosis is not strict, the disease is still common.

1. **Ulcerative tuberculosis** is secondary to pulmonary tuberculosis, and arises as the result of swallowing tubercle bacilli. It is characterised by the presence of multiple ulcers in the terminal ileum, the long axis of each ulcer lying transversely (fig. 1107). The serous coat overlying the ulcerated segment is thickened, injected, and sparsely bespattered with tubercles. Perforation is rare, but in patients who overcome the infection subsequent stricture or strictures of the ileum are rather frequent.

Clinical Features.—Diarrhœa is the predominant symptom; there is also loss of weight. The stools have a fœtid odour, and contain pus and occult blood. Often the patient has received, or is receiving, treatment for pulmonary tuberculosis; more rarely pulmonary tuberculosis is detected for the first time in the course of the investigations.

Radiology.—A barium meal often discloses complete absence of filling of the lower ileum, the cæcum, and most of the ascending colon, due to hypermotility of the ulcerated segment.

Treatment.—A prolonged course of chemotherapy (p. 32) is given. Provided the intestinal ulceration is not a terminal event of advanced pulmonary tuberculosis, healing often occurs. Operation is required in the rare event of perforation. Occasionally cicatrisation causes intestinal obstruction, and calls for surgical intervention.

2. **Hyperplastic tuberculosis** occurs most commonly in the ileo-cæcal region, although solitary or multiple lesions of the lower ileum are met with occasionally. This form of intestinal tuberculosis is consequent upon the ingestion of *Mycobacterium tuberculosis* by a patient with a high resistance to the organism. In Western countries *mycobacterium tuberculosis bovis* is often the causative organism, while in the East the human variety is the culprit (Toufeeq). The infection establishes itself in lymphoid follicles, and spreads to the submucous and subserous planes. The resulting chronic inflammation causes much thickening of the intestinal wall, and consequent narrowing of its lumen. There is early involvement of regional lymph nodes, which may caseate. Unlike regional ileitis (which in many respects this disease simulates), abscess and fistula formation are rare.

Untreated, sooner or later subacute or acute intestinal obstruction supervenes, and in the East, not infrequently, impaction of an enterolith within the narrowed lumen is the precipitating cause.

Clinical Features.—Attacks of abdominal pain with intermittent diarrhœa are the premonitory symptoms. Frequently, the presenting picture is that of the 'blind loop' syndrome (p. 965). The ileum above the partial obstruction is distended and the stasis and consequent infection lead to steatorrhœa, anæmia and loss of weight. Sometimes the presenting picture is that of a mass in the right iliac fossa in a patient with vague ill health. This finding raises the possibility of an appendix mass, a carcinoma of the cæcum, Crohn's disease or a tuberculous or actinomycotic granuloma of the cæcum. The problem can be quite perplexing (fig. 1110).

FIG. 1110.—The difficulties in diagnosis of a mass connected with the cæcum. In this case the lump outlined on the skin was thought at first to be an *appendix abscess.* After the cæcum and ascending colon had been excised the specimen had many of the appearances of *tuberculosis.* Histologically the mass proved to be a *carcinoma.*

Ahmed Khan Toufeeq, Contemporary. Professor of Surgery, Sir Ganga Ram Hospital, Lahore, Pakistan.

FIG. 1111.—Ileocæcal tuberculosis. The filling defect also occurs in carcinoma of the cæcum. *(Professor A. K. Toufeeq, Lahore, Pakistan.)*

Radiography.—In an established case a barium meal reveals a long, narrow filling defect consisting of the terminal ileum and ascending colon, lying vertically. The cæcum may become subhepatic (fig. 1111).

Treatment.—When the diagnosis is certain, and the patient has not yet developed obstructive symptoms, sanatorium treatment with chemotherapy is advised and may completely cure the condition. If obstruction is present, operative treatment is required. Right hemicolectomy with removal of the diseased segment of ileum is the treatment of choice. In patients with intestinal obstruction, and those in poor general condition, a defunctioning ileocolostomy similar to that recommended for regional ileitis is advisable. If necessary resection can be undertaken later, for frequently striking improvement occurs after ileocolostomy and general treatment, and unless formal resection is done there is always a considerable risk of further recrudescence of the disease, which may involve the recent by-pass anastomosis as well.

ACTINOMYCOSIS OF THE RIGHT ILIAC FOSSA

Actinomycosis develops when a breach of the mucous membrane, caused by disease or trauma of a foreign body, permits the entry of *Actinomyces israeli* (p. 33) into the deeper layers. Abdominal actinomycosis, which is comparatively rare, occurs with equal frequency in rural and urban communities. Unlike intestinal tuberculosis, cicatrisation and consequent narrowing of the lumen of the intestine do not occur, neither do the mesenteric lymph nodes become involved. However, suppuration supervenes, and the disease spreads into the retroperitoneal tissues. Eventually, the abdominal wall becomes the seat of multiple indurated discharging sinuses, and the liver becomes involved by way of the portal vein.

Clinical Features.—The usual history is that appendicectomy has been performed for acute or subacute appendicitis. Possibly, had the appendix been subjected to histological scrutiny, actinomyces would have been found. More usually this examination is omitted or the organism is not discovered, and about three weeks after the operation a mass forms in the right iliac fossa, and soon afterwards the wound commences to discharge. At first the purulent discharge is thin and watery; later, because of secondary infection, it becomes thicker and odorous. Other sinuses form, and fæcal fistulæ are liable to develop. At any stage of the disease, if pus is collected and allowed to trickle down the side of a test-tube, sulphur granules may be discovered. A swab is insufficient. The pus should be sent for immediate bacteriological examination.

Another clinical type is that of a patient, most usually a young adult male, who presents with vague abdominal pain. On examination a firm, slightly tender mass is found in the right iliac fossa. Extension of the disease to the psoas muscle sometimes causes flexion of the hip. Such a finding is characteristic, but is only present when the condition is moderately advanced. Little or no help is derived from radiology in distinguishing actinomycosis of the right iliac fossa from hypertrophic tuberculosis or carcinoma

of the cæcum; a deformity of the cæcum is found in all these conditions. Actinomycosis rarely gives rise to obstructive symptoms. When, as is sometimes the case, there is a history of a more or less sudden onset of pain some weeks previously, a subsiding appendix abscess is probably diagnosed, but the mass does not resolve. There is loss of weight, anæmia, and occasional pyrexia. In most instances laparotomy is performed with one of the following findings: (*a*) an abscess is encountered and drained; (*b*) the mass is found to be densely adherent to the posterior abdominal wall, and irremovable. In such a case, a by-pass ileo-transverse colostomy as for Crohn's disease (p. 980) is wise; (*c*) the mass is sufficiently mobile for right hemi-colectomy to be carried out.

Treatment (p. 34).

PNEUMATOSIS CYSTOIDES INTESTINALES

Multiple gas cysts of the intestinal wall are pathological curiosities. Translucent, thin-walled cysts ranging from 1 to 2 or more centimetres in diameter, containing gas, mainly nitrogen, and having a lining of flattened cells of doubtful origin, occur in clusters under the serosa or in the mesenteries on the intestines. The condition nearly always affects the small intestine, but occasionally the colon, and even the rectum, are implicated. It is believed that air enters a breach in the mucosa, as would occur in the case, say, of a duodenal ulcer, and the air is driven onwards by peristalsis. The cysts, which are obvious on a plain radiograph, are usually symptomless, but occasionally they so occlude the lumen of the intestine that resection is necessary. A new treatment using an oxygen-enriched atmosphere for the patient to breathe over several weeks has been successful in causing the cysts to disappear, but they usually come back within a year of the treatment. The success of the treatment depends upon replacing the nitrogen in the cysts by oxygen, which is then re-absorbed with ensuing collapse of the cysts.

TUMOURS OF THE SMALL INTESTINE

Compared with the large intestine, the small intestine is rarely the seat of a neoplasm.

Benign.—Adenoma, submucous lipoma and leiomyoma occur from time to time, and sometimes reveal themselves by causing an intussusception. The second most common complication is intestinal bleeding from an adenoma, in which event the diagnosis is frequently long delayed because the tumour is overlooked at a radiological examination by barium meal, and often at operation as well, to be discovered perhaps only after a second or third operation.

Peutz-Jeghers syndrome (small intestinal polyposis) consists of (*a*) familial intestinal hamartomatous polyposis affecting mainly jejunum, where it is a cause of hæmorrhage, and often of intussusception, and (*b*) melanosis of the oral mucous membrane and the lips. The melanosis takes the form of melanin spots which are sometimes present on the digits and the peri-anal skin, but the pigmentation of the lips (fig. 1112) is the *sine qua non*. *Histology*.—The polyps can be likened to trees. The trunk and branches are smooth muscle fibres and the foliage is virtually normal mucosa. ⟶

Treatment.—As a malignant change rarely occurs, resection is necessary only for serious bleeding or intussusception. Large single polyps can be removed by enterotomy, or short lengths of heavily involved intestine can be resected. It is now possible to snare these lesions by means of a fibrecolonoscope.

Malignant :

Sarcoma (40 per cent.).—Lymphosarcoma and spindle-cell sarcoma—more usually the former—occur in the first five decades, the average age of the patient being thirty-five years. There are usually multiple lesions and the disease may follow idiopathic

John Law Augustine Peutz, 1886–1957. Chief Specialist for Internal Medicine, St. John's Hospital, The Hague, Holland.
Harold Jos Jeghers, Contemporary. Professor of Internal Medicine, New Jersey College of Medicine and Dentistry, Jersey City, U.S.A.

steatorrhœa. The neoplasm tends to convert the affected intestine into a rigid tube without much interference with the size of its lumen until the disease is advanced. Loss of weight and anæmia are the chief early symptoms. Perforation into the peritoneal cavity occurs more often than is the case with other neoplasms of the small intestine.

FIG. 1112.—Melanin spots on the lips of a patient afflicted with Peutz-Jeghers syndrome. *(Major P. C. M. Mehta, Indian Medical Service.)*

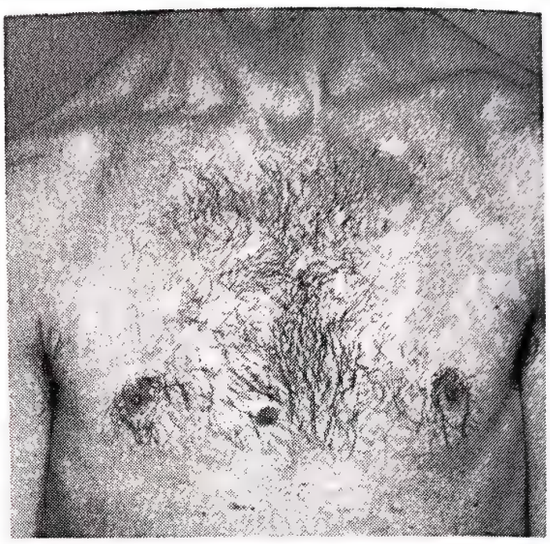

FIG. 1113.—Patient with secondary carcinoid tumour of the liver (primary in the terminal ileum) exhibiting flushing after a small dose of alcohol. *(Dr. P. J. D. Snow, Manchester.)*

Carcinoma (35 per cent.) occurs at the usual carcinoma age. The jejunum is affected three times more often than the ileum. The most frequent symptoms are melæna and those of intestinal obstruction, and in some cases a palpable tumour is present. It is unusual for malignant tumours to cause intussusception. Because the content of the small intestine is fluid, by the time intestinal obstruction has ensued metastases have occurred. Another train of symptoms is dyspepsia associated with melæna and increasing anæmia, in which case a tumour, often of the papilliferous variety, may be revealed radiologically at a barium meal.

Carcinoid (Argentaffin) Tumour (25%).—These tumours occur throughout the gastrointestinal tract and also in the bronchus, testis and ovary.

The appendix is the commonest site (65%) p. 1044. The next most common site is the ileum (25%). They arise in the cells of Kulchitsky at the base of the crypts of Lieberkühn. The primary is usually less than 10 mm in diameter. When they metastasise, the liver is usually involved with numerous secondaries, larger and more yellow than the primary growth. When this has occurred the ' carcinoid syndrome ' may become evident.

The tumour produces 5-H.T. (hydroxy-tryptamine; serotonin) which may be present as 5 hydroxy indole-acetic acid in the urine during attacks. It also produces kinins, indoles, prostaglandins and perhaps histamine.

The clinical syndrome itself consists of reddish-blue cyanosis, flushing attacks diarrhoea, borborygmi, asthmatic attacks, and eventually sometimes pulmonary and tricuspid stenosis. Classically the flushing attacks are induced by alcohol (fig. 1113).

The cyanotic flushing and asthmatic attacks have been attributed to 5-H.T. and histamine—the brick-red to kinins.

Five-H.T. is responsible for the gastrointestinal symptoms. Prostaglandins may have similar effects to the kinins.

Treatment.—This tumour must be taken seriously. A radical operation is advisable where metastases are not found. For example, right hemicolectomy for lesions in the ileum or abdomino-perineal for lesions low in the rectum.

Where metastases have occurred, excision of the local lesion and if feasible partial hepatectomy should be considered. It should be borne in mind, however, that such patients may survive for up to 10 years having frequent carcinoid attacks. Medical

Nicholas Kulchitsky, 1856–1925. Professor of Histology, Kharkov, Ukraine, U.S.S.R.

measures include giving serotonin antagonists, long acting anti-histaminics and alpha-methyl dopa which may help to reduce the severity of attacks. For hepatic metastases 5-fluorouracil given into the hepatic artery is under trial.

TUMOURS OF THE LARGE INTESTINE

Benign

Adenomatous Polyps are dark red pedunculated neoplasms (fig. 1114). A *villous adenoma* is simply a different morphological expression of the same pathological process, and is usually sessile, and may cause diarrhœa and hypokalæmia.

A solitary adenoma of the colon (fig. 1115) is acquired (see below for the multiple familial variety). It occurs in patients over forty years of age, and

FIG. 1114.—Pedunculated adenomatous polyp of the large intestine. Longitudinal section. (*J. H. Saint, F.R.C.S., Santa Barbara, California.*)

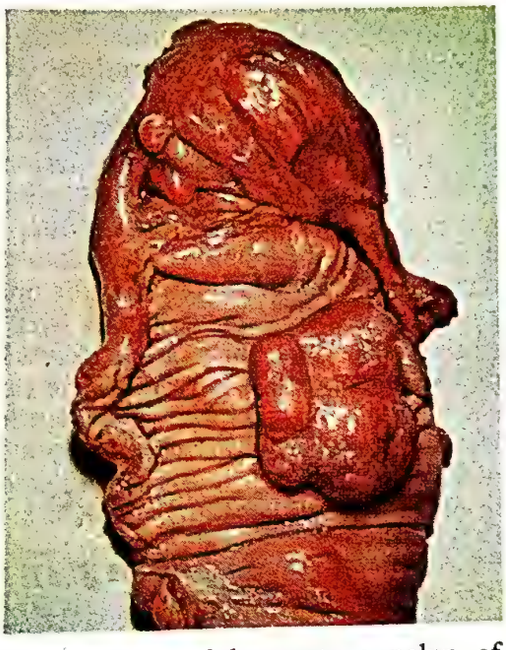

FIG. 1115.—Adenomatous polyp of the colon. (*Max Pemberton, F.R.C.S., Enfield, Middlesex.*)

unless it is pedunculated, it cannot be distinguished macroscopically from a papilliferous carcinoma. In specimens of papilliferous carcinoma of the colon, often tiny adenomas are found adjacent to the parent tumour.

Treatment.—Because the lesions have a malignant potential they should be removed. Those beyond the reach of the sigmoidoscope require laparotomy, but this should only be undertaken if the lesion is larger than 1 cm in diameter and has been demonstrated on two barium enemas. Fibre endoscopic removal is available in an increasing number of centres.

Familial Adenomatous Polyposis of the Colon, which must be distinguished from Peutz-Jegher's syndrome (p. 985), juvenile polyposis coli (p. 1085), and pseudopolyposis (p. 974), is transmitted from both sexes to both sexes, though males are affected more frequently than females. Lockhart-Mummery and Cuthbert Dukes studied 1069 members of 58 families; of these members 218 had polyposis, and 154 of them developed colonic carcinoma. The adenomatous polypi are most frequently situated in the sigmoid and the rectum. Often hundreds of tumours are present. The patient complains of attacks of lower abdominal pain associated with loss of weight, diarrhœa, and tenesmus, and the passage of blood and mucus, and sometimes pus—all symptoms very like those of ulcerative colitis. A rectal examination may

Hugh Evelyn Lockhart-Mummery, Contemporary. Surgeon, St. Thomas's Hospital, London.

reveal one or more adenomatous polypi. Sigmoidoscopy shows a variety of neoplasms ranging from small sessile pink elevations to pedunculated tumours. A barium enema, especially a contrast barium enema (p. 991), outlines the larger polypi.

Prevention.—(1) All members of the family should be examined at ten years. Repeat every two years. (2) Most of those who are going to get polypi will have them at twenty and these require operation. (3) If there are no polypi at twenty, continue with five-yearly examination till fifty. If there are still no polypi there is no inherited gene. Carcinomatous change before the age of twenty is very rare.

Treatment.—If operation is necessary, complete colectomy is advisable. A stump of rectum can remain and the terminal ileum anastomosed to it, the reasons being (*a*) the risk of carcinoma in the rectal stump is small if the patient is carefully followed-up; (*b*) an artificial anus is avoided; (*c*) other members of the family can be persuaded more easily to undergo the operation before late symptoms develop.

Hamartomatous Polyps.—Peutz-Jeghers polyps may occur in the colon (p. 985) either as solitary or multiple lesions. The other type of hamartomatous polyp is the juvenile or mucous polyp (p. 1085) which may occur as multiple lesions of the colon, often associated with a congenital defect such as malrotation of the intestine, Meckel's diverticulum or congenital heart lesions. They have no malignant potential and are only removed if they produce troublesome pain, bleeding or hypoproteinæmia.

Hæmangioma.—A localised submucous telangiectasis is the cause of bleeding, which is often profuse. When the lesion is beyond the sigmoidoscopy field often the only method of detecting it is to operate while the bleeding is in progress. The distribution of blood within the intestine is noted; scrutiny of the blood-containing portion of the intestine usually reveals a dilated leash of veins in one portion of the mesocolon. At this site the intestine is opened and the tumour is resected. Arteriography is being used in many centres with great success.

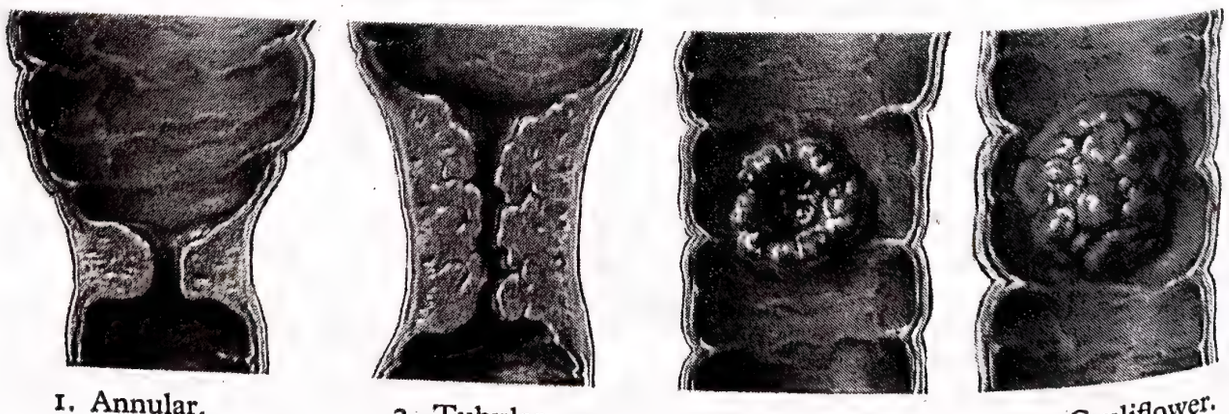
Lipoma is less frequently encountered in the large than in the small intestine, and is almost confined to the cæcum. The tumour is submucous and in more than half the cases it is the cause of an intussusception. Other symptoms to which it gives rise are almost impossible to distinguish from those of a carcinoma; even macroscopical or microscopical blood is found in the stools. A barium study may suggest a lipoma because of its smooth contour.

Malignant

CARCINOMA OF THE COLON

Pathology.—Microscopically, the neoplasm is a columnar-celled carcinoma originating in the epithelial cells that line the colon, or in the crypts of Lieberkühn. Macroscopically the growth takes one of four forms (fig. 1116):

Type 4 is the least malignant form, and this papilliferous carcinoma commences as a benign adenoma. The annular variety carries a relatively good prognosis, not because the growth is of low-grade malignancy, but because it gives rise to early obstructive symptoms, and therefore is often extirpated before metastases have occurred (Grey Turner).



1. Annular. 2. Tubular. 3. Ulcer. 4. Cauliflower.

FIG. 1116.—The four macroscopical varieties of carcinoma of the colon.

George Grey Turner, 1877–1951. Professor of Surgery, Post-Graduate Medical School, London.

Site.—The most frequent site is toward the termination of the colon, viz. the pelvic colon and the rectosigmoid junction (fig. 1117).

The Spread of Carcinoma of the Colon.—Generally speaking, it is a comparatively slowly growing neoplasm, and if extirpated thoroughly at a reasonably early period a cure can be hopefully anticipated.

Local Spread.—The growth is limited to the bowel for a considerable time. It spreads round the intestinal wall, and to a certain extent longitudinally, but usually it causes intestinal obstruction before it has penetrated adjacent structures. Particularly in the ulcerative variety, penetration of the serous coat is apt to occur and, according to the segment involved, adjacent structures then become invaded by the growth. When a hollow viscus is thus implicated an internal fistula results; also the perforation may lead to the formation of a local abscess and an external fæcal fistula.

Lymphatic Spread.—The lymph nodes draining the colon are grouped as follows:

1. *The epicolic lymph nodes*, situated in the immediate vicinity of the bowel wall.
2. *The paracolic lymph nodes*, lying in relationship to the leash of blood-vessels proceeding to the colonic walls.
3. *The intermediate lymph nodes*, arranged along the ileo-colic, right colic, mid colic, left colic, and the sigmoid arteries. In the last instance the paracolic lymph nodes are often absent.
4. *The main lymph nodes*, aggregated around the superior and inferior mesenteric vessels, where they take origin from the abdominal aorta.

Spread by the blood-stream occurs late. Metastases are carried to the liver.

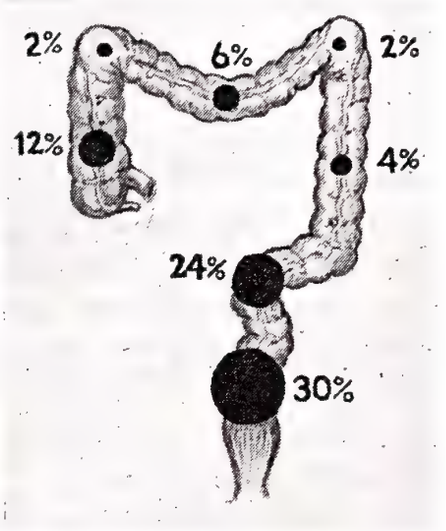


FIG. 1117.—Relative frequency of carcinoma in various portions of the large intestine omitting the rectum proper. (*Mayo Clinic statistics.*)

Clinical Features.—Carcinoma of the colon usually occurs in patients over fifty years of age, but it is not rare earlier in adult life. Exceptionally it appears in childhood, when, owing to delayed diagnosis, prognosis is poor. Twenty-five per cent. of cases present as emergencies with intestinal obstruction or peritonitis. It must be remembered that in any case of colonic bleeding in patients over forty years of age, complete investigation of the colon is required.

Men are attacked more frequently than women (3 : 2), although carcinoma of the ascending colon is encountered more often in women.

While certain outstanding symptoms frequently prevail in all types (fig. 1116) and at all sites (fig. 1117), it is instructive to contrast and to compare the symptoms produced by a carcinoma of the left side of the colon with that of the right, and to refer to the symptomatology of carcinoma of the sigmoid and that of the transverse colon.

Carcinoma of the Left Side of the Colon.—As will be seen on reference to fig. 1117, in about 75 per cent. of cases the neoplasm is situated on the left side of the colon. Neoplasms in this situation usually are of the stenosing variety (fig. 1116, 1 and 2) and as here the fæcal content is relatively solid, and the lumen of the bowel comparatively narrow, the main symptoms are those of increasing intestinal obstruction in about 25 per cent. of cases.

Symptoms	*Right Colon*	*Left Colon*	*Sigmoid*
Abdominal pain	78	68	51
Alteration of bowel habit	30	58	70
Loss of weight	50	15	20
Vomiting (frequently with colic)	32	15	0
Anorexia	18	9	0
Faintness, breathlessness	20	9	6
Bleeding per rectum	8	9	29
Lump present	67	46	39
Indigestion	8	0	0
Acute-on-chronic obstruction	8	21	29

The duration of symptoms is extremely variable; 5·5 months is the average.

(*E. G. Muir's statistics—figures given are percentages.*)

Pain.—This is usually intestinal colic. If it becomes a constant ache, it suggests inoperability or pericolitis.

Alteration of Bowel Habit.—An adult who has had regular bowel movement all his life, in a short space of time develops irregularity. The patient often states that he has *increasing* difficulty in getting the bowels to move, and that he has to take *increasing* doses of purgatives. Because of the drastic purgation, or on account of irritation by the scybala causing excessive secretion of mucus above the constricting neoplasm, attacks of constipation are followed by diarrhœa.

Palpable Lump.—Very often the lump that is felt on abdominal, rectal, or abdomino-rectal examination, is not the growth itself, but impacted fæces above it (Oldham). When the carcinoma is situated in a pendulous pelvic colon a hard movable swelling is often felt in the rectovesical pouch.

Distension.—Lower abdominal distension is not uncommon, and, like the pain, is relieved by passing flatus.

Carcinoma of the sigmoid follows the general pattern of the above, but there are differences.

Pain, when it occurs, is usually colicky from the commencement.

Tenesmus.—Growths of papilliferous type situated low in the colon are inclined to give rise to a feeling of the need for evacuation, which may result in tenesmus accompanied by the passage of mucus and blood, especially in the early morning.

Bladder symptoms are not unusual, and in some instances they herald colo-vesical fistula.

Carcinoma of the transverse colon may be mistaken for a carcinoma of the stomach because of the position of the tumour together with the anæmia and lassitude that it sometimes engenders.

Carcinoma of the cæcum and ascending colon presents in several guises:

(*a*) Anæmia, severe and unyielding to treatment, is a frequent predominat-

Sir Edward Grainger Muir, 1906–1973. Surgeon, King's College Hospital, London. President, Royal College of Surgeons of England.
James Bagot Oldham, Contemporary. Formerly Surgeon, Royal United Hospitals, Liverpool.

ing feature. Should a palpable tumour be present, the diagnosis is, to some extent, simplified.

(*b*) The presence of a mass in the right iliac fossa often proves a diagnostic conundrum (fig. 1110).

(*c*) Cæcal carcinoma sometimes is discovered unexpectedly at operation for acute appendicitis or for an appendix abscess that 'fails to resolve'. On rare occasions the appendix is inflamed, or even gangrenous, from obstruction to its lumen by the carcinoma.

(*d*) Less commonly a papilliferous growth is the apex of an intussusception. A lump, present at one time and smaller or absent at another (owing to partial reduction), associated with attacks of acute abdominal pain, is characteristic of this complication.

METHODS OF INVESTIGATION

Sigmoidoscopy should be performed in all cases where blood and mucus have been passed and also in suspected cases when a barium enema is negative, because early growths in the lower part of the pelvic colon are not always visualised by radiography.

Radiography after a barium enema often shows a carcinoma of the colon as a constant, irregular filling defect (fig. 1118). On the other hand, negative radiography in comparatively early cases of carcinoma of the colon is not by any means conclusive evidence of the absence of a growth. In 75 cases of carcinoma of the colon examined radiologically, no abnormality was detected in 8 per cent. This entailed considerable delay in diagnosis (Ramsay).

A tumour of the cæcum is more likely to be discovered by a barium meal than a barium enema. As a rule, in suspected cases of carcinoma of the colon, a barium meal is inadvisable because inspissated barium can precipitate intestinal obstruction if the lumen of the bowel is narrowed.

FIG. 1118.—Barium enema showing a carcinoma of the descending colon.

Contrast Enema.—In cases of a neoplasm involving only the mucous membrane, a contrast enema is very valuable. The barium emulsion is partly evacuated and air is injected into the colon. By this means the walls of the colon become delineated and a neoplasm that fails to alter the contour of the barium-filled colon may be demonstrated.

Exfoliative cytology.—In experienced hands colonic exfoliative cytology is a valuable adjunct in the diagnosis of obscure cases of carcinoma of the colon. To obtain satisfactory results, the patient must be prepared carefully by a somewhat laborious procedure. After an interval of 5 to 10 minutes, the returned fluid is collected and centrifuged. Films from the sediment are prepared and stained. Successful diagnoses have been made by this method in growth situated in all parts of the colon.

Colonoscopy.—With the availability of the new fibreoptic instrument its usefulness is under assessment, but it has been shown already that this technique can supplement radiography in the diagnosis of both polyps and carcinoma of the colon. It can also help to prevent carcinomas arising by diagnosing and treating colonic polyps at an early stage (Williams). Unfortunately the technique is time consuming, and the apparatus is expensive, which will probably restrict its availability to special centres.

Gordon Stuart Ramsay, Contemporary. Surgeon, Royal London Homœopathic Hospital, London.
Christopher Beverley Williams, Contemporary. Physician, St. Mark's Hospital for Diseases of Colon and Rectum, London.

TREATMENT

Pre-operative Treatment.—When there is no intestinal obstruction, blood transfusion to correct anæmia, if present, enemas to cleanse the bowel, a high caloric and low residue diet, together with succinylsulphathiazole, 2 g four-hourly for five days, are required. This sulphonamide gives watery stools so that the bowel mucosa is clean for purposes of anastomosis and it effectively reduces the number of virulent organisms ordinarily present in the colon. This is probably all that is required. Other antibiotics such as neomycin may completely sterilise the bowel but the risk of staphylococcal enteritis (p. 19) after its use is present.

When intestinal obstruction is present, preliminary drainage of the intestine proximal to the obstruction must be performed (p. 1005).

Operation.—*The Test of Operability.*—The abdomen having been opened in the first place through a short paramedian incision, which is extended if the growth is removable: (1) the liver is palpated for secondary deposits, the presence of which is not necessarily a contraindication to resection, as the best palliative treatment for carcinoma of the colon is removal of the tumour; (2) the peritoneum, particularly the pelvic peritoneum, is inspected, if possible, and palpated for neoplastic implantations; (3) the various groups of lymph nodes that drain the involved segment are palpated. Their enlargement does not necessarily mean that they are invaded by metastases, for the enlargement may be inflammatory; (4) the neoplasm is examined with a view to ascertaining if it is fixed or free, and if it is operable. "The whole colon above the last 7·5 cm of the pelvic portion is either mobile or can be mobilised" (Ogilvie).

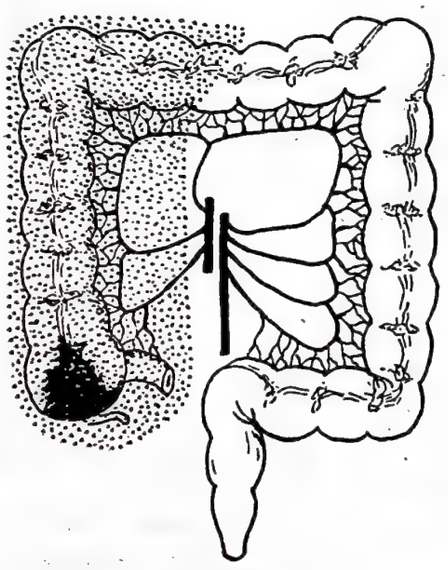

FIG. 1119.—Area to be resected when the growth is situated in the cæcum.

The operations to be described are designed to remove the lymph nodes which may be involved by metastases from the particular primary growth concerned. Lesser resections are indicated, however, should hepatic metastases render the condition incurable.

Carcinoma of the cæcum or the ascending colon is treated, when resectable, by right hemicolectomy (fig. 1119).

The abdomen is opened through a right paramedian incision. The technique of right colectomy should include at the outset ligatures placed around the bowel to prevent intraluminar spread. The peritoneum 2·5 cm or more lateral to the ascending colon is incised and the incision is carried around the hepatic flexure. The right colon is elevated, with the leaf of peritoneum containing its vessels and lymph nodes, from the posterior abdominal wall, care being taken not to injure the ureter, spermatic vessels, or the duodenum. The peritoneum is separated medially to near the origin of the ileo-colic artery, which is divided between ligatures, as also is the right colic artery when that vessel has a separate origin from the superior mesenteric. The mesentery of the last 30 cm. of ileum, and the leaf of raised peritoneum attached to the cæcum, ascending colon and hepatic flexure, after ligation of the blood-vessels contained therein, is divided as far as the proximal third of the transverse colon

Sir Heneage Ogilvie, 1887–1971. Surgeon, Guy's Hospital, London.

(fig. 1119). The surgeon, having verified that the blood supply to the proposed intestinal stumps is adequate, forthwith clamps and divides the ileum and the transverse colon at the levels of their respective severed mesenteries, and excises the free intestine. An end-to-end anastomosis between the ileum and transverse colon is then carried out and their respective mesenteries approximated with catgut. The abdomen is then closed.

Carcinoma of the Hepatic Flexure.—When the hepatic flexure is the seat of the neoplasm the resection must be extended correspondingly (fig. 1120).

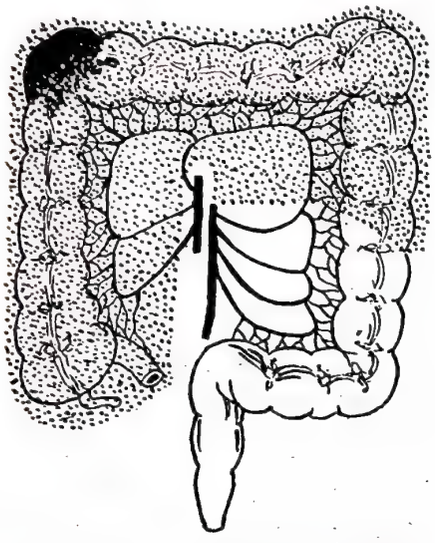

FIG. 1120.—Area to be resected when the growth is situated at the hepatic flexure.

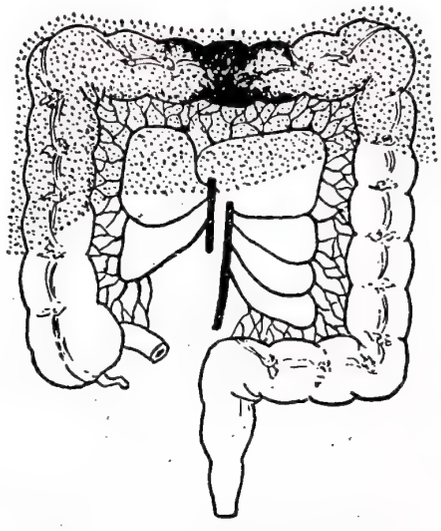

FIG. 1121.—Area to be resected when the neoplasm is situated in the transverse colon.

Carcinoma of the Transverse Colon.—When there is no obstruction, excision of the transverse colon and the two flexures (fig. 1121), together with the transverse mesocolon and the greater omentum, followed by end-to-end anastomosis, is a satisfactory procedure.

Carcinoma of the Splenic Flexure or descending colon. The extent of the resection is shown in fig. 1122.

The phrenico-colic ligament is divided, and after incising the parietal peritoneum from the splenic flexure to the pelvic colon, the splenic flexure, descending colon, and pelvic colon are raised from the posterior abdominal wall in the same way as the ascending colon is raised on the right side. When this has been achieved, the left branch of the middle colic and the left colic arteries are ligated near their origins, and the peritoneal leaf with its contained lymph nodes is divided. Excision with end-to-end anastomosis is then carried out.

Carcinoma of the Pelvic Colon.—A left paramedian incision gives a good approach. The left half of the colon is mobilised completely (fig. 1123).

In order that the operation be rendered radical, the inferior mesenteric artery below its left colic branch, together with the related paracolic lymph nodes, must be included in the resection. This entails carrying the dissection as far as the upper third of the rectum, and accordingly the incision in the lateral leaf of peritoneum is extended downward to an appropriate level.

In every case of resection of the colon with anastomosis, drainage down to the site of anastomosis should be provided.

Modern methods of bowel preparation render one-stage resection and anastomosis reasonably safe in *non-obstructed* cases of colonic carcinoma but if any doubt exists a protective colostomy must be added. The methods of dealing with large bowel obstruction due to colonic carcinoma are described on p. 1007.

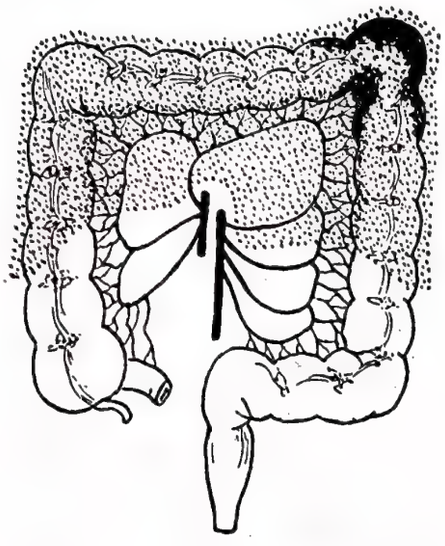

FIG. 1122.—Area to be resected when the neoplasm is situated at the splenic flexure, or the proximal part of the descending colon.

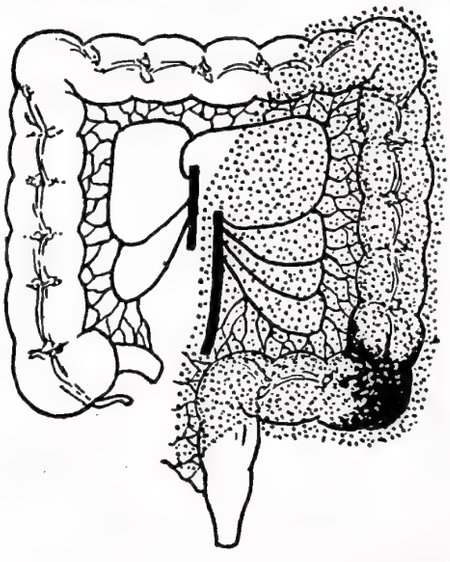

FIG. 1123.—Area to be resected in the case of a carcinoma of the pelvic colon.

Post-operative Care following Colonic Resection.—Post-operative treatment includes the administration of antibiotics to guard against possible infection of the anastomotic area by *Cl. welchii*. Fluids are not given by mouth after anastomotic operations until flatus is passed.

When a Growth is found to be Inoperable.—In the upper part of the left colon, transverse colostomy is performed. In the pelvic colon, left iliac colostomy is preferable. With an inoperable growth in the ascending colon, ileo-colostomy is the best procedure. However, about 90 per cent. of colonic carcinomas can be resected, if necessary at a ' second look ' operation, when infection will have subsided following the by-passing of fæces. As these are slow-growing neoplasms, after subsequent colostomy-closure, these patients often enjoy several years of trouble-free life.

FÆCAL FISTULÆ

An external fistula communicating with the cæcum sometimes follows an operation for gangrenous appendicitis or the opening of an appendix abscess. A fæcal fistula can occur from necrosis of a gangrenous patch of intestine after the relief of a strangulated hernia, or from a leak after an intestinal anastomosis. The opening of an abscess connected with chronic diverticulitis or carcinoma of the colon frequently results in a fæcal fistula. Tuberculous peritonitis, ileo-cæcal actinomycosis, amœbiasis, and regional ileitis (in this instance nearly always following operation) are also causes of fæcal fistulæ, which may be multiple. About 4 per cent. of chronic fæcal fistulæ in hospital are kept open by patients pushing in knitting needles or other articles for reasons best known to themselves.

William Henry Welch, 1850–1934. Professor of Pathology, Johns Hopkins University, Baltimore, Maryland, U.S.A.

External fæcal fistulæ can be divided into three varieties: 1. A track lined by mucous membrane which protrudes above skin level. 2. A direct track lined by granulation tissue communicating with the exterior. 3. A long, tortuous track lined by fibrous tissue and partly epithelialised. The discharge from a fistula connected with the duodenum or jejunum is bile-stained and causes severe excoriation of the skin. When the ileum or cæcum are concerned, the discharge is fluid fæcal matter; when the distal colon is involved, it is solid or semi-solid fæcal matter. In some cases, when the leak from the small intestine or cæcum is small, it may be difficult to distinguish a fæcal discharge from fæculent pus. If methylene blue is administered by mouth and a fæcal leak is present, the blue colour will be distinguished easily in the discharge a few hours later. Often the site of the leak and the length of the fistula can be determined by radiography after a barium meal or barium enema. Should this fail to demonstrate the internal orifice, injection of lipiodol into the external opening will usually give the desired information.

Treatment.—Fæcal fistulæ, especially those in connection with the small intestine, tend to heal spontaneously, provided there is no obstruction beyond the fistulous opening. The abdominal wall must be protected from erosion by the use of a disposable ileostomy bag (p. 977).

The higher the fistula in the intestinal canal the more skin excoriation must be expected. This reaches its zenith in the case of a duodenal fistula (p. 829). A sump drain (p. 923) to remove the enzyme-laden discharge is a fundamental requirement. Such fistulæ cause dehydration and hypoproteinæmia and intravenous parenteral feeding will be required. If there is no prospect of rapid healing, a feeding jejunostomy is often a life-saving measure (p. 829).

Isogel or Pulv. cretæ aromat. 4 g q.i.d. will make the fæces more solid and avoidance of eggs and fish will help to reduce the malodour.

A fæcal fistula with mucosa visibly continuous with the skin edge will never close spontaneously. In some of these cases, where the opening is a large one, the intestine tends to prolapse upon the surface.

The operative treatment for closure of a fæcal fistula consists in making an incision encircling the fistula and dissecting up the tract through the abdominal wall and the peritoneum. The base of the fistula, now free, is crushed, ligated and oversewn. The abdominal wall is then closed in layers. In the case of a colo-cutaneous fistula connected with colonic diverticulitis, if the fistula fails to heal after a few weeks, resection of the affected segment is usually advisable (p. 971). Should the mass from which the fistula arises prove to be an inoperable carcinoma, a defunctioning colostomy should be performed at a higher level. In complicated fistulæ, an operation to defunction the loop of intestine involved is probably the best procedure. When there is no obvious cause for the fistula, the discharge must be examined on several occasions for *actinomyces* or *mycobacterium tuberculosis*.

COLOSTOMY

A *colostomy* is an artificial opening made into the large bowel in order to divert fæces (and flatus) to the exterior, where they may be collected in an adhesive bag.

Depending on the purpose for which the diversion has been necessary, a colostomy may be *temporary* or *permanent*.

Temporary Colostomy

This is most commonly established to relieve a distal obstruction of the sigmoid colon either by a carcinoma or diverticulitis. Other indications include vesico-colic fistula, protection of a low colo-rectal anastomosis after anterior resection, to prevent fæcal peritonitis developing after traumatic injury to the rectum or colon, and to facilitate the operative treatment of a high fistula-in-ano.

A temporary colostomy is made by bringing a loop of bowel to the surface (' loop colostomy ') where it is held in place by a glass rod passed through the mesentery. When firm adhesion of the colostomy to the abdominal wall has taken place after 7 days, the rod can be removed. As the colostomy has been established for obstruction (or other emergency situations) it is opened immediately at the end of the operation, and the edges of the colonic incision stitched to the surrounding skin margins (fig. 1124).

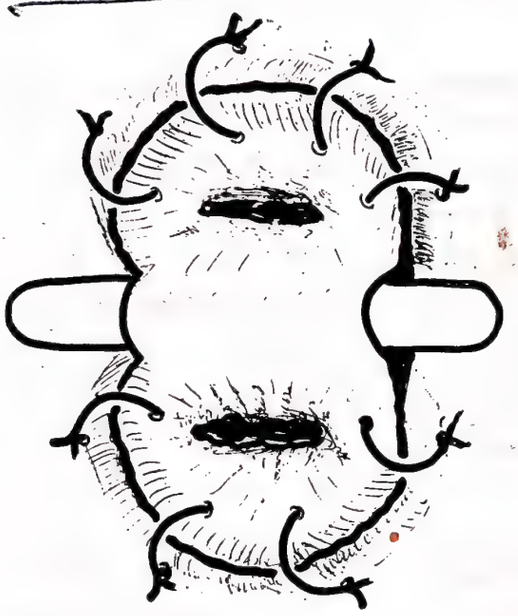

FIG. 1124.—Usual temporary loop colostomy opened over a rod, and immediate suture of colon wall to surrounding skin.

A loop of colon can be most easily brought to the surface by using large bowel that has a mesentery: most loop colostomies are therefore made in the transverse colon, and if the disease involves the left side of the colon, the right half of the transverse colon is preferred so that the entire left side is left available for any subsequent formal operation, e.g. left hemicolectomy for a carcinoma of the sigmoid colon. The sigmoid colon is also suitable for a loop colostomy.

Following surgical cure of the distal lesion for which the temporary stoma was constructed, the colostomy is closed. Colostomy closure is most easily and safely accomplished when the stoma is ' mature ', i.e. after the colostomy has been established for two months. Closure is usually performed nowadays by an *intraperitoneal* technique, as this has been shown to be safer than the *extraperitoneal* methods, and to be accompanied by fewer closure breakdowns with fæcal fistulæ.

Double-barrelled Colostomy.—This colostomy was designed to that it could be closed by crushing the intervening ' spur ' by an enterotome. It is rarely used now, but occasionally the colon is divided so that both ends can be brought separately to the surface. This ensures that *absolute* rest is given to the distal segment of the colon and rectum (Devine).

Permanent Colostomy

This is usually formed after excision of the rectum for a carcinoma by the abdomino-perineal technique.

It is formed by bringing the distal end (' end colostomy ') of the divided colon to the surface in the left iliac fossa, where it is stitched in place imme-

Sir Hugh Devine, 1878– *Surgeon, Melbourne, Australia.*

diately by sutures placed between the colonic margin and the surrounding skin.

The point at which the colon is brought to the surface must be carefully selected to allow a colostomy bag to be applied without impinging on the bony prominence of the anterior superior ilial spine. The best site is usually through the lateral edge of the rectus sheath 6 cm above and medial to the bony prominence (fig. 1125).

An important point after the colostomy has been made is to close the 'lateral space' between the intraperitoneal segment of the sigmoid colon and the peritoneum of the pelvic wall to prevent internal herniation or strangulation of loops of small bowel through the deficiency.

Colostomy bags and appliances.—Fæces from a permanent colostomy are collected in disposable adhesive bags. A wide range of such bags is currently available. An increasingly popular type employs a Karaya-gum seal (washer) that does not irritate the skin and needs to be changed less often than the regular 'stick-on' type (fig. 1126).

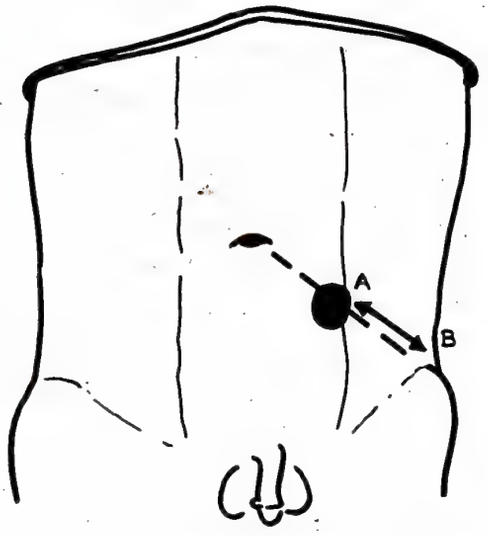

FIG. 1125.—Usual site of a permanent (end) colostomy in the left ilial fossa. Note distance A–B = 2·5 cm at least.

FIG. 1126.—The common *stick-on* bag and the alternative bag with a Karaya-gum seal (Hollister type).

In large district hospitals, stoma therapists and stoma clinics are being set up to offer advice to patients on stoma care, and to acquaint patients with the latest services.

An abdominal belt is commonly worn, but usually a light elastic 'roll-on' type rather than the heavy belts (St. Mark's pattern) previously advised.

Complications of Colostomies

The following complications can occur to *any* colostomy, but are more common after a badly performed technique:

1. *Prolapse.*
2. *Retraction.*
3. *Necrosis* of distal end.
4. *Stenosis* of the orifice.
5. *Colostomy hernia.*

6. *Bleeding* (usually from granulomas around the margin of the colostomy).
7. *Colostomy* ' *diarrhœa* ' (this is usually an infective enteritis and responds rapidly to treatment by Neomycin 1·0 g every 8 hours).

Many of these complications necessitate that the colostomy should be reformed. Often this can only be done satisfactorily by re-opening the abdomen, freeing up the colostomy which is then re-established in a fresh spot.

CÆCOSTOMY

In desperately ill patients with advanced obstruction, if the lesion is situated in the right half of the colon, a cæcostomy may have to be performed. In late cases of obstruction, the cæcum may become so distended that rupture of the cæcal wall may be anticipated. This may occur spontaneously, giving rise to faecal peritonitis or at operation when an incision in the abdominal wall reduces its supportive role and allows the viscus to expand. In such cases the over-distended viscus should be decompressed by suction as soon as the peritoneum is opened. The cæcum may then require partial mobilisation. In thin patients it may then be possible to carry out direct suture of the incised cæcal wall to the abdominal skin of the right iliac fossa. More commonly, the decompression is performed by introducing a wide bore-tube (No. 22 Foley or Winsbury-White catheter) which is stitched in place by invaginating purse-string stitches—so placed as to ' inkwell ' the site of entry.

A cæcostomy is only a short-term measure to allow a few days for the condition of the patient to improve. Re-operation should normally be carried out within 7 days of establishing the cæcostomy.

CHAPTER 48

INTESTINAL OBSTRUCTION

INTESTINAL obstruction is a common surgical emergency and because of its serious nature it demands early diagnosis and speedy relief. It may be classified into two types:

1. **Dynamic.**—Here there is increasing peristalsis working against an obstructing agent, which may be in the *lumen*, such as a bolus of incompletely digested material, inspissated fæces, or a gall stone; *in the wall*, such as an inflammatory or malignant stricture; or *outside the wall*, as in herniæ or adhesions.

2. **Adynamic** (p. 1022).—In this condition, peristalsis ceases and no true propulsive waves occur—as in paralytic ileus or mesenteric vascular occlusion.

DYNAMIC OBSTRUCTION

These are classified clinically into three types:

1. *Acute obstruction* confined to the small gut with central abdominal pain, early vomiting, central abdominal distension, and constipation.

2. *Chronic obstruction* confined to the large bowel with lower abdominal colic at first and absolute constipation and distension later.

3. *Acute-on-chronic obstruction* which spreads from the large bowel to involve the small intestine and gives early pain and constipation, followed by general distension and vomiting.

Pathology

At the outset, the intestine *above* the point of obstruction endeavours to overcome the obstruction by vigorous peristalsis. Increased peristalsis continues for a period of from forty-eight hours to several days; the more distal the point of obstruction, the longer does it remain vigorous. If the obstruction is not relieved, a time is reached when increasing distension causes peristalsis to become less and less; finally, peristalsis ceases, and the obstructed intestine becomes flaccid and paralysed.

For two or three hours following the obstruction, the intestine *below* the point of obstruction exhibits normal peristalsis, and absorption from it continues, until the residue of its contents has been passed onwards. Then the empty intestine becomes immobile, contracted, and pale, and so it remains, until the obstruction has been overcome, or death ensues.

Distension.—This occurs proximal to the obstruction, and begins immediately after the obstruction occurs. The cause of distension is two-fold:

(*a*) **Gas.**—This consists of swallowed atmospheric air (68 per cent.), diffusion from blood into the bowel lumen (22 per cent.), and the products of digestion and bacterial activity (10 per cent.). When the oxygen and carbon dioxide has been absorbed into

the blood-stream, the resultant mixture is made up of nitrogen (90 per cent.), and hydrogen sulphide.

(*b*) **Fluid.**—This is made up by the various digestive juices—about 8,000 ml. per twenty-four hours.

Above pylorus.	4,000 ml.	Saliva 1,500 ml. Gastric 2,500 ml.
Below pylorus.	4,000 ml.	Bile and pancreatic 1,000 ml. Succus entericus 3,000 ml.

In obstruction, absorption from the gut is retarded but excretion of water and electrolytes into the lumen persists and may even be increased. Deprivation of water and electrolytes, therefore, is due to:

(*a*) Vomiting.
(*b*) Defective absorption.
(*c*) Sequestration in lumen of bowel.

The severity of depletion and speed with which it becomes manifest is dependent upon the level of obstruction. It is most severe and occurs early in high small intestinal obstruction, later in ileal obstruction, and is slow to appear in colon obstruction. (For effects of fluid and electrolyte loss, see Chapter 6.)

Intestinal Toxins.—It is well known that release of intestinal obstruction may be followed by death, particularly in cases of strangulation. In unrelieved strangulation, toxic substances appear in the peritoneal cavity only when the viability of the bowel wall is affected. However, when obstruction is relieved, these toxins may pass on to the bowel where absorption can occur. It is probable that the substances involved are endotoxins of gram-negative bacilli. This factor stresses the need for intestinal decompression before and during operation.

Strangulation of the bowel occurs when it is trapped by a hernia or a band, or involved in a volvulus or intussusception in such a way that its *blood supply is progressively interfered with.* It is a very dangerous condition and demands early treatment. The first effect of strangulation is to compress the veins so as to cause the strangulated bowel, and its involved mesentery, to become blue and congested. Mesenteric vascular occlusion alone gives rise to gangrene without mechanical obstruction.

The Onset of Gangrene.—Much depends on the tightness of the constricting agent. When the venous return is completely occluded, the colour of the intestine turns from purple to black. About this time, in many instances, owing to increased œdema at the point of obstruction, the arterial supply is jeopardised. Then the peritoneal coat loses its glistening appearance, the mucous membrane becomes ulcerated, and moist gangrene is imminent.

Loss of blood volume into the congested segment is proportional to the length of that segment. When, as is often the case in strangulated external hernia, only a few inches are involved, the amount of blood thus imprisoned is inconsequential; on the other hand, when a large coil of intestine becomes strangulated the loss of blood is sufficient to render the patient oligæmic; when several feet of small intestine are involved the volume of circulating blood is so reduced as to imperil the patient's life.

Distension.—For a considerable time the strangulated segment (fig. 1127 (B)) alone distends, the greatest distension occurring when the venous return is completely obstructed while the arterial supply remains unimpaired. Unlike non-strangulating obstruction, early distension of the proximal intestine (fig. 1127 (A)) is absent; indeed, for a time varying from

a few minutes to several hours the proximal intestine contracts. After this varying interval, vigorous peristalsis occurs in the proximal segment, but is still unaccompanied by distension. By the time gangrene of the strangulated segment is imminent, retrograde thrombosis is proceeding along the related tributaries of the mesenteric vein. Distension then appears both on the proximal and distal sides of the strangulation (fig. 1127 (A) and (C)) (Chesterman).

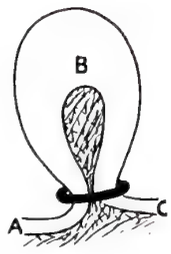

FIG. 1127.

Transmigration of Bacteria and Toxins.—When the wall of the intestine becomes partly devitalised, both bacterial toxins and the products of tissue autolysis pass into the peritoneal cavity, there to be absorbed into the circulation. This is followed by the migration of bacteria, and peritonitis follows. So it comes about that strangulation in an *external* hernia is far less dangerous than intraperitoneal strangulation, for in the former the transudate containing lethal toxins and bacteria is confined to the comparatively small absorptive area of the hernial sac.

FIG. 1128.—Carcinomatous stricture of the hepatic flexure: closed-loop obstruction.

Closed-loop obstruction is present in the majority of cases of intestinal strangulation. In its typical form it is seen in carcinomatous stricture of the colon (fig. 1128). Distally the colon is occluded by the neoplasm, while in one-third of cases the ileo-cæcal valve prevents regurgitation of the contents of the large intestine into the ileum, and consequently that part of the colon proximal to the neoplasm is closed at both ends (fig. 1128). As a result of anti-peristalsis the pressure within the cæcum becomes so high as to compress the blood-vessels within its walls. If the obstruction is unrelieved, stercoral ulceration, gangrene, and perforation of the cæcum will eventually occur.

CLINICAL FEATURES OF ACUTE INTESTINAL OBSTRUCTION

There are four important symptoms and signs: pain, vomiting, distension, and constipation. These must be carefully looked for in each case.

Acute Obstruction

1. *Abdominal pain* is the first symptom : it commences suddenly, and often without warning. It becomes increasingly severe, then passes off gradually, only to return at intervals of a few minutes. These attacks of intestinal colic, which last from three to five minutes, spread all over the abdomen, but are localised mainly at the umbilicus. In between attacks the patient is often quite free from pain. Recurring attacks of severe abdominal pain are a leading feature of all varieties of acute intestinal obstruction, with the sole exception of paralytic ileus (p. 1022).

2. *Vomiting.*—When the jejunum is mechanically obstructed, vomiting occurs with the first and each succeeding attack of pain. In the much more common obstruction of the ileum the patient may vomit once, following which there is an interval of several hours during which time the attacks of pain

Judson Tyndale Chesterman, Contemporary. Thoracic Surgeon, City General Hospital, Sheffield, England.

occur without vomiting. Ultimately copious, forcible, oft-repeated vomiting sets in. As acute intestinal obstruction progresses, the character of the vomitus alters. Initially it contains partly digested food; next it consists entirely of mucoid fluid; thereafter the vomitus becomes yellow or green from regurgitation of bile; finally, it is fæculent.

3. *Distension.*—In early cases of obstruction of the small intestine abdominal distension is often slight, or even absent. Centrally placed distension is present in fully established cases of obstruction to the ileum. *Visible peristalsis* may be present (fig. 1129). In order to observe it the abdomen must be watched for several minutes. *Borborygmi* are sometimes loud enough to be heard by the unaided ear. More often auscultation is necessary. The sound of turbulent peristalsis coinciding with an attack of colic is valuable evidence of intestinal obstruction. In all cases of suspected intestinal obstruction it is essential to *examine the common hernial sites*. An irreducible external hernia may be present although the patient is entirely unaware of it.

FIG. 1129.—Visible peristalsis. Intestinal obstruction due to the strangulated right femoral hernia, to which the arrow points.

4. *Constipation.*—In complete intestinal obstruction, after the contents of the bowel below the obstruction have been evacuated, there is constipation, and usually neither fæces nor flatus is passed, i.e. *absolute* constipation. It should be noted that there may be a natural action of the bowels after the onset of the attack, and that it is commonplace for an enema to yield a small fæcal result.

The rule that constipation is present in intestinal obstruction does not apply in cases of Richter's hernia (p. 1107), gall stone obturation (p. 1019), mesenteric vascular occlusion (p. 1021), and intestinal obstruction associated with a pelvic abscess (p. 940).

Dehydration.—Repeated vomiting and also loss of absorptive power by the distended intestine leads to dehydration, and when the patient is first examined obvious signs of dehydration—a dry skin, a dry tongue, and sunken eyes—may be present. The output of urine is small; it is concentrated, and contains little chloride.

Chronic Obstruction.—This is commonly due to carcinoma or diverticulitis of the colon. Here *constipation* appears first, may last for days or weeks and finally becomes absolute when the passage of flatus ceases. Abdominal *distension* then occurs, especially in the flanks. No matter where the obstruction lies, whether in the ascending, transverse, or descending portions of the colon or even in the rectum, the brunt of the obstruction is borne by the cæcum (fig. 1130). This has been likened to a gun back-

Blow

firing into its breech, and the cæcum becomes ballooned. *Pain* accompanies the distension and there are regular bouts of colic, usually in the hypogastrium. Soon after the onset of intestinal colic, if the abdomen is watched, the cæcum sometimes can be seen to distend with each attack of colic, and subside as the colic passes off. It is not uncommon for *vomiting* to be delayed for two or three days, and on this account signs of dehydration are exceptional. On abdominal palpation, a neoplasm occasionally can be felt in the line of the colon; but more usually the relatively small lump occasioned by a cicatrising neoplasm is obscured by the distension. A rectal examination will enable a carcinoma of the rectum, or a mass of impacted fæces, to be felt, and it may be possible to feel a neoplasm in the pelvic colon occupying the recto-vesical pouch. An enema is usually given but, in the presence of absolute obstruction, is returned without force, fæces, or flatus.

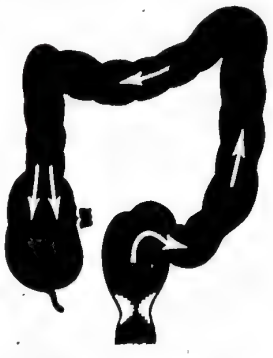

FIG. 1130.—Wherever the large intestine is obstructed the cæcum bears the brunt.

Acute-on-Chronic Obstruction.—This starts with all the features of chronic obstruction but after a few days the pain, vomiting, and central distension betoken the fact that the ileo-cæcal valve is open and fæculent fluid has passed up into the ileum where it is rapidly vomited.

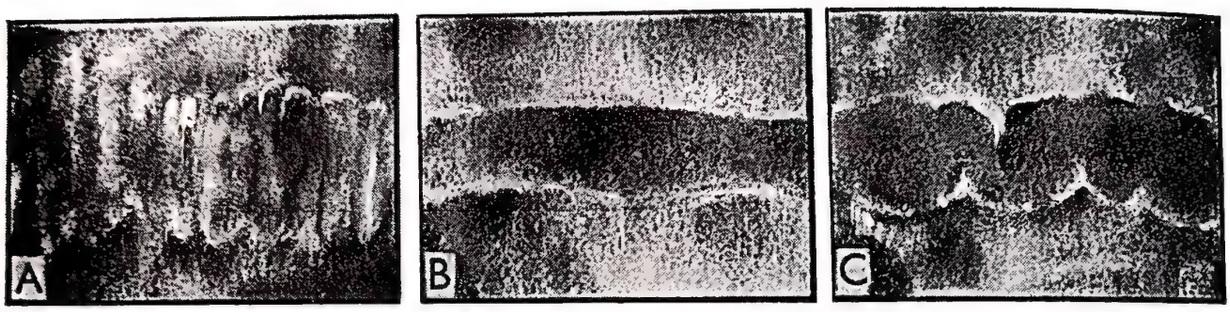
Strangulation.—It is of the highest importance to distinguish strangulating from non-strangulating intestinal obstruction, because if the former is not relieved by an urgent operation, gangrene follows quickly. The diagnosis is made entirely by clinical methods; the picture is usually that of an obstruction together with a degree of shock which is sometimes severe. In some instances the differentiation is not difficult, for when the strangulation is a tight one, unlike non-strangulating obstruction, pain is never completely absent. In strangulation, the symptoms usually commence very suddenly and spasms of intestinal colic recur three or four times a minute. Generalised tenderness and sometimes rigidity are indicative that an early laparotomy should be performed. Much more difficulty is encountered when the strangulation commences as a mild venous occlusion. In such circumstances the presence and character of local tenderness is of great significance, and frequently two or more clinical examinations at half-hourly intervals are required to collect sufficient data to make a confident diagnosis of strangulation. In non-strangulating obstruction there may be an area of localised tenderness at the site of obstruction; in strangulation there is always tenderness over an intra-abdominal strangulated coil and the pain is made worse if the palpating hand is suddenly removed. *This rebound tenderness is a distinctive sign of strangulation.* Cases of intestinal obstruction in which pain persists in spite of one, or at the most two, hours of treatment by gastro-duodenal aspiration, even in the absence of any of the above signs, should be diagnosed as intestinal strangulation. Where the strangulation occurs in an external hernia the lump is *tense, tender, irreducible,* there is *no expansile cough impulse* and it has *recently increased in size.* These points are most valuable in diagnosis.

X-RAY DIAGNOSIS

In all cases, 'scout' *films* of the abdomen, with the patient standing and lying down, must be taken in the X-ray department as soon as possible. Ideally, this should be preceded by an enema.

Gas Shadows.—When the jejunum, the ileum, or the colon is distended with gas, each has a characteristic appearance that allows it to be distinguished radiologically. The diameter of the viscus is no criterion as to whether it is small or large intestine. Obstructed small intestine is revealed by relatively straight segments that generally lie more or less transversely; obstructed large intestine is disclosed by its haustration markings; a distended cæcum is shown by a rounded gas shadow.

Jejunum is characterised by its valvulæ conniventes that pass from the antimesenteric to the mesenteric border, spaced regularly, giving rise to a concertina effect (fig. 1131 (*a*)).



(*a*) Jejunum (*b*) Ileum (*c*) Colon

FIG. 1131.—Gas shadows characteristic of various parts of the intestine.

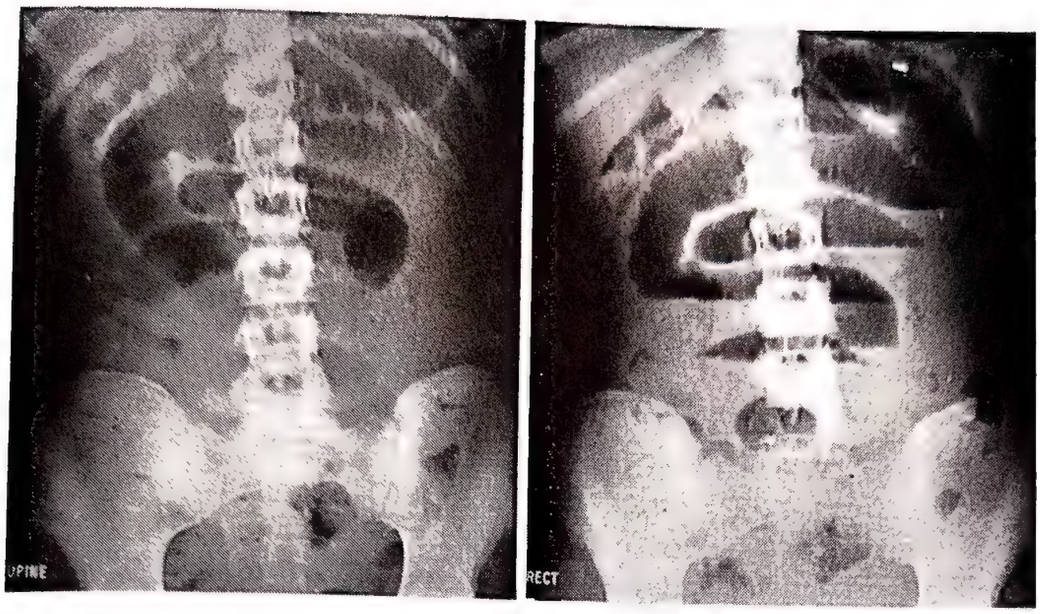
Ileum.—The distal ileum is piquantly described by Wangensteen as being 'characterless' (fig. 1131 (*b*)).

Large intestine (the cæcum excepted) shows haustral folds. Haustral folds, unlike the valvulæ conniventes, are spaced irregularly and the indentations are not placed opposite one another (fig. 1131 (*c*)).

Fluid Levels.—In infants under the age of two years a few fluid levels in the small intestine are a normal occurrence. In adults, two inconstant fluid levels must be regarded as physiological. One is at the duodenal cap; the other, which is more infrequent, is within the terminal ileum. In intestinal obstruction it takes a little time for the gas to separate from the fluid; consequently fluid levels appear later than gas shadows. When paralysis of the intestine has occurred, fluid levels become more conspicuous and more numerous. By the time fluid levels are pronounced, obstruction is advanced. The number of fluid levels is proportionate to the degree of obstruction and to its site in the small intestine; the nearer the obstruction is to the ileo-cæcal valve, the larger the number of fluid levels (fig. 1132). Obstruction *low* in the colon does not commonly give rise to fluid levels in the small intestine, but in the case of obstruction *high* in the large intestine, this phenomenon is not unusual, because in many individuals the ileo-cæcal valve is incompetent.

In obstruction of the large intestine, a plain radiograph always shows a large amount of gas in the cæcum. In most cases a barium enema is contra-indicated during an attack of intestinal obstruction.

Owen Harding Wangensteen, Contemporary. Emeritus Professor of Surgery, University of Minnesota, Minneapolis, U.S.A.



(*a*) (*b*)

FIG. 1132.—(*a*) Gas filled small bowel loops; patient supine. (*b*) Fluid levels with gas above; ' step-ladder ' pattern. Small bowel obstruction by adhesions; patient erect.

Multiple gas-filled loops and fluid levels in both small and large bowel are seen in established paralytic ileus. Here, however, bowel sounds are absent or much reduced.

TREATMENT OF ACUTE INTESTINAL OBSTRUCTION

There are three measures for combating and overcoming the effects of intestinal obstruction. They are: (1) gastro-duodenal or, when possible, gastro-intestinal suction drainage; (2) replacement and maintenance of fluid and electrolytic balance; (3) relief of the obstruction, usually by operation.

The first two are always necessary preliminaries to the relief of obstruction by operation, and they are also the mainstays of post-operative treatment. In some cases, as will be shown, they are used exclusively.

In every case of acute intestinal obstruction the first step is to empty the stomach by a transnasal aspirating tube and to keep the stomach empty by withdrawing the contents with a syringe or by continuous suction. The second step is to correct the fluid and electrolytic balance (Chapter 6). When, on clinical examination, the cause of the obstruction is not obvious, radiographs of the abdomen are taken and the clinical and radiographic data are correlated. The main indications for early operation (as soon as the fluid and electrolytic depletion has been corrected) are:

1. Obstructed or strangulated external hernia (Chapter 52).
2. Internal intestinal strangulation.
3. Acute or acute-on-chronic obstruction.

The most urgent of these is intestinal strangulation. Gastro-duodenal aspiration should be continued throughout the operation, and also in most

instances the intravenous infusion, which, in cases of strangulation, should be supplemented by blood transfusion.

Relief of Obstruction by Operation.—When the cause of the obstruction lies within the abdomen but its site is doubtful, a right lower paramedian incision is employed.

When the Obstruction lies in the Small Intestine.—The hand is passed to the cæcum. In obstruction of the small intestine the cæcum is collapsed. The site of obstruction may be obscured by dilated coils of intestine, in which event an unobstructed contracted coil of ileum is sought and followed upwards. This will guide the fingers to the site of obstruction which, if deeply placed, is exposed by displacing distended coils away from the site with warm, moist abdominal packs. Occasionally it is necessary to withdraw several coils of distended intestine before the site of obstruction can be displayed satisfactorily. Eviscerated coils must be kept covered by abdominal packs. The obstruction is relieved by one of the various methods described under special forms of intestinal obstruction.

Emptying the Intestine at Operation.—If there is much distension, it is wise to deflate the bowel using Savage's intestinal decompressor. The tube is introduced into the lumen through a stab-wound in the bowel at its most distended part. The bowel is progressively emptied by threading it over the instrument for its full length (fig. 1133). The stab-wound is closed in two layers transversely. If this, or a similar instrument, is not available, an ordinary sucker or a rubber catheter attached to a sucker is an adequate substitute. By these means closure of the abdominal wall is facilitated and intestinal toxins mostly eliminated.

FIG. 1133.—Savage's decompressor introduced into the small intestine which is plicated over it.

Measures to be taken when the small Intestine is Strangulated.—If, as is frequently the case in intra-abdominal strangulation, blood-stained fluid is present in the peritoneal cavity, the fluid should be removed by suction or mopped up as completely as possible, for it is toxic and infected. After the relief of strangulation a decision must be reached as to whether the segment that was strangulated is viable. When it is black and the peritoneal coat has lost its sheen, when the mesentery shows a lack of arterial pulsation, or thrombosis of its veins, it is non-viable, if not already gangrenous, and, if practicable, resection followed by anastomosis is carried out. In doubtful cases when the intestine is blue, purple, or dark red, the effect of wrapping it in

Paul Thwaites Savage, Contemporary. Surgeon, Whittington Hospital, London.

a warm moist abdominal pack is noted. At the same time the anæsthetist administers pure oxygen for three minutes. By these means viable is differentiated from non-viable intestine thus:

Intestine	*Viable*	*Non-viable*
Circulation	Dark colour becomes lighter; mesentery bleeds, if pricked.	Dark colour remains; no bleeding if mesentery is pricked.
Peritoneum	Shiny.	Dull and lustreless.
Intestinal musculature	Firm. Pressure rings may or may not disappear. Peristalsis may be observed.	Flabby, thin, and friable. Pressure rings persist. No peristalsis.

Special attention should always be paid to the sites of constriction (' pressure rings ') at each end of the segment, which if of doubtful viability, should be enfolded by passing sutures through the sero-muscular coats and covering the area with omentum.

Pressure rings having received attention, viable intestine is returned to the abdominal cavity and the laparotomy incision is closed. When the strangulated intestine is deemed non-viable, it is resected and the continuity of the alimentary canal restored by end-to-end anastomosis.

When the obstruction occurs in the large intestine it is usually due to a carcinoma, or occasionally, in the case of the pelvic colon, to its imitator, diverticulitis, and the obstruction is of the acute-on-chronic variety. Acute-on-chronic obstruction of the large intestine should always be treated by early operation. If the patient's condition is good, laparotomy is performed through a right or left paramedian incision, according to the site of the obstruction. If the site is unknown, a right lower paramedian incision is employed. Distension of the cæcum at once confirms that the obstruction lies in the large intestine. Palpation of the pelvic colon and, if that be collapsed, the transverse colon, will readily lead to the obstruction. When removable obstruction is present in the cæcum, ascending colon, at the hepatic flexure, or in the proximal part of the transverse colon, emergency *right hemicolectomy* (p. 992) is the correct procedure. If the growth is irremovable or the patient extremely ill, an ileo-transverse enterostomy will relieve the obstruction. If the obstruction lies at the splenic flexure, in the descending colon, the pelvic colon, or in the rectum, *transverse colostomy* is performed (fig. 1134). The obstructing growth is then removed at a second operation and the colostomy closed.

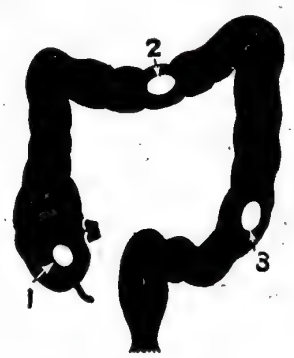


FIG. 1134.—The sites for an artificial anus in acute-on-chronic intestinal obstruction. 1. Cæcostomy. 2. Transverse colostomy. 3. Left iliac colostomy.

In very old or enfeebled patients when a carcinoma of the rectum is fixed and probably irremovable, left iliac colostomy is the best site for a permanent artificial anus.

By placing the colostomy some inches proximal to the growth and excising it together with the growth at a second-stage operation, the number of operations and the length of hospitalisation can be reduced.

Blind cæcostomy should be avoided, except in desperate cases. Modern methods of fluid replacement and anæsthesia render an expeditious laparotomy as safe as the blind procedure.

GASTRO-INTESTINAL SUCTION DRAINAGE

When intestinal strangulation can be ruled out and the obstruction lies in the small intestine, a period of a few hours' gastro-intestinal suction drainage is the best form of preliminary treatment.[1] Suction drainage should also be employed almost exclusively in paralytic ileus. In mechanical obstruction the combined effects of relieving distension by suction and the administration of fluid intravenously greatly improve the general condition of the patient for operation. Locally, diminution in size of the distended coils of intestine facilitates the operation and closure of the wound. Another most important consideration is that if highly toxic intestinal contents are aspirated before operation, it spares the patient the danger of absorbing this material after the obstruction has been relieved.

Maintenance of Fluid and Electrolytic Balance.—The fluid and the salt loss must be restored. Commonly as much as 3·5 litres of normal saline solution are required if the patient shows signs of severe dehydration, but considerably less if such signs are absent. A balance chart must be compiled, and the daily needs of the patient adjusted (p. 93).

ACUTE INTESTINAL OBSTRUCTION OF THE NEWBORN

Congenital atresia[2] **and stenosis**[3] are the most common causes of intestinal obstruction in the newborn. The site of the obstruction is as follows:

Duodenum	33 per cent.
Jejunum	15 ,,
Ileum	25 ,,
Ascending colon	10 ,,
Multiple sites	17 ,,

The high incidence of multiple sites makes it imperative to examine the whole of the small intestine and the ascending colon at operation. Congenital abnormalities of the heart and great vessels are frequently associated with these lesions; only atresia below the duodenum escapes this association. Ileal atresia is commonly due to a vascular accident *in utero*.

Atresia and Stenosis of the Duodenum.—Atresia and stenosis occur with about equal frequency. Unless the obstruction is partial, persistent vomiting occurs from birth. The vomitus may or may not be bile-stained, depending on whether the septum lies below or above the duodenal papilla. Distension is often absent, but visible peristalsis is sometimes seen passing from left to right.

[1] Even when strangulation can be ruled out, not more than six or eight hours should be expended in this form of treatment. If operation is delayed over twenty-four hours, in spite of suction drainage, the mortality is nearly doubled.

[2] Atresia = imperforation. [3] Stenosis = narrowing.

FIG. 1135.—Duodenal atresia. 'Double-stomach' appearance on erect film. Gas and fluid levels in both stomach and duodenum.

Radiography.—A plain film often confirms the diagnosis. The stomach and upper part of the duodenum are grossly distended with air, the so-called 'double stomach' (fig. 1135).

In cases of partial obstruction a small amount of gastrografin injected through a gastric aspiration tube is useful for demonstrating the location of the obstruction; as soon as the films have been exposed, the medium must be aspirated.

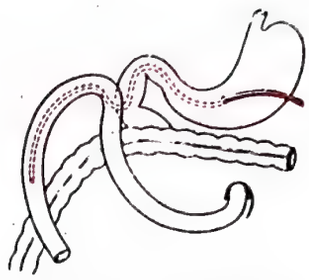

FIG. 1136.—Duodeno-jejunostomy with gastrostomy for feeding below the anastomosis. (*After the late G. H. McNab, F.R.C.S., London.*)

Differential Diagnosis.—Suprapapillary duodenal atresia is distinguished from œsophageal atresia (p. 761) by the fact that there is no dribbling of saliva. The absence of a palpable lump serves to differentiate duodenal obstruction from infantile pyloric stenosis (p. 788). Duodenal obstruction in infancy can also be caused by volvulus of the midgut (p. 1010), obstruction due to a band (p. 1017), or to an annular pancreas (p. 909).

Treatment.—Operation should be carried out as soon as dehydration has been combated. Duodeno-jejunostomy (fig. 1136) is the operation of choice. After completing the anastomosis, a stab incision is made through the wall of the pyloric antrum. Through this incision a rubber catheter is passed, and its tip guided through the anastomosis. A Witzel's valvular opening is constructed in the wall of the stomach and the tube is brought out through the laparotomy incision.

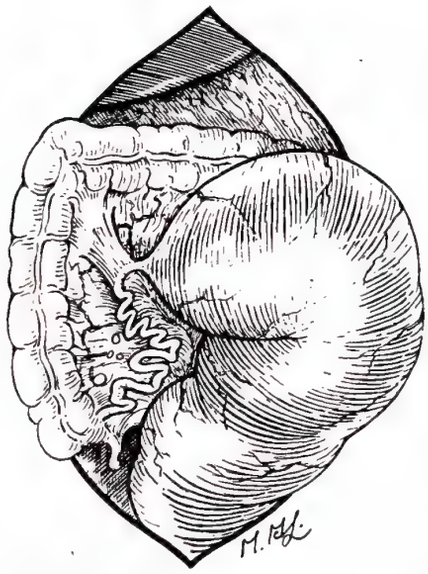

FIG. 1137.—Congenital atresia of the ileum. (*V. Swain, F.R.C.S., London.*)

Atresia or Stenosis of the Ileum (less frequently of the jejunum).—The overriding importance of very early diagnosis of this condition lies in the fact that the distension immediately above the septum soon becomes so great that the vascular supply of the intestinal wall becomes jeopardised, and gangrene and perforation result. In atresia of the ileum (fig. 1137) the infant is either born with central distension of the abdomen, or distension appears within twenty-four hours of birth. In jejunal atresia early distension is lacking, but vomiting soon occurs. In both conditions some meconium is likely to be evacuated.

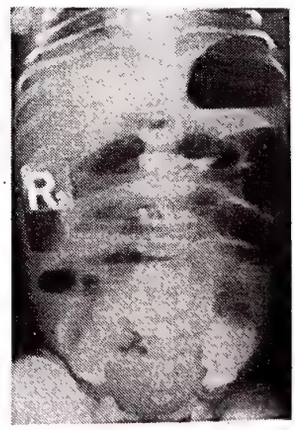

FIG. 1138.—Plain radiograph in a case of congenital atresia of the ileum. (*Professor J. H. Louw, Cape Town.*)

Radiography.—Obstruction of the small intestine cannot be diagnosed by plain X-rays unless fluid levels are seen in addition to the distended coils (fig. 1138). By the time fluid levels are present, the obstruction is in an advanced state.

Treatment.—In the case of the ileum a satisfactory procedure is a Paul-Mikulicz anastomosis (fig. 1139). After the abdomen has been closed, and the wound protected with a dressing, a small Paul's tube is tied into the proximal and a small catheter into the distal limb of the spur. Four days later the tubes are removed and a crushing clamp is applied to the septum. When the stenosis lies in the jejunum, so devastating are the effects of even a temporary jejunal fistula that primary end-to-end anastomosis (fig. 1140), although a more difficult operation, must be recommended.

Friedrich Oskar Witzel, 1856–1925. Surgeon, Bonn, Germany.
Frank Thomas Paul, 1851–1941. Surgeon, Liverpool Royal Infirmary, Liverpool, England.
Johann von Mikulicz-Radecki, 1850–1905. Professor of Surgery, Breslau, Germany (now Wroclaw, Poland).

Arrested Rotation.—The cæcum remains in the left hypochondrium, and a peritoneal band is found running from the cæcum to the right side of the abdomen, and then across the second part of the duodenum. This is the transduodenal band of Ladd (fig. 1141). The symptoms (repeated vomiting), due to pressure on the duodenum, and the radiographic appearances are identical with those of duodenal stenosis.

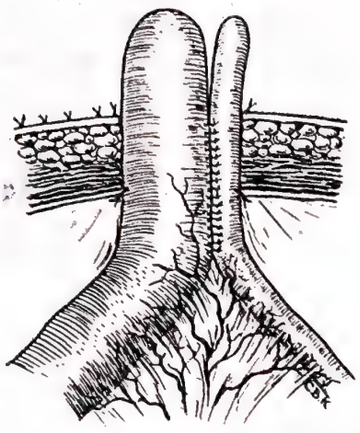

FIG. 1139.—Spur enterostomy for ileal atresia. (*After the late G. H. McNab, F.R.C.S., London.*)

Treatment.—Early laparotomy is essential. The pressure on the duodenum can be relieved immediately by dividing the attachment of the band near the parietal peritoneum. Often there is a second peritoneal band, extending from the middle line to the commencement of the jejunum; this also must be divided. The cæcum and colon are brushed over to the *left* side of the abdomen, leaving the small bowel on the right side (Nixon). The abdomen is closed. The results of timely operation in these cases are excellent.

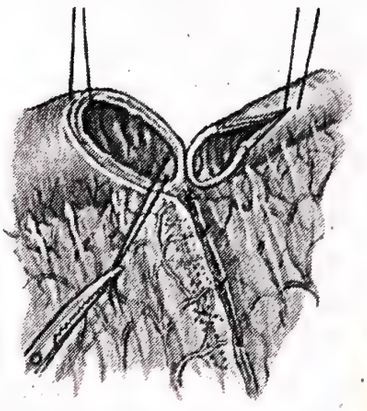

FIG. 1140.—End-to-end anastomosis. (*After the late Sir Denis Browne, F.R.C.S., London.*)

Volvulus of the Midgut (*syn.* Volvulus Neonatorum).—Arrested rotation described above, predisposes to volvulus of the midgut. The floating cæcum, together with the whole of the small intestine, which has a narrow attachment, revolves. Broadly speaking, the clinical features are similar to, and the radiological findings are identical with, those of arrested rotation which, indeed, is present. The onset, however, is more catastrophic, and dehydration occurs more rapidly than in arrested rotation *per se*. In addition, abdominal distension is often evident.

Treatment.—When the abdomen is opened, only distended coils of small intestine (which may or may not be cyanotic) and the stomach are seen. The whole of the mid-gut must be delivered on to the surface, where the intestine is protected with warm, moist abdominal packs. Only after this step has been taken is it possible to see the volvulus (fig. 1142) which usually takes place in a clockwise direction. Untwisting is only half the operation; of equal importance is to divide the second obstructive lesion—the transduodenal band of Ladd—which is often present.

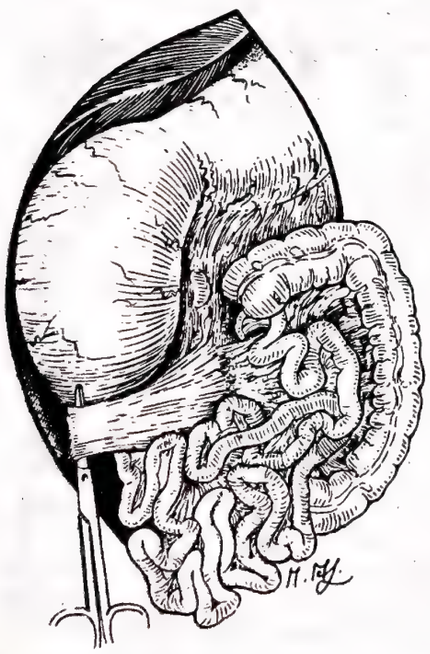

FIG. 1141.—Incomplete rotation of the cæcum and Ladd's transduodenal band compressing the duodenum. (*V. Swain, F.R.C.S., London.*)

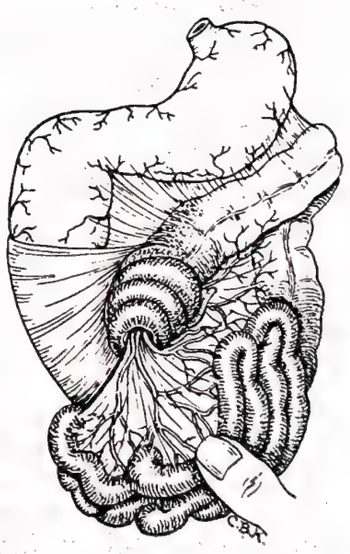

FIG. 1142.—Volvulus of the midgut.

Meconium ileus is the neonatal manifestation of mucoviscidosis (fibrocystic disease of the pancreas, p. 910). The terminal ileum becomes filled with meconium mixed with viscid mucus, notably from the pancreas, and during the latter months of fœtal life this mixture becomes progressively inspissated (fig. 1143). The infant is born with intestinal obstruction. At times the coil filled with inspissated meconium can be felt as a rubbery mass. A typical radiograph shows distended small intestine, some of which is mottled. Unlike ileal atresia, there is no abrupt termination of the gas-filled intestine.

Pathognomonic Test.—Into a bowl of vomitus is placed a piece of exposed X-ray

William Edwards Ladd, 1880–1967. Professor of Child Surgery, Harvard University, Boston, Massachusetts, U.S.A.

Harold Homewood Nixon, Contemporary. Surgeon, Hospital for Sick Children, Great Ormond Street, London.

film, and there it is left for half an hour. If trypsin is present, the gelatine that constitutes the sensitised coat of the film will be digested. In meconium ileus the film is merely rendered a little soft.

40% of cases are associated with complications, either volvulus neonatorum, atresia or meconium peritonitis (Dickson). When the physical signs of an acute intra-abdominal process are present, laparotomy must be carried out. When this is not so, however, a Gastrografin or Hypaque enema should be given to make the diagnosis. Since the colon is much reduced in size the radio-opaque fluid passes easily upwards to the ileum, and may on occasion disperse the obstructing meconium and relieve the condition.

Treatment.—For laparotomy, adequate pre-operative preparation is essential. The only condition with which meconium ileus can be confounded is Hirschsprung's disease (p. 961) affecting the whole colon, but in the latter condition (*b*) and (*c*) of fig. 1143 are lacking. The method of loosening the tenacious meconium from the mucous membrane by injections of 1% hydrogen peroxide through the bowel wall is not as satisfactory as believed previously. Recourse has to be made to a definitive resection of the most dilated segment. The proximal ileum is anastomosed end-to-side of collapsed colon beyond the obstruction (the Bishop-Koop operation). The distal ileal opening is formed into an ileostomy, through which the thick meconium can be eased postoperatively, assisted by irrigation of suitable lubricant solutions. The ileostomy becomes a mucous fistula which may need to be closed later.

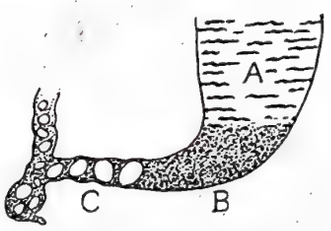

FIG. 1143.—Operative findings in meconium ileus : (*a*) Treacly fluid ; (*b*) Putty-like material ; (*c*) Meconium pellets.

Post-operative Complications.—In the section dealing with fibrocystic disease of the pancreas (p. 910), attention has been directed to the susceptibility of infants with mucoviscidosis to pulmonary complications. Oxygen and antibiotic therapy, in addition to the usual post-operative regimen for intestinal obstruction, are given.

ACUTE INTUSSUSCEPTION

One portion of the gut becomes invaginated into another immediately adjacent; almost always it is the proximal into the distal. Very rarely indeed is an intussusception retrograde.

Ætiology.—In a few cases there is some obvious cause, e.g. a polypus,

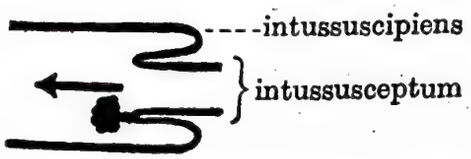

FIG. 1144.—The mechanism of the production of an intussusception.

a papilliferous carcinoma, a submucous lipoma, or an inverted Meckel's diverticulum (p. 967). Obviously such a protrusion invites intussusception (fig. 1144). In intussusception of infants it is generally agreed that:

1. Idiopathic intussusception occurs most often between the sixth and ninth months.
2. There is a change in diet—the infant is weaned.
3. An idiopathic intussusception usually commences in some part of the last 50 cm. of the small intestine.
4. The maximum aggregation of Peyer's patches is in the lower ileum.

Theory—1. Change of diet brings about a change of intestinal flora. 2. This predisposes to inflammation of the intestinal tract. 3. Which in turn causes inflammation and swelling of Peyer's patches. 4. A swollen Peyer's patch produces an elevation protruding into the lumen of the gut comparable to one of the known causes of intussusception.

Another theory:—Intussusception often shows a seasonal incidence related to attacks of upper respiratory infection. After an operation for intussusception antibodies to

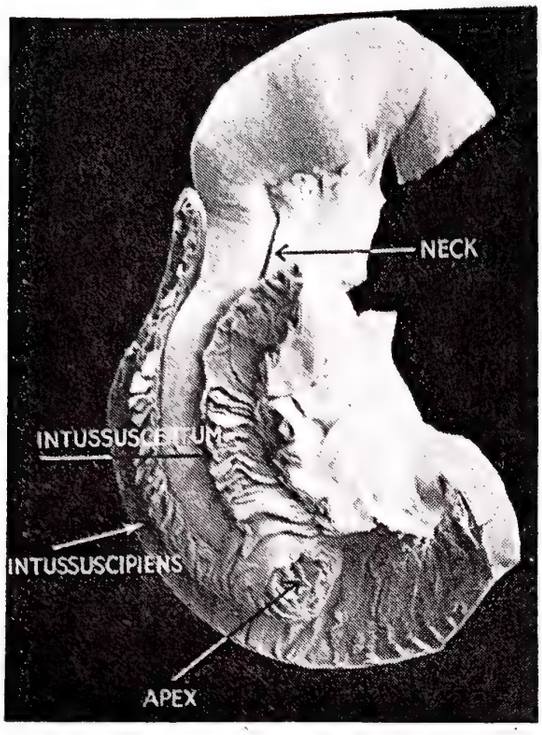

FIG. 1145. — An intussusception dissected to show its constituent parts.

certain viruses have been isolated and it is presumed that these cause swelling of Peyer's patches.

Pathology.—An intussusception is composed of three parts:

1. The entering, or inner, tube.
2. The returning, or middle, tube.
3. The sheath, or outer, tube.

The outer tube is called the *intussuscipiens*, The inner and middle tubes together form the *intussusceptum*. The neck is the junction of the entering layer with the mass. That part which advances is the apex, and the mass which constitutes the intussusception (fig. 1145) increases as it advances.

The blood supply of the inner layers of the intussusception is liable to be impaired. The onset of early gangrene is dependent upon the tightness of the invagination. Because of the great pressure exerted upon it by passing through the ileo-cæcal valve, an ileo-colic intussusception provides most examples of early gangrene.

Types of Intussusception (After Gross)

(*In 702 cases*)	% *of Series*
Ileo-ileal	5
Ileo-colic	77
Ileo-ileo-colic	12
Colo-colic	2
Multiple	1
Retrograde	0·2
Others	2·8

A definite cause was found at operation in only 43 cases

Clinical Features of Intussusception in Infants.—Usually the patient is a fine, lusty male child between six and nine months of age. The onset is sudden. The child has a paroxysm of abdominal pain, draws up his legs, and screams. He may vomit shortly after the onset of the attack, but this is not a constant occurrence; not until the intussusception has been present for about twenty-four hours is vomiting a conspicuous feature. The attacks, which last a few minutes and recur about every fifteen minutes, are accompanied by *facial pallor*. They become progressively more severe. In between the attacks he lies listless and looks somewhat drawn. In the early stages a normal stool is frequently passed; later blood and mucus are evacuated—the well-known ' red-currant jelly ' stool.

On Examination.—The abdomen is not distended. It should be palpated, between the spasms, with a warm hand slipped beneath the bedclothes, care being taken not to arouse the dozing infant. Typically a lump is felt

Robert Edward Gross, Contemporary. Ladd Professor of Children's Surgery, Harvard University Medical School, Boston, Massachusetts, U.S.A.

which may harden on palpation (fig. 1146), but if the lump is lying under the right or left costal margins, it may not be possible to feel it, even under an anæsthetic. There is said to be a feeling of emptiness in the right iliac fossa. On rectal examination, if the intussusception has travelled far enough, its apex, a conical mass which is aptly likened to the cervix uteri, will be felt,

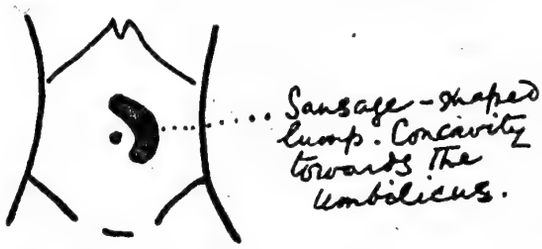

FIG. 1146.—The physical signs recorded in a typical case of intussusception in an infant.

especially on bimanual examination. In the large majority of cases the intussusception has not advanced far enough for the apex to be felt per rectum, but in most cases blood-stained mucus will be found on the examining finger.

In a few instances the intussusception actually protrudes through the anus. This does not necessarily imply that the intussusception is of long standing, but rather that the patient is possessed of a long mesentery, rendering the small intestine unduly mobile.

FIG. 1147.—Barium enema showing ileo-colic intussusception.

Unrelieved, the pain becomes continuous. After twenty-four to thirty-six hours the abdomen commences to distend, and vomiting becomes copious. Absolute intestinal obstruction follows, and death from this cause, or from peritonitis secondary to the gangrene, is probable. Once in a while a natural cure occurs due to sloughing of the intussusceptum.

Radiography.—Plain films of the abdomen usually reveal increased gas shadows in the small intestine, and at times an absence of the cæcal gas shadow. Radiography following a barium enema (fig. 1147) gives positive evidence of the presence of an ileo-colic intussusception, but if the intussusception is ileo-ileal, and the ileo-cæcal valve is competent, this form of examination is negative.

Differential Diagnosis

1. *From Acute Entero-colitis.*—Unlike intussusception, diarrhœa is a leading symptom. As in intussusception, abdominal pain and vomiting often occur; likewise blood and mucus may be passed, but in entero-colitis fæcal matter or bile is always present in the stools.
2. *From Purpura with Intestinal Symptoms* (*syn.* Henoch's Purpura).—There is likely to be the characteristic rash, which might be mistaken for flea-bites. Intussusception is a not uncommon accompaniment of this form of purpura, consequently the differential diagnosis is not of vital importance, for exploratory laparotomy must be performed in suspicious cases.
3. *From Prolapse of the Rectum.*—This can be eliminated readily. In prolapse the projecting mucosa can be felt continuous with the perianal skin. In intussusception protruding from the anus, the finger passes indefinitely into the depths of a sulcus (figs. 1222 and 1223).

Intussusception in adolescence is nearly always caused by an inverted Meckel's diverticulum (p. 967).

Eduard Heinrich Henoch, 1820–1910. Professor of Diseases of Children, Berlin.

Intussusception in adults is most often due to a papilliferous carcinoma; consequently, the colo-colic type is frequent. Rarer causes are a papilloma or a submucous lipoma. Idiopathic intussusception is extremely uncommon, except in Egypt immediately after the Mohammedan fasting seasons (Mooro).

Preliminary Treatment.—If necessary, the general condition of the patient is improved by the administration of dextrose-saline solution. Especially in cases of more than twelve hours' duration, gastric aspiration should be carried out and continued during and after the operation.

Reduction by Hydrostatic Pressure.—In early cases, Australasian surgeons[1] in particular favour reduction by hydrostatic pressure. In the operating theatre an unlubricated catheter is passed into the rectum of the anæsthetised infant. The catheter is connected to the tubing of a reservoir filled with saline solution, and elevated to the height of 1 metre. The solution is allowed to run into the bowel for four minutes, while the buttocks are pressed together to prevent escape of the fluid. The catheter is then removed, and the fluid is allowed to escape into a bowl. Several such injections are made. After the first injection the fluid returned is blood-stained; subsequently, if reduction of the intussusception is effected, flatus and fæcal matter are passed. If there is the *slightest* doubt as to whether the intussusception has been reduced completely, laparotomy is performed but, as a result of the hydrostatic pressure, in most instances the intussusception is so reduced in size, and is so near its place of origin, that a grid-iron incision in the right iliac fossa is all that is necessary. Scandinavian surgeons favour the use of a barium enema to accomplish the reduction (fig. 1147). The more usual method of treatment is to proceed with the operation, without resorting to these preliminary measures.

Operative Reduction.—The abdomen is opened through a right lower paramedian incision. The first part of the reduction is accomplished by squeezing the lowest part of the sausage-like mass, if possible without exteriorising the bowel, and little by little the intussusception is reduced (fig. 1148). The last part of the intussusception is the most difficult to reduce and should be withdrawn and gently compressed in a warm, saline-soaked pack, to lessen the œdema. In the majority of instances reduction is completed easily by squeezing the apex of the intussusception, as shown in fig. 1149. After reduction is completed, the terminal portion of small intestine, the caput cæci, and the appendix will be seen reddened and stiffened with œdema.

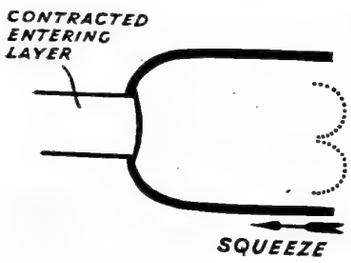

FIG. 1148.—Diagram showing the method of reducing an intussusception.

Owing to earlier diagnosis, the number of irreducible intussusceptions is decreasing; and the mortality is correspondingly lower.

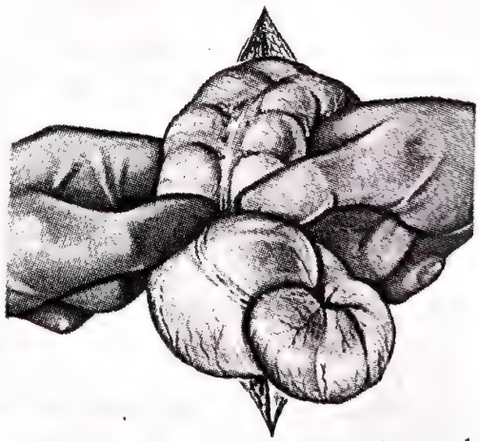

FIG. 1149.—Reducing the terminal part of the intussusception. (*After R. E. Gross.*)

Methods of effecting Reduction in Difficult Cases

1. The little finger is inserted into the neck of the intussusception and an endeavour is made to separate adhesions between the intussuscipiens and intussusceptum, after which reduction is re-attempted (Cope's method).

[1] Intussusception is common in the urban districts of Australia.

Abdel Mooro, Contemporary. Professor of Surgery, Cairo, Egypt.
Sir Zachary Cope, 1881–1975. Surgeon, St. Mary's Hospital, London.

2. The thumb and forefinger are placed as shown in fig. 1149, and gentle pressure is exerted. Gradually the pressure is increased. In this way œdema is squeezed from the region of the ileo-cæcal valve.

Resection of an Irreducible or Gangrenous Intussusception.—Previous methods consisted of exteriorising the ileum and colon by various manœuvres. With exact methods of electrolyte balance and of fluid replacement, these have been abandoned and resection with end-to-end anastomosis is the rule.

After-treatment.—When reduction is effected easily, gastric aspiration should be continued for twelve to twenty-four hours and dextrose-saline administered intravenously, or subcutaneously with hyaluronidase. In infants, nepenthe one drop (0·06 ml.) is given by mouth every three or four hours for three doses. On the second day the gastric tube is removed and sips of water are given. A few hours later, feeding is commenced with the mother's milk if the infant is breast-fed. In cases where resection has been necessary, intravenous alimentation is required.

Recurrent intussusception occurs in only 2 per cent. of cases of idiopathic intussusception. If a second operation is necessary, the last few inches of the ileum should be anchored to the ascending colon by sutures in order to avoid still further recurrence.

VOLVULUS

A volvulus results from axial rotation of a portion of the alimentary tract.

(*a*) **Volvulus Neonatorum** (p. 1010).

(*b*) **Volvulus of the small intestine,** other than the above, usually occurs in the lower ileum, and is favoured by the presence of an adhesion passing from the antimesenteric border of an intestinal loop (fig. 1150) to the parietes or to the female pelvic organs. In Africans, volvulus involving many feet of small intestine without causative adhesions occurs rather commonly. The consumption of a large meal of maize and vegetables seems to predispose to the condition.

FIG. 1150.

Treatment is to untwist the loop, if possible. A causative adhesion should be divided and the stump of its intestinal attachment buried in the intestinal wall by a purse-string suture.

(*c*) **Volvulus of the cæcum** occurs occasionally, especially when the right half of the colon is lax and mobile. Volvulus of this part of the large intestine occurs nearly always in a clockwise direction. The first twist obstructs the ascending colon; if a second twist occurs, it obstructs the ileum also. The highest incidence is between twenty-five and thirty years of age. The symptoms are those of acute obstruction of the small intestine. In about 25 per cent. of cases there is a palpable tympanitic swelling not, as a rule, in the right iliac fossa, for in process of torsion the mobile cæcum moves out of the right iliac fossa into the mid-abdomen, or even to the left side. A plain radiograph shows loops of gas-filled ileum, and sometimes an especially large gas shadow which can be recognised as the cæcum. At first, the obstruction is not absolute; fæces and flatus may be expelled after an enema, but unless spontaneous untwisting occurs, the attacks of intestinal colic continue.

Treatment.—Laparotomy is performed, and in early cases it is usually possible to untwist the bowel. Sometimes before untwisting can be accomplished, it is necessary to deflate the ballooned cæcum by the insertion of a needle. Untwisting should be followed by cæcostomy, which serves two purposes—it relieves distension and it fixes the organ to the abdominal wall, thereby preventing a recurrence. If the cæcum is gangrenous or its viability is not assured, right hemicolectomy (p. 992) is carried out.

(*d*) **Volvulus of the pelvic colon** is common in Eastern Europe, India, Scandi-

navia, and Peru. The predisposing causes are indicated in fig. 1149. The loop may rotate half a turn, in which event spontaneous rectification sometimes occurs. After the loop has rotated 1½ turns the veins involved in the torsion are compressed, and the loop becomes greatly congested. If, as is sometimes the case, it rotates more than 1½ turns, the blood supply is cut off entirely and the loop becomes gangrenous. The rotation nearly always occurs in an *anti-clockwise* direction.

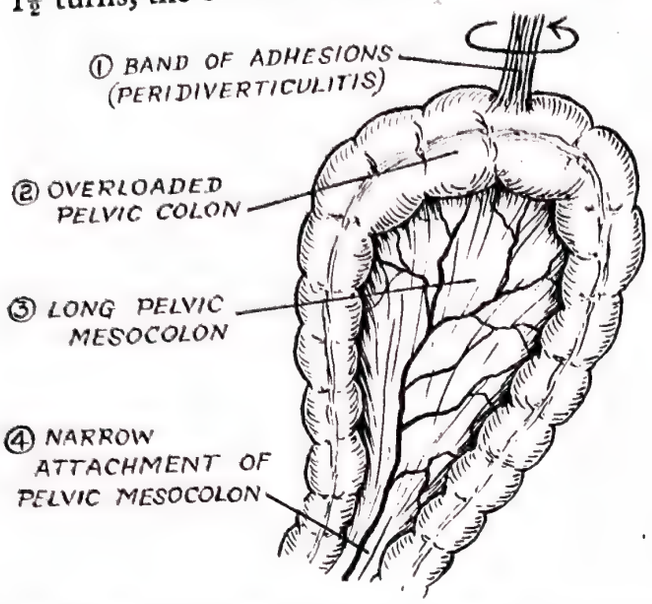

FIG. 1151.—The predisposing causes of volvulus of the sigmoid colon.

Clinical Features.—Males are more commonly affected than females, and the sufferers are usually middle-aged or elderly. There is often a history of acute attacks of left-sided abdominal pain, probably due to a partial volvulus, that untwists itself and is followed by the passage of large quantities of flatus and fæces. As a rule the onset of volvulus of the pelvic colon is sudden and is characterised by severe abdominal pain, often coming on while the patient is straining at stool. Abdominal distension soon follows; in no other condition does extreme abdominal distension, partly due to the diffusion of CO_2 from distended veins, occur so quickly. If the patient is examined two or three hours after the commencement of the attack, the distension is mainly left-sided. In a matter of six hours the whole abdomen becomes distended. Hiccough and retching occur early; vomiting is late. Constipation is absolute, but an enema may be returned blood stained. A plain X-ray film of the abdomen shows massive distension of the colon with gas.

Treatment.—Sigmoidoscopy should be carried out and when the obstruction is reached an attempt is made to coax a soft rectal tube into the twisted gut. This will immediately deflate the gut and operation can be delayed for a few days until the patient is more fit. If deflation does not succeed, laparotomy must be performed immediately. An attempt is made to untwist the gas-filled viscus (fig. 1151);

(*a*) (*b*)

FIG. 1152.—Volvulus of the sigmoid colon (*a*) before and (*b*) after untwisting.
(*S. U. Rahman, F.R.C.S., Manchester.*)

meanwhile a rectal tube is passed by a nurse and guided into position by the surgeon with his hand inside the abdomen. When the colon is deflated, a resection and end-to-end anastomosis can be carried out. Some surgeons prefer to exteriorise and resect the volvulus by the Paul-Mikulicz procedure. This method is specially valuable if there is any suggestion of impending gangrene. Redundancy of the colon makes the performance of this procedure simple (fig. 1153).

OBSTRUCTION BY ADHESIONS AND BANDS

By Adhesions

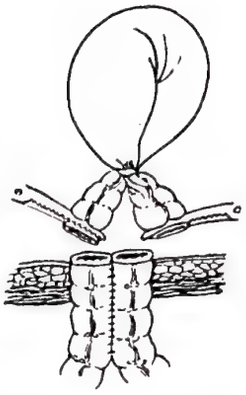

FIG. 1153.—The Paul-Mikulicz operation applied to volvulus of the pelvic colon.

Peritoneal irritation from whatever cause results in local outpouring of fibrin which produces adhesions between apposed peritoneal surfaces. The fibrinous adhesions may disappear when the source of irritation is removed, or they may become vascularised and be replaced by mature fibrous tissue.

Many studies have been made to determine the factors that cause adhesions. Infection is a potent but variable cause. Foreign materials—particularly talc, silk thread, barium sulphate and asbestos—stimulate granuloma formation resulting in fibrous adhesions. Trauma, vascular occlusion—and particularly venous occlusion—generate adhesions.

Numerous substances have been instilled into the peritoneal cavity in the hope of preventing adhesion formation. Hyaluronidase, hydrocortisone, silicone, fibrinolysin, Dextran, polyvinylpyrrolidine (PVP), chondroitin, and streptomycin solutions have all been tried. No single substance has been demonstrated to be completely effective and safe in clinical use.

Type 1.—Post-operative *fibrinous* (' bread and butter ') adhesions are unlikely to produce complete intestinal obstruction unless paralytic ileus is also present. This type of obstruction commences between the third and sixth post-operative days. After some months fibrinous adhesions completely disappear.

Type 2.—Post-operative *fibrous* adhesions are strong bands and occur at a site where an abdominal organ is deficient of blood supply and becomes adherent to the omentum or parietal peritoneum in order to gain an additional blood supply. They can give rise to intestinal obstruction at any time after an abdominal operation.

Type 3.—Adherence of a loop of intestine to an inflamed intraperitoneal structure, e.g. a tuberculous mesenteric lymph node (fig. 1072). The adhesive area occurs at the site of previous granulation tissue.

Type 4 follows chemical irritation from materials such as talc glove powder entering the peritoneal cavity by accident, or sulphonamide or penicillin placed there by design.

Post-operative adhesions giving rise to intestinal obstruction usually involve the lower ileum. Operations for acute appendicitis and gynæcological procedures are the most common precursors of this condition and demand early re-operation.

Treatment.—Gastro-intestinal suction drainage, combined with intravenous fluid therapy, is extremely beneficial; occasionally it is curative, but only in *Type* 1. On this account especial vigilance is necessary, for strangulation, if not present initially, is liable to develop during the course of such treatment. When, as is usually the case, operation is required, although many adhesions are often present, frequently only one of them is found to be the cause of the obstruction, in which case the condition can easily be remedied by dividing this adhesion. At other times the intestine is angulated by adherence to the parietes, to the mesentery, to another coil of

FIG. 1154.—Adhesions causing intestinal obstruction by angulation.

intestine (fig. 1154) or, in the female, to the uterus or adnexa. In these circumstances it is sometimes possible to free the obstructed intestine by dissection. In order to prevent recurrence the bare areas should be covered with omental grafts.

In *Type* 1 the adhesions can usually be separated with a finger, thereby releasing the obstruction. When adhesions are widespread and the small intestine so matted that a definite point of obstruction cannot be found, it may be best to do a Noble plication (p. 1024).

By a Band

A band (usually one band only is culpable) is occasionally the cause of acute obstruction to the small intestine. Such a band may be:

(*a*) Congenital: often an obliterated vitello-intestinal duct (p. 1099).

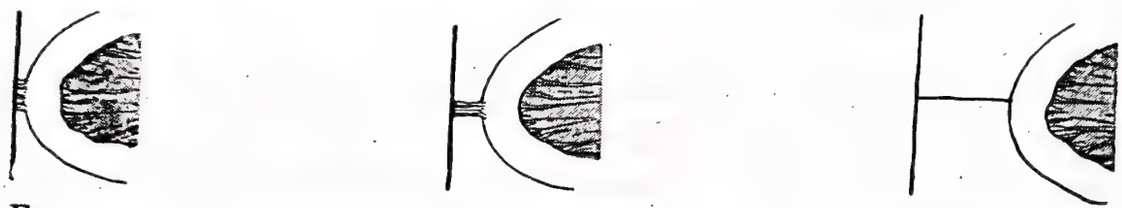

FIG. 1155.—Metamorphosis of an inflammatory peritoneal band from an adhesion.

(*b*) A string-like, frequently thin and fragile, band (fig. 1155) following previous bacterial peritonitis.

(*c*) A portion of greater omentum, adherent usually to the parietes, constitutes an obstructing band of relative stoutness (fig. 1156).

FIG. 1156.—Intestinal obstruction occurring under a portion of greater omentum adherent to the parietal peritoneum.

Treatment.—Provided the involved intestine is viable, division of the band and release of the obstructed loop is the simplest and one of the most satisfactory operations in surgery. Entrapment of a coil of small intestine beneath a string-like band is notorious for producing early gangrene. Even when the imprisoned intestine, after release, regains its pristine hue, if the narrow areas that have suffered direct compression by the band show any colour changes, they should be invaginated. Gangrenous intestine must be resected.

OBSTRUCTION DUE TO AN INTERNAL HERNIA

A portion of the small intestine passes into one of the retroperitoneal fossæ or into a congenital defect of one of the mesenteries, there to be imprisoned. The potential internal herniæ are as follows:

1. * **The Foramen of Winslow.**—The portal vein, common bile duct, and hepatic artery lie in its free border.
2. * **A Hole in the Mesentery.**
3. **A Hole in the Transverse Mesocolon.**
4. **A Defect in the Broad Ligament.**
5. **Congenital or Acquired Diaphragmatic Hernia** (p. 727).

* vide infra p. 1019.

Jacob Benignus Winslow, 1669–1760. Professor of Anatomy, Physic and Surgery, Paris.

6. **One of the retroperitoneal fossæ,** of which the following are most important:

Fossæ about the Duodenum

(*a*) * *The Left Paraduodenal Fossa.*—The inferior mesenteric vein lies in its free border.

(*b*) * *The Right Duodeno-jejunal Fossa.*—The superior mesenteric artery runs in its free border.

Fossæ about the Cæcum and Appendix (fig. 1157).

(*a*) *Superior Ileo-cæcal Fossa.*—Between the general mesentery and a fold of peritoneum raised by the anterior cæcal branch of the ileo-colic artery.

(*b*) *Inferior Ileo-cæcal Fossa.*—Between the 'bloodless' fold of Treves and the mesentery of the appendix.

(*c*) *The retro-cæcal fossa* behind the cæcum.

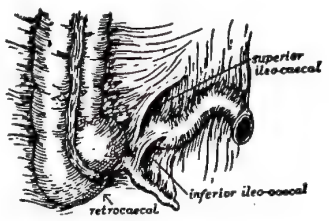

FIG. 1157.—Peritoneal fossæ around the cæcum and appendix.

The intersigmoid fossa is situated in the base of the pelvic mesocolon.

The supravesical fossa is bounded by the median and lateral umbilical folds (obliterated urachus and umbilical arteries). A loss of weight with coincident loss of prevesical fat deepens the fossa.

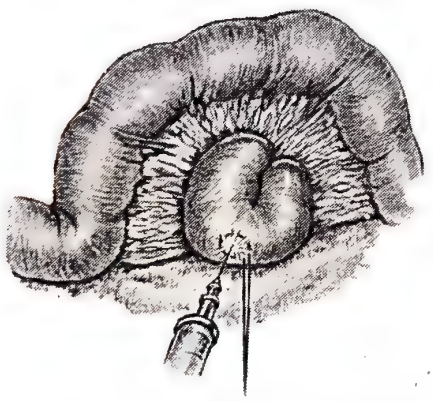

FIG. 1158.—Strangulation through a hole in the mesentery. Deflating the obstructed coil before attempting reduction.

An internal hernia is an uncommon cause of intestinal obstruction; a pre-operative diagnosis can be only a guess.

Treatment.—In those internal herniæ marked with a * an important blood-vessel runs in the edge of the hernial orifice, and to divide the constricting agent (which is the correct treatment for the other varieties) may cause serious bleeding. When confronted with the difficult problem of how to release imprisoned intestine without dividing the constricting agent, the reader is referred to fig. 1158.

OBSTRUCTION FROM STRICTURE OF THE SMALL INTESTINE

Cicatricial contracture is usually an aftermath of tuberculous ulceration or Crohn's disease (p. 980). Multiple strictures are usually present. Malignant stricture is rare, although both carcinoma and sarcoma occur from time to time (p. 985). Gradual contraction of a stricture causes a chronic obstruction of the small intestine with dilatation and hypertrophy of the intestinal wall. Clinically there is some colic and distension, associated with the features of the blind-loop syndrome (p. 965), i.e. steatorrhœa, loss of weight, anæmia, avitaminosis, and cachexia.

Treatment.—Except in emergency, a simple stricture should never be by-passed by a lateral anastomosis. A blind-loop syndrome is sure to follow. A simple stricture should be excised locally, and a malignant stricture widely, and the continuity of the intestine restored by end-to-end anastomosis.

OBSTRUCTION BY OBTURATION OF THE SMALL INTESTINE

Obstruction by a gall-stone[1] usually occurs in elderly obese women because the gall-stone, which is 2·5 cm or more in diameter, requires some years to reach this dimension, and more years elapse before it ulcerates through the gall-bladder into the duodenum. It passes down the small

[1] Formerly called gall-stone 'ileus'. Ileus, from ιλεος (Greek) = colic.

Sir Frederick Treves, 1853–1923. Surgeon, The London Hospital.

intestine, and becomes impacted about 60 cm from the ileo-cæcal valve (fig. 1159), because this is the narrowest part of the small gut. The symptoms are elusive. The patient has recurrent mild colic, accompanied by copious vomiting. As the obstruction is incomplete, there is often some result from an enema, and remissions of symptoms are frequent, but the vomiting returns, and by this time it is bilious; as time goes on it becomes fæculent. Occasionally a radiograph demonstrates the calculus within the small intestine. In any event, the small intestine will be seen to be distended with gas. There is no abdominal distension until late, and late intestinal obstruction in an old person is an almost hopeless condition. On rare occasions a large gall-stone ulcerates through the fundus of the gall bladder into the transverse colon, and from time to time it remains in the large intestine long enough to increase in size, by the deposition of fæcal matter upon it, so that eventually it becomes impacted in the rectum.

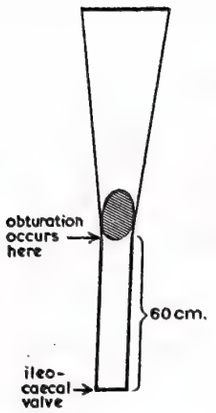

FIG. 1159.—Site of impaction of gall-stone.

Treatment.—Through a lower right paramedian incision the loop containing the stone is delivered and packed off most carefully. Occasionally, it is possible to crush the stone between the fingers while it is still in the lumen. If not, the intestine is opened and the stone removed. It is an advantage to sew up the incision in the intestine transversely, to avoid constriction. A gall-stone that causes intestinal obstruction is nearly always barrel-shaped and unfaceted (fig. 1160). If there is a facet, it is essential to palpate the intestine above the obstruction for a possible fellow-calculus. The area of the gall bladder should be left strictly alone, as even gentle manipulation can break down a cholecyst-duodenal fistula.

FIG. 1160. — Gall-stone removed from the lower end of the ileum.

Bolus obstruction is particularly liable to occur after partial gastrectomy (p. 825), when insufficiently masticated articles of food will be hurried into the small intestine where they become impacted at the narrowest portion of the intestine, i.e. about 60 cm (fig. 1159) from the ileo-cæcal valve. Normally they would be retained in the stomach until they had become partially digested. Brussels sprouts, dried fruit, and, particularly, unmasticated orange pulp have caused intestinal obstruction in these circumstances.

Treatment.—Timely laparotomy is required. An attempt should be made to squeeze the bolus gently onward into the cæcum, and there to break it up by kneading. Should the bolus be impacted so firmly that this manœuvre proves impracticable—and such is likely only in cases of obstruction by dried fruit or when a stricture of the small intestine is present—enterotomy must be performed. After the obstructing material has been removed the opening in the intestine is sutured, the coil mechanically cleansed before returning it to the abdomen, which is then closed.

Obstruction by stercolith gives rise to symptoms identical with those of obstruction by a gall-stone, for a stercolith, contrary to what might be expected, is usually formed and found in the small intestine, particularly in cases where a jejunal diverticulum or a stricture in the ileum is present. On careful dissection of a stercolith it is not unusual to find a nucleus of recognisable material, e.g. tomato skins.

Obstruction due to Worms.—An aggregation of *ascaris lumbricoides* is sometimes the cause of low small intestinal obstruction in children, usually under ten years of age, and especially those living in or near the tropics. There is debility out of proportion to that produced by the obstruction. The obturation is inclined to follow the ingestion of an anti-helminthic. If it is not known that the patient is suffering from ascaris infestation, a worm in the vomitus or the presence of eosinophilia may be the means of making a correct pre-operative diagnosis. In this form of intestinal obstruction laparotomy must be performed, and if possible the tangled mass should be kneaded along the ileum into the cæcum.

EMBOLISM AND THROMBOSIS OF THE MESENTERIC VESSELS

Arterial embolism is more common than spontaneous thrombosis, and the superior mesenteric vessels are implicated far more frequently than the inferior; the latter is often silent due to a better collateral circulation.

Embolism of the Superior Mesenteric Artery.—The embolus is derived from a vegetation on the mitral valve, the left auricular appendage (especially in mitral stenosis), an atheromatous plaque arising from the aorta, or from a pyæmic infarct of the lung which has led to thrombosis of the pulmonary vein.

Primary thrombosis of the superior mesenteric artery is the result either of arteriosclerosis or thrombo-angiitis obliterans.

Primary thrombosis of the superior mesenteric veins occurs occasionally in portal hypertension and in pyelephlebitis.

No matter whether the occlusion is arterial or venous, hæmorrhagic infarction occurs although, in the case of embolism, a short-lived pallor has been observed at early laparotomy. The intestine and its mesentery become swollen and œdematous, demarcation between infarcted and healthy intestine being gradual. Blood-stained fluid is exuded into the peritoneal cavity and the lumen of the infarcted intestine becomes filled with blood. When the main trunk of the superior mesenteric artery becomes occluded, infarction of nearly the whole of the small intestine, the cæcum, and part of the ascending colon occurs (fig. 1161). More frequently a branch of the main vessel is implicated and the area of infarction is proportionately less.

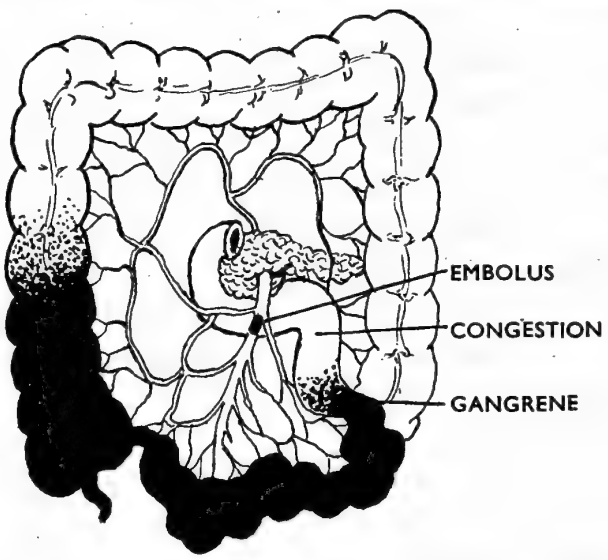

FIG. 1161.—Embolus lodged in the main trunk of the superior mesenteric artery. Showing the widespread gangrene that results.

Clinical Features.—The most important clue in early diagnosis (so essential to success) is continuous severe midline abdominal pain in a patient with auricular fibrillation or atherosclerosis.

Repeated vomiting and persisting *pain* ushers in this catastrophe.

Facial pallor and a fall in systolic pressure resembles an internal hæmorrhage; indeed, the volume of blood lost to the circulation *is* a serious internal hæmorrhage.

Abdominal rigidity is a late sign, and is absent in early cases.

Rebound tenderness may be present. In late cases the patient passes blood, often decomposed, per rectum. On X-ray, gas is usually completely absent from the small intestine. When it is known that the patient is suffering from one of the conditions that predispose to mesenteric thrombosis and embolism, the correct diagnosis is not difficult.

Treatment.—In the early case, when the diagnosis has been confirmed at laparotomy, superior mesenteric embolectomy should be attempted. In the later cases the affected bowel should be resected. In all cases, blood transfusion is required and anti-coagulant treatment should be commenced twelve to twenty-four hours after operation.

In patients who recover, intestinal obstruction is liable to occur later from fibrosis of an area of small intestine.

Infarction of the large intestine is rare. Lodgment of an embolus in the middle colic artery should be treated by resection of the transverse colon with exteriorisation of both ends. If the patient survives and is deemed fit for a further operation, the bowel ends can be joined; otherwise the colostomy must be permanent.

Mesenteric vascular occlusion carries a higher mortality than any other type of intestinal obstruction. This is not surprising when one considers the type of patient prone to this disaster.

Ischæmic Colitis is the term given to describe the structural changes in the colon as a result of deprivation of blood. Such episodes are similar to those in the heart or brain and occur specially in the region of the splenic flexure whose blood supply is particularly precarious. They are classified into gangrenous (see above) stricturing and transient forms (Marston). The presenting syndrome is lower abdominal pain of abrupt onset, vomiting, fever and the passage of bright red blood per rectum. The

FIG. 1162.—Ischæmic colitis—site of lesion in a woman of 67 with six months' rectal bleeding; occasional colicky pain and vomiting. Lesion resected with recovery. (*Adrian Marston, F.R.C.S., London.*)

age is that expected in degenerative vascular disease and at operation the length of colon has the appearance of a hæmorrhagic infarct which may require immediate resection. In the cases where no operation is performed, a stricture may appear on a barium enema as a tubular narrowing over several inches of bowel most often in the region of the splenic flexure. The differential diagnosis is from carcinoma, Crohn's disease (p. 980) and ulcerative colitis. An aortogram is usually conclusive.

PARALYTIC ILEUS (*syn.* ADYNAMIC OBSTRUCTION)

This has already been defined as a state in which the intestine fails to transmit peristaltic waves, and is due to failure in the neuromuscular mechanism—i.e. in the myenteric plexus (Auerbach) and the submucous plexus (Meissner). This results in a collection of fluid and gas in the intestine, with resulting distension, vomiting, absent or high 'tinkling' bowel sounds, and failure to pass flatus.

The following varieties are recognised:

1. *Post-operative.*—Some degree of ileus, either local or general, may follow any abdominal operation. In the absence of infection, it is not serious. Indeed, it has been shown that intestinal motility and absorption commonly returns to normal in about sixteen hours—well ahead of gastric and colonic activity. Post-operative ileus may be prolonged if there is hypoproteinæmia, or latent renal failure (*vide infra*), or if gastrointestinal suction is continued beyond the point at which effective bowel sounds have returned.

2. *Infective.*—Peritonitis gives rise to prolonged ileus, but several factors may be involved. At the outset, peristalsis ceases as a normal response to prevent dissemination, but afterwards, bacterial toxins prevent the normal activity of the nerve plexuses. When the bowel begins to recover, the early, feeble peristaltic waves may not be able to overcome the obstructive effect of the newly formed slender adhesions between loops of intestines, and so further quiescence of activity follows. In this kind of ileus, there are therefore mechanical as well as neurogenic factors to be considered.

Jeffrey Adrian Priestley Marston, Contemporary. Surgeon, Middlesex Hospital, London.
Leopold Auerbach, 1828–1897. Professor of Neuropathology, Breslau, Germany (now Wroclaw, Poland).
Georg Meissner, 1829–1905. Professor of Physiology, Göttingen, Germany.

3. *Reflex.*—This form of ileus may occur following fractures of the spine or ribs, retroperitoneal hæmorrhage, or even the application of a plaster jacket.

4. *Uræmia.*—This type, with distension, vomiting, and hiccoughs is well recognised, and is seen in renal failure. It may follow prostatectomy.

5. *Hypokalæmia.*—A low serum potassium may cause ileus.

Clinical Features.—Ileus is suspected if, 48 hours after laparotomy:

(*a*) There has been no passage of flatus.

(*b*) There is no return of normal bowel sounds on auscultation.

Abdominal distension becomes more marked and drum-like (tympanitic); in the absence of gastric aspiration, there is effortless vomiting of large volumes of dirty fluid. There is no colic, and often no abdominal pain at all. There may be respiratory distress from the abdominal distension and the pulse-rate increases. Prolonged distension increases the risk of wound dehiscence. Radiologically, the abdomen shows gas-filled loops of intestine with multiple fluid levels.

It is important to recognise three types of bowel sounds:

(1) The *normal* low-pitched borborygmi each lasting about a second and occurring every twenty seconds or so.

(2) The prolonged, rapidly recurring and noisy borborygmi of *dynamic obstruction.*

(3) The high-pitched tinkling note 'like bells at evening pealing', which occurs every ten to thirty seconds, and is distinctive of *paralytic ileus.* It is due, not to peristalsis, but to the overflow of fluid from one distended loop to another.

Management.—The essence of this is prevention and the incidence has been greatly reduced by routine naso-gastric suction and withholding fluids by mouth after laparotomy until normal bowel sounds and/or the passage of flatus returns. Further, electrolyte balance should be achieved before, and maintained after operation. Specific treatment is directed to the cause, but there are some principles which have general application:

(1) The primary cause must be removed.

(2) Normal bowel activity will return if distension is relieved by adequate gastro-intestinal decompression. It is probably the distension of the gut (possibly exacerbated by the air swallowing of anxiety), that causes the ileus, rather than the ileus that causes the distension. Thorough decompression is therefore essential (p. 1006). If a post-operative indwelling gastric tube is used, it must not be spigoted but be kept open to permit swallowed air to be evacuated.

(3) Morphine or pethidine in repeated small doses are well proved and valuable sedatives in these cases.

(4) Close attention to the fluid and electrolyte balance, especially the serum potassium and the blood urea, is essential (Chapter 6).

(5) Peristaltic stimulants have no place in treatment. The object is to *rest* the bowel, not to stimulate it, i.e. don't flog a tired horse!

Measurement of abdominal girth at the umbilicus is the only way of being certain of increase or decrease of distension. This should be done four- or six-hourly. As recovery occurs, segmentation returns before peristalsis. This may cause 'wind pains', but is soon followed by the passage of flatus.

Resolution is often accompanied by a short period of diarrhœa. No treatment is necessary for this.

If paralytic ileus is prolonged and threatens life, laparotomy should be carried out and the bowel decompressed with a Savage's sucker (p. 1006).

RECURRENT ATTACKS OF ACUTE INTESTINAL OBSTRUCTION

Recurrent attacks of intestinal obstruction due to adhesions are usually the aftermath of peritonitis. The difficult problem of preventing further trouble, where the patient has had repeated attacks of intestinal obstruction due to adhesions necessitating operation, can be relieved by a plication operation.

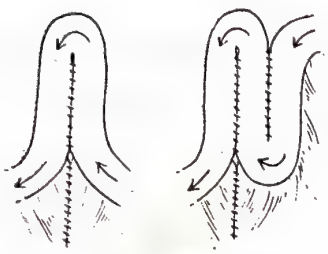

FIG. 1163.—Noble's plication operation.

Noble's plication operation (fig. 1163) is useful though time-consuming. After the abdomen has been opened by an adequate incision, all involved intestine is freed by dissection, which may include the whole of the small bowel. Adjacent coils (average length 15 to 20 cm) are sutured together along their mesenteric borders. If only a portion of the small intestine is plicated, the resulting folds of mesentery must be united to prevent internal herniæ. This accomplished, the abdomen is closed. This operation has been criticized recently and is certainly no panacea.

CHRONIC INTESTINAL OBSTRUCTION

The various abnormalities and diseases giving rise to chronic intestinal obstruction are described in Chapters 47 and 50. There remains one condition to be considered here.

Fæcal impaction in the rectum and the colon occurs principally in elderly, and often bed-ridden, patients. It is all too often overlooked, in which case the patient suffers unnecessary distress.

The symptoms are those of chronic intestinal obstruction, and attacks of spurious diarrhœa are a common accompaniment. A fæcal accumulation may form a palpable abdominal mass which can be indented. When the mass is situated in the rectum, it can be indented by the palpating finger.

Treatment.—Enemas are usually insufficient. Repeated bowel washouts and the use of various proprietary fæcal plasticisers (e.g. Dioctyl) by mouth or by enema, may result in disimpaction. Otherwise the anal sphincter must be dilated under general anæsthesia and the mass removed with the aid of fingers and tablespoon.

Thomas Benjamin Noble, 1895–1958. Surgeon, Community Hospital, Indianapolis, Indiana, U.S.A.

CHAPTER 49

THE VERMIFORM APPENDIX

SURGICAL ANATOMY

THE vermiform appendix is present only in man, certain anthropoid apes, and the wombat.[1] Morphologically, it is the undeveloped distal end of the large cæcum found in many lower animals. It is true that many herbivores are provided with a wide-lumened cæcal diverticulum in which bacteriolytic breakdown of cellulose takes place. However, the walls of this diverticulum lack the heavy deposition of lymphoid tissue that characterises the *vermiform* appendix (Last).

The appendix varies considerably in length and circumference. The average length is between 7·5 and 10 cm. Specimens of over 30 cm. in length have been recorded. The appendix averages 0·5 cm. longer in the male than in the female. The lumen, which should admit a matchstick, is irregular, being encroached upon by the multiple longitudinal folds of mucous membrane.

From without inwards, the structure of the appendix is as follows. There is a peritoneal coat which completely invests it, except along the narrow line of attachment of the mesoappendix. The muscular coat resembles that of the small intestine. There is a well-developed submucous coat containing, especially in childhood and youth, a large number of lymphoid follicles. The mucous membrane resembles that of the large intestine, but there are fewer crypts of Lieberkühn.

The **mesoappendix** which springs from the lower surface of the mesentery is subject to great variations. Sometimes as much as the distal one-third of the appendix is bereft of mesoappendix. Especially in childhood, the mesoappendix is so transparent that the contained blood-vessels can be seen. In many adults it becomes laden with fat, which obscures these vessels.

The **appendicular artery**, a branch of the lower division of the ileo-colic artery, passes behind the terminal ileum to enter the mesoappendix a short distance from the base of the appendix. It then comes to lie in the free border of the mesoappendix; but for a variable distance from the tip, where the mesoappendix is lacking, the artery lies directly on the muscle wall beneath the peritoneal coat. **An accessory appendicular artery** may be present (fig. 1164).

The appendicular vein is a radicle of the ileo-colic vein, which drains into the portal system.

Lymphatic Vessels.—Four, six, or more lymphatic channels traverse the mesoappendix to empty into the ileo-cæcal lymph nodes.

McBurney's point lies at the junction of the lateral third with the medial two-thirds of a line joining the anterior superior iliac spine and the umbilicus (fig. 1165). McBurney's point is the classical site of greatest tenderness in appendicitis, and also a most useful point to have in mind when a grid-iron incision is made.

Inconstancy of Position.—The relative frequency of the more usual positions occupied by the organ is depicted in fig. 1166. In addition, the appendix must necessarily share in abnormalities in position of the cæcum. The most frequent of these is failure of the cæcum to descend, which results in the base of the appendix being situated in the right hypochondrium. Very occasionally the cæcum and

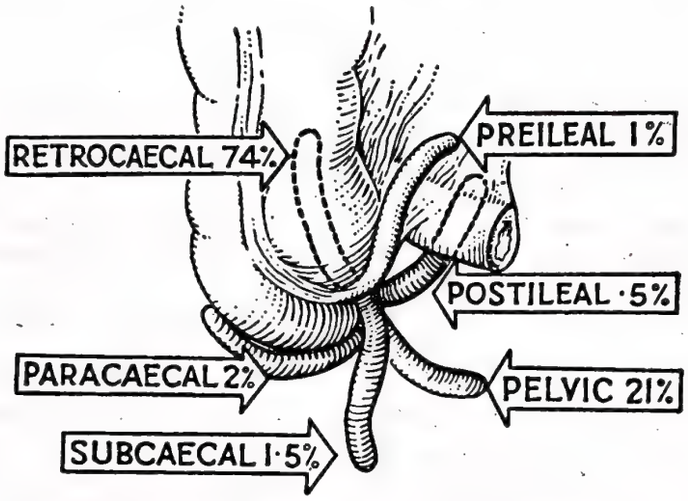

FIG. 1166.—The various positions of the appendix. (*After Sir Cecil Wakeley London, formerly P.R.C.S.*)

appendix are situated in the left iliac fossa or in the left hypochondrium (see below).

Locating the Appendix.—The traditional method consists of following one of the tæniæ coli downwards till the appendix is reached. If the organ is still not visible and it is certain that it has not been removed, it will probably be found adherent to posterior cæcal wall.

CONGENITAL ABNORMALITIES

Agenesis.—Once in 100,000 persons the vermiform appendix is absent; possibly some of these are congenital, but most are due to sloughing of an appendix that had intussuscepted previously (p. 1044).

Duplication.—A few cases of double appendix have been reported; in some instances one of the twin appendices has been found acutely inflamed and the other uninvolved.

Left-sided Appendix.—*Situs inversus viscerum*, a congenital abnormality where there is complete transposition of thoracic and abdominal viscera, occurs once in 35,000 individuals, and is more common in males. In such cases, of course, the vermiform appendix is situated on the left as it is also in some cases of non-rotation of the mid-gut (fig. 1167).

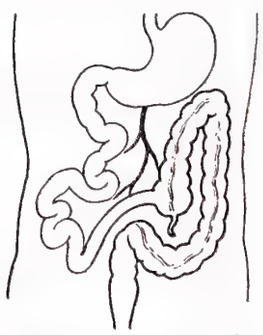

FIG. 1167.—Left-sided caecum and appendix due to incomplete intestinal rotation. (*After Findlay and Humphreys.*)

ACUTE APPENDICITIS

During recent years the mortality from acute appendicitis has been falling. Earlier diagnosis and appendicectomy while the inflammation is still confined to the appendix, the recognition by the general public that it is dangerous to take or give to a child a purgative in the presence of undiagnosed abdominal

pain, more discrimination in performing immediate appendicectomy in late cases, a greater appreciation of the importance of accurate fluid and electrolytic balance, better anæsthesia, and the control of infection by antibiotics have all played a part in bringing about this improvement. Nevertheless, hospital statistics[1] show that in cases where the inflammation is no longer limited to the appendix, the mortality rate is 5 per cent. in males and 6 per cent in females. In men over sixty-five, the mortality may be as much as 25 per cent. owing to the general effects of arteriosclerosis.

All are agreed that early diagnosis with prompt appendicectomy is the goal. On the other hand, some patients fail to seek medical advice until a late hour. In such cases there must be no rule of thumb, and when to operate and when not to operate becomes a matter of refined judgment. If the attack has been present for some days, the patient's condition is satisfactory and if there is a lump, it is often wise to adopt the delayed treatment (p. 1039).

Ætiology

Until the close of the nineteenth century appendicitis remained unrecognised. Unquestionably, before this time it was a comparatively rare disease, but there can be no doubt that it existed even in remote times, for an acutely inflamed, perforated appendix was found preserved in the mummy of a young royal princess of Egypt (Spencer).

The riddle of appendicitis—its actual cause and its meteoric rise from an insignificant disease to the most common serious intra-abdominal inflammatory affection of Western civilised races—has been a matter for much speculation. So far no satisfactory explanation has been forthcoming. The following ætiological factors are important, but for the most part they are purely contributory.

Race and Diet.—Appendicitis is particularly common in the highly civilised European, American, and Australasian countries, while it is rare in Asiatics, Africans, and Polynesians. Rendle Short showed that if individuals from the latter races migrate to the countries where appendicitis is common, they soon acquire the local susceptibility to the disease. Even apes in captivity appear to acquire the human liability to appendicitis. These significant facts satisfy many that the rise of appendicitis amongst the highly civilised is due to departure from a simple diet rich in cellulose to one relatively rich in meat. But this cannot be the whole explanation, for acute appendicitis occurs in lifelong vegetarians and even in babes at the breast.

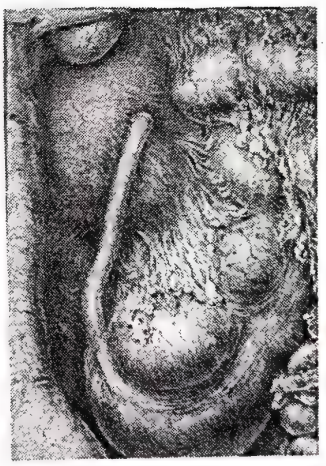

FIG. 1168.—Long retrocæcal appendix. This type tends to be familial.

Social Status.—In England, acute appendicitis is more common among the upper and middle classes than in those belonging to the so-called working class. Thus the mortality from acute appendicitis is about 20 per cent. higher in men of social classes I and II (professional and managerial workers) than it is in social class V (unskilled labourers) (Registrar-General, 1954).

Familial Susceptibility.—That there is sometimes a familial tendency to the disease cannot be disputed. This generally accepted fact can be accounted for by an hereditary abnormality in position of the organ, which predisposes to infection. Thus the whole family may have long retrocæcal appendices (fig. 1168) with comparatively poor blood supply, and many of its members fall victims to appendicitis in one form or another.

Obstruction of the Lumen of the Appendix.—When an acutely inflamed

[1] Statistics from the Social Medical Research Unit of the Medical Research Council, The London Hospital, 1957.

Arthur Morgan Spencer, Contemporary. Formerly Medical Superintendent, Powick Hospital, nr. Worcester, England.
Arthur Rendle Short, 1880–1953. Professor of Surgery, Bristol, England.

appendix has been removed, some form of obstruction to its lumen can be demonstrated in a large percentage of cases. The obstructing agent is usually a fæcolith or a stricture; exceptionally, a foreign body or a round worm or thread-worms are found.

FIG. 1169.—Fæcoliths. X-ray of an appendix after removal.

Fæcoliths (fig. 1169) vary in size and have a laminated structure. They are composed of inspissated fæcal material, calcium and magnesium phosphates and carbonates, bacteria and epithelial debris; rarely, a foreign body is incorporated in the mass. The presence of a fæcolith or fæcoliths postulates some form of appendicular stasis.

Worms. — Worms (fig. 1170) and other intestinal parasites can injure the appendicular mucous membrane and occasionally block its lumen.

FIG. 1170.—An appendix filled with oxyuria vermicularis.

The Abuse of Purgatives.—It is abundantly clear that the ingestion of purgatives, particularly castor oil, by patients with 'stomach ache', and the violent peristaltic action which results, favours, and often determines, perforation of an inflamed appendix. 'Purgation means perforation' is a wise adage.

Epidemic Form.—From time to time acute appendicitis occurs as an epidemic. In this instance the infection is streptococcal, and the portal of entry almost certainly the naso-pharynx.

Bacteriology

There is no one organism mainly responsible for appendicitis. Cultures from inflamed appendices usually reveal that the infection is mixed and there is hardly a pyogenic organism which has not been isolated from such specimens. The most common organisms present are a mixture of *Esch. coli* (found in 85 per cent. of cases), enterococci (30 per cent.), non-hæmolytic streptococci, anaerobic[1] streptococci, together with *Cl. welchii* (30 per cent.) and bacteroides (p. 936). Sometimes there is synergistic action among these organisms that renders each species more pathogenic than it would be in pure culture. In most instances the infecting organisms are normal inhabitants of the lumen of the appendix.

Pathology

The menace of acute appendicitis lies in the frequency with which the peritoneal cavity is infected from this focus:

1. By perforation.
2. By transmigration of bacteria through the appendicular wall.

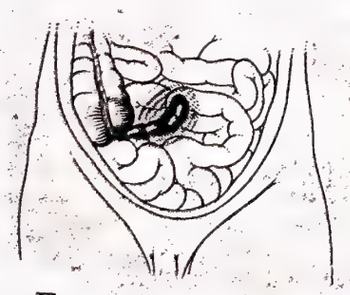

FIG. 1171.—When an inflamed appendix lies amidst coils of small intestine the risk of peritonitis is high.

The greater omentum, the 'abdominal policeman', attempts to arrest the spread of peritoneal invasion, whilst violent peristalsis from ingested purgatives tends to spread it. Obviously, if the inflamed appendix lies dangling amidst coils of small intestine (fig. 1171), the threat of peritonitis is increased; should early perforation occur, diffusing peritonitis is inevitable.

It is of great importance to recognise two types of acute appendicitis.

(*a*) **Non-obstructive Acute Appendicitis.**—The inflammation usually

[1] The foul odour of exudates connected with appendicitis with perforation is caused by anaerobic streptococci or anaerobic bacilli, and not by *Esch. coli*, as is so commonly believed.

commences in the mucous membrane; less often in the lymph follicles. Like any inflammatory process, it terminates in one of the following ways: (1) Resolution; (2) Ulceration; (3) Suppuration; (4) Fibrosis; (5) Gangrene. All grades of inflammation occur and once infection reaches the loose submucous tissues it progresses rapidly. The organ becomes turgid, dusky red, and hæmorrhages occur into the mucous membrane. The vascular supply of the distal part of the appendix is often in jeopardy because it is intramural and liable to occlusion by inflammation or thrombosis. This may lead to gangrene of the tip. Non-obstructive appendicitis may progress sufficiently slowly for protective adhesions to form, and the resulting peritonitis is localised. In many instances the infection never progresses beyond the mucous lining (i.e. catarrhal inflammation) but although the attack passes off, it is unlikely that a *status quo ante* is ever regained. Because the tip suffers most, fibrosis usually occurs therein and this is a classical finding in recurrent appendicitis (fig. 1185).

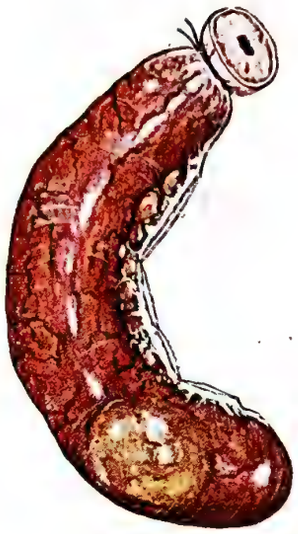

FIG. 1172.—Acute appendicitis. Perforation imminent.

(*b*) **Obstructive Acute Appendicitis.**—About one-third of cases of acute appendicitis belong to this group. The obstruction can be in the lumen (fæcolith, foreign body, or parasites); in the wall (almost invariably inflammatory, but exceptionally by a carcinoma of the cæcum); outside the wall (adhesions and kinking). Of these, much the most common is a fæcolith. On occasions the appendix becomes strangulated in an inguinal or femoral hernia. A kink is unlikely to cause complete obstruction.

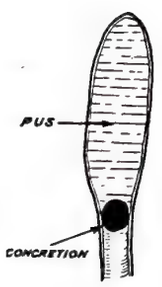

FIG. 1173.—Acute obstructive appendicitis.

In obstructive appendicitis the products of inflammation become pent up (fig. 1173) so that the inflammation proceeds more rapidly and more certainly to gangrene or perforation. Often within twelve to eighteen hours the appendix distal to the obstruction becomes gangrenous (fig. 1174). Close examination of gangrenous appendices directly after their removal shows conclusively that they usually belong to the obstructive group (Wilkie). Perforation occurs most often at the site of an impacted fæcolith before protective adhesions have had time to form. The escaping purulent and gaseous contents are under high pressure and early widespread peritonitis is liable to ensue.

FIG. 1174.—Acute obstructive appendicitis with gangrene. There is a large fæcal concretion impacted in the proximal end of the lumen of the organ.

Sir David Percival Dalbreck Wilkie, 1882–1938. Professor of Surgery, Edinburgh.

Clinical Features (Fitz)

Age Incidence.—Rare before the age of two, acute appendicitis becomes increasingly common during childhood and adolescence. The maximum incidence is between the ages of twenty and thirty; thereafter there is a gradual decline, but no age is exempt.

The patient often gives a history of similar slight attacks. The attack can commence at any time, but frequently it does so in the early hours of the morning, awakening the patient from sleep. Recent constipation is usual.

Non-obstructive Acute Appendicitis.—Typically there are three main features:

1. **Abdominal Pain which Shifts.**—Usually the first symptom is pain around the umbilicus, in the epigastrium, or it may be generalised. This is *visceral* pain and is therefore somewhat vague (p. 960). It is due to distension of the appendix. In non-obstructive cases the pain is constant but in obstructive cases it is colicky. After a few hours the pain shifts to the point where the inflamed appendix irritates the parietal peritoneum, which is very sensitive. This pain is *somatic* or *peritoneal*, accurately localised and constant. A clinical and often valuable observation is that coughing causes pain in acute appendicitis but the pain is absent in the case of a stone in the ureter (p. 1035).

2. **Upset of Gastric Function.**—Protective pylorospasm occurs and this may be manifested by anorexia, nausea, vomiting a brown-furred tongue, and a foul breath. Typically the vomiting is of short duration and stops as soon as the stomach is empty. In the majority of instances the patient is constipated but occasionally diarrhœa occurs, especially in the very young or when the appendix lies in the post-ileal or pelvic position.

3. **Localised Tenderness at the Site of the Appendix.**—As soon as the pain has shifted, there is localised tenderness either at McBurney's point or elsewhere, as determined by the site of the appendix (fig. 1119). This tenderness may be confined to the pelvis and thus *rectal examination must be done in every case of lower abdominal pain.*[1] The identification of the site of the appendix is important; it will determine the operative approach. With the passage of time, accurate localisation becomes more difficult as muscular rigidity becomes evident in addition to the tenderness.

General Features.—During the first six hours there is rarely any alteration in the temperature or pulse-rate; after that time slight pyrexia[2] (37·2° to 37·7° C) with corresponding increase in the pulse-rate to 80 or 90, is usual. In severe cases, as time passes the temperature rises to about 38·3° C but seldom more, and the pulse-rate becomes correspondingly elevated. In 90 per cent. of cases the white cell count is greater than 10,000 cells per cu mm (10×10^9/l).

In Obstructive Appendicitis the sequence of clinical events occurs much more quickly and early diagnosis and treatment are accordingly much more

[1] "If you don't put your finger in the rectum, you may put your foot in it."
[2] In 20 per cent. of cases the temperature is 37° C or less.

Reginald Heber Fitz, 1843–1913. Professor of Medicine, Harvard University, Boston, Massachusetts, U.S.A. Published a classical paper on appendicitis in 1886 which drew attention to the disease and framed the clinical features.

urgent. The onset is abrupt and there may be severe generalised abdominal colic from the start. The temperature is often normal, but vomiting is common, so that the clinical picture mimics acute intestinal obstruction. In a few hours, however, tenderness appears in the right iliac fossa and the diagnosis will become clear.

The special features which may be encountered when the appendix occupies one of its more secluded positions are:

Retrocæcal.—Rigidity is often absent ('silent' appendix) and even on deep pressure tenderness may be lacking, the reason being that the cæcum, distended with gas, prevents the pressure exerted by the hand from reaching the inflamed structure, and gurgling may even be elicited. However, deep tenderness is often present in the loin, and rigidity of the quadratus lumborum may be in evidence. Psoas spasm, due to the inflamed appendix being in contact with that muscle, may be sufficient to cause flexion of the hip joint; to extend the joint causes abdominal pain. Hyperextension of the hip joint may induce abdominal pain when the degree of psoas spasm is insufficient to cause flexion of the hip.

Pelvic.—When the appendix lies entirely within the pelvis there is usually complete absence of abdominal rigidity, and often tenderness over McBurney's point is lacking as well. In some instances deep tenderness can be made out just above and to the right of the symphysis pubis. In either event a rectal examination reveals tenderness in the recto-vesical pouch or the pouch of Douglas, especially on the right side. Psoas spasm may also be present when the appendix is in this position: alternatively, spasm of the obturator internus is sometimes demonstrable when the hip is flexed and internally rotated. If an inflamed appendix is in contact with the obturator internus, this manœuvre will cause pain in the hypogastrium (Zachary Cope). An inflamed appendix in contact with the bladder may cause frequency of micturition. A child sometimes postpones micturition as this causes pain (McFadden). Occasionally early diarrhœa results from an inflamed appendix being in contact with the rectum.

Post-ileal.—Although this is rare, it accounts for some of the cases of 'missed appendix'. Here the inflamed appendix lies behind the terminal ileum. It presents the greatest difficulty in diagnosis because the pain may not shift, diarrhœa is a feature, marked retching may occur and tenderness, if any, is ill-defined, though it may be present immediately to the right of the umbilicus. As the appendix irritates the lower ileum, the patient usually passes small loose stools soon after eating or drinking. The temperature may be around 39° C.

Maldescended (*subhepatic*).—The tenderness is in the subhepatic region (p. 1033). It is sometimes mistaken for acute cholecystitis.

ACUTE APPENDICITIS IN INFANTS, DURING PREGNANCY, AND IN THE ELDERLY

Acute Appendicitis in Infants.—In infants under thirty-six months of age the incidence of perforation is over 80 per cent. (Fields), and the mortality

James Douglas, 1675–1742. Anatomist and Obstetrician, London.
Sir Vincent Zachary Cope, 1881–1975. Surgeon, St. Mary's Hospital, London.
George Dixon Fisher McFadden, Contemporary. Late Senior Surgeon, Belfast City Hospital, Belfast, Northern Ireland.
Irving Anatole Fields, Contemporary. Associate Professor of Surgery, Loma Linda University, Los Angeles, U.S.A.

is considerably higher than the general mortality; indeed, when acute appendicitis occurs during the first year of life, only 50 per cent. of the patients reach their first birthday. One of the reasons for the rapid onset of diffuse peritonitis is that the greater omentum, being comparatively short and undeveloped, is unable to give much assistance in localising the infection[1]. Even more important is the difficulty in arriving at an early diagnosis, and particularly in differentiating the condition from enteritis; also acute appendicitis can complicate enteritis. In addition, acute appendicitis may be associated with acute respiratory infection or one of the exanthemas.

Acute Appendicitis in Children.—It is rare to find a child with appendicitis who has not vomited and they usually have complete aversion to food. In addition, they do not sleep during the attack and very often bowel sounds are completely absent in the early stages.

Acute Appendicitis in Pregnancy.—Pregnancy with its shift of the vermiform appendix to the central or upper abdomen favours peritonitis: the nearer to term, the greater the danger, even in cases of appendicitis without perforation. After the sixth month acute appendicitis carries a maternal mortality of 20 per cent.—ten times greater than in the first three months (Parker). As pregnancy advances the pain becomes higher and more lateral. When it is necessary to exclude pyelonephritis, microscopical examination of specimens of urine will help to settle this important question. In doubtful cases it is best to perform early appendicectomy. The pregnant patient with acute perforated appendicitis aborts or goes into premature labour in 50 per cent of cases, while in acute non-perforated appendicitis this figure is reduced to 30 per cent.

Acute Appendicitis in the Aged.—Gangrene and perforation occur much more frequently in elderly patients. Elderly patients with lax abdominal walls or obesity may harbour a gangrenous appendix with little evidence of it. In addition, the picture may simulate sub-acute intestinal obstruction and if enemas are given, peritonitis may be spread more widely.

THE DIFFERENTIAL DIAGNOSIS OF ACUTE APPENDICITIS

Although acute appendicitis is the commonest abdominal emergency the diagnosis at times can be extremely difficult. It is wise to consider carefully possible diseases of the chest, the abdomen, the pelvis, the genito-urinary system, the central nervous system, and the spine[2]. For these purposes it is helpful to visualise the body as a house (fig. 1175) and compare six parts of the house to the appropriate anatomical regions.

1. **The Attic** (i.e. *The Naso-pharynx and Thorax*)

---

[1] The omentum is an apron of fat in the adult, but it is a mere bib in children.

[2] " Distension, rigidity, vomiting, pain,
Are actors abdominal which often deign
To act on behalf of the chest, spine or brain,
Or general ills of which typhoid's the main."
From " The Acute Abdomen in Rhyme " by ' Zeta ' (Sir Zachary Cope)

Robert Bernard Parker, Contemporary. Obstetrician and Gynæcologist, Selly Oak Hospital, Birmingham, England.

TONSILLITIS. In children abdominal colic may arise from swallowed exudate (' Tonsil tummy ').

PNEUMONIA AND PLEURISY, especially at the right base, give rise to right-sided abdominal pain. These conditions, however, are associated with an increased respiration rate and pain prevents deep inspiration. Pleural friction or altered breath-sounds occur on auscultation, and a chest X-ray may be helpful.

2. **The Upper Storey** (i.e. *Diaphragm to the level of the Umbilicus*)

PERFORATED PEPTIC ULCER (notably a perforated duodenal ulcer with duodenal contents passing along the paracolic gutter to the right iliac fossa).—As a rule there is a history of dyspepsia and a very *sudden* onset of pain which starts in the epigastrium and passes down the right side of the abdomen. In appendicitis the pain starts in the umbilical region. Rigidity and tenderness in the right iliac fossa are present in both conditions, but in perforated duodenal ulcer the rigidity is usually greater in the right hypochondrium. X-ray may show gas under the diaphragm (fig. 889, p. 807).

ACUTE CHOLECYSTITIS.—Murphy's sign and especially the radiation of pain through to the right scapula are important features (Boas' sign, p. 893). Retching and noisy vomiting are common. Jaundice may be present. In cases of difficulty in differentiating acute cholecystitis from acute appendicitis, the history and location of physical signs are of prime importance.

CYCLICAL VOMITING.—The patient is an infant or a young child, and there is a history of previous similar attacks. Rigidity is absent and acetone is found in the urine, but acetonuria may accompany starvation.

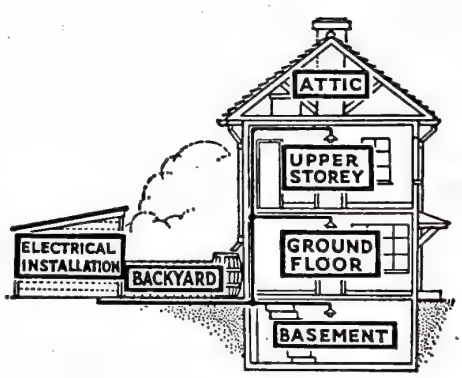

FIG. 1175.—See text. Note the water butt in the backyard (bladder).

3. **The Ground Floor** (i.e. *Umbilicus to the Brim of the Pelvis*)

ENTERO-COLITIS.—In this condition there is intestinal colic together with diarrhœa and vomiting but localised tenderness does not usually occur. There is often a history of a local epidemic. Post-ileal appendicitis may mimic this condition almost completely and it is better to look and see than to wait and see.

NON-SPECIFIC MESENTERIC LYMPHADENITIS.—The patient, usually a child, is completely free from pain in between attacks, which last a few minutes. Cervical lymph nodes may be enlarged. Shifting tenderness when the child turns on to his left side, if present, is convincing evidence. This condition is a common difficulty in children and if doubt exists a laparotomy is advisable. Some hold the view that appendicectomy may help resolution of the lymph nodes.

INTESTINAL OBSTRUCTION.—Here there is persisting colicky pain around the umbilicus with vomiting first of the stomach, then of the intestinal contents. The bowel-sounds are noisy and a plain erect X-ray shows fluid levels.

REGIONAL ILEITIS in its acute form may be indistinguishable from acute

John Benjamin Murphy, 1857–1916. Professor of Surgery, Northwestern University, Chicago, U.S.A.
Ismar Isidor Boas, 1858–1938. Gastro-enterologist, Augusta Hospital, Berlin.

appendicitis unless a doughy mass of inflamed ileum can be felt. A history of diarrhœa suggests regional ileitis rather than appendicitis.

CARCINOMA OF THE CAECUM (p. 1037), when obstructed, may mimic appendicitis in patients in the carcinoma age-group.

MECKEL'S DIVERTICULITIS (p. 967).

4. **The Basement** (i.e. *The Pelvis*)

It is in women of the child-bearing age that pelvic disease so often mimics acute appendicitis:

SALPINGITIS.—Unlike early acute appendicitis, early salpingitis should be treated by non-operative measures. The history of a vaginal discharge, of menstrual irregularities and dysmenorrhœa, or burning pain on micturition, are all helpful differential diagnostic points. The onset of symptoms usually follows a period and the pain *starts* low down and remains there (fig. 1176). On rectal or vaginal examination the enlarged tender Fallopian tubes may be palpated. A bacteriological cervical swab is cultured and will provide information about the sensitivity of the organism. When the condition is mainly right-sided, the differential diagnosis is so difficult that it is wiser to explore the abdomen.

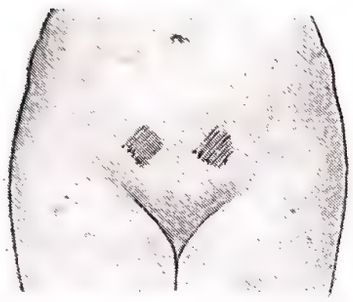

FIG. 1176.—Typical distribution of abdominal tenderness in acute salpingitis.

ECTOPIC GESTATION.—It is unlikely that a *ruptured* ectopic pregnancy, with its well-defined signs of hæmoperitoneum, will be mistaken for acute appendicitis, but the same cannot be said for a right-sided tubal abortion, or still more for a right-sided unruptured tubal pregnancy. In the latter, the signs are very similar to those of acute appendicitis, except that the pain *commences* on the right side and stays there. The pain is severe and continues unabated till operation. Usually there is a history of a missed period. The cervix is softened and often severe pain is felt when it is moved on vaginal examination. In addition, in tubal abortion, the signs of intraperitoneal bleeding usually become obvious after a while. The patient should be questioned specifically regarding referred pain in the shoulder, especially a quarter of an hour after the foot of the bed has been raised on blocks.

RUPTURED OVARIAN FOLLICLE (*syn.* mittelschmerz) usually occurs halfway between periods—i.e. about the fourteenth to the sixteenth day, especially in early womanhood. The signs are similar to those of very early tubal abortion, but of course the history of a missed period is absent, as also is the sign of a soft cervix. There is often a previous history of such attacks and the condition does not progress. Tenderness and rigidity are seldom pronounced.

TWISTED RIGHT OVARIAN CYST.—Here the pain is severe, is often referred to the loin, and is made worse when the patient rolls over. The pulse-rate progressively rises while the temperature remains normal. Sometimes the cyst is not easy to feel. If examination of the pelvis under anæsthesia is practised preparatory to laparotomy, a mistake will seldom be made.

Gabriele Falloppio (Fallopius), 1523–1563. Professor of Anatomy, Surgery and Botany, Padua, Italy.

DIVERTICULUM OF CÆCUM (solitary) (p. 972).—This is rare. When inflamed it is indistinguishable from acute appendicitis.

5. **The Backyard** (i.e. *The Retroperitoneal Structures*)

RIGHT URETERIC COLIC.—In typical ureteric colic, pain commences in the loin and passes to the groin; this symptom, combined with the presence of urinary symptoms, serves to distinguish many cases from acute appendicitis. When ureteric colic is due to a stone in the right ureter there is often considerable tenderness in the right iliac fossa. Coughing causes pain in acute appendicitis, but not with a ureteric calculus. A plain X-ray may show a stone in the line of the right ureter and microscopy of the urine will reveal red cells. If an intravenous pyelogram is done, it may show dilatation or diminished excretion in the right urinary tract. However, if early acute retrocæcal appendicitis cannot be ruled out, it is safer to operate.

RIGHT-SIDED ACUTE PYELONEPHRITIS is accompanied and often preceded by increased frequency of micturition. It may cause difficulty in diagnosis, especially in women. The leading features are tenderness confined to the loin, fever (temperature 39° C) and possibly rigors and pyuria. It presents special difficulty in pregnancy.

6. **The Electrical Installation** (i.e. *Central Nervous System*)

Pre-herpetic pain of the right tenth and eleventh dorsal nerves is localised over the same area as that of appendicitis. It does not shift and is associated with marked hyperæsthesia. There is no intestinal upset nor rigidity. The herpetic eruption may be delayed for thirty-six to forty-eight hours.

Tabetic crises are now rare. Severe abdominal pain and vomiting usher in the crisis. Other signs of tabes confirm the diagnosis.

Spinal conditions are sometimes associated with acute abdominal pain especially in children and the elderly. These may include Pott's disease of the spine, secondary carcinomatous deposits, senile osteo-porosis, and myelomatosis. The pain is essentially due to compression of nerve roots and may be precipitated by movement. There is rigidity of the lumbar spine and intestinal symptoms are absent. In a doubtful case spinal X-rays will often be a guide.

Other conditions to be remembered are:

The abdominal crises of porphyria which may simulate appendicular colic (p. 1030) are characterised by violent intestinal colic with constipation, and are liable to be precipitated by the administration of barbiturates, the symptoms being produced by areas of intestinal spasm. The urine of these patients is usually orange in colour, which is often dismissed as 'concentrated'. If the specimen of urine is left exposed to daylight for even a short space of time, it becomes amber in colour, particularly near the surface. There are several conclusive laboratory tests for porphyrinuria. A plain X-ray of the abdomen often displays short segments of intestinal spasm with related gaseous distension of the small and large intestine. In obscure cases of intestinal colic it is well to remember this condition, especially when it is associated with mental or neurological symptoms.[1]

'Diabetic abdomen' denotes the severe abdominal pain and vomiting which occasionally precedes coma. The urine should be tested in every abdominal emergency.

Acute Pancreatitis.—In early cases there may be vomiting and pain in the right iliac fossa.

PERFORATION AND GANGRENE

When perforation or gangrene occurs within twelve to twenty-four hours after the commencement of the attack, as is sometimes the case in acute

[1] It is almost certain that the bouts of mental instability from which King George III (who died in 1820) suffered were due to porphyria.

Percivall Pott, 1714–1788. Surgeon, St. Bartholomew's Hospital, London.

appendicular obstruction, diffuse peritonitis is liable to occur. In non-obstructive appendicitis particularly, and in obstructive appendicitis when perforation or gangrene develops after a period of twenty-four hours, the resulting peritonitis often becomes localised, especially when the appendix lies in a relatively secluded portion of the peritoneal cavity.

LOCAL, DIFFUSING AND DIFFUSE PERITONITIS are discussed in Chapter 46.

THE APPENDIX MASS (*syn.* PERI-APPENDICULAR PHLEGMON)

On the third day (rarely sooner) after the commencement of an attack of acute appendicitis, a tender mass can frequently be felt in the right iliac fossa beneath some rigidity of the overlying musculature, the other quadrants of the abdomen being free from rigidity or tenderness. Alternatively, the mass is situated within the pelvis. The mass, which at this time is not yet an appendix abscess, and may never become one, is composed mainly of the greater omentum, œdematous cæcal wall, and œdematous portions of the small intestine. In its midst is a perforated or otherwise inflamed vermi-

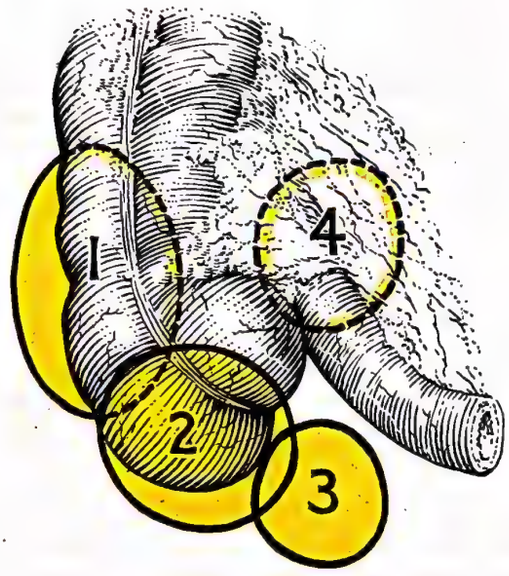

FIG. 1177.—Positions of an appendix abscess palpable from the abdomen. 1. Retrocæcal. 2. Subcæcal. 3. Retrorectus (behind the rectus abdominis muscle). 4. Post-ileal (pre-ileal occupies the same position as 4, but lies in front of the ileum).

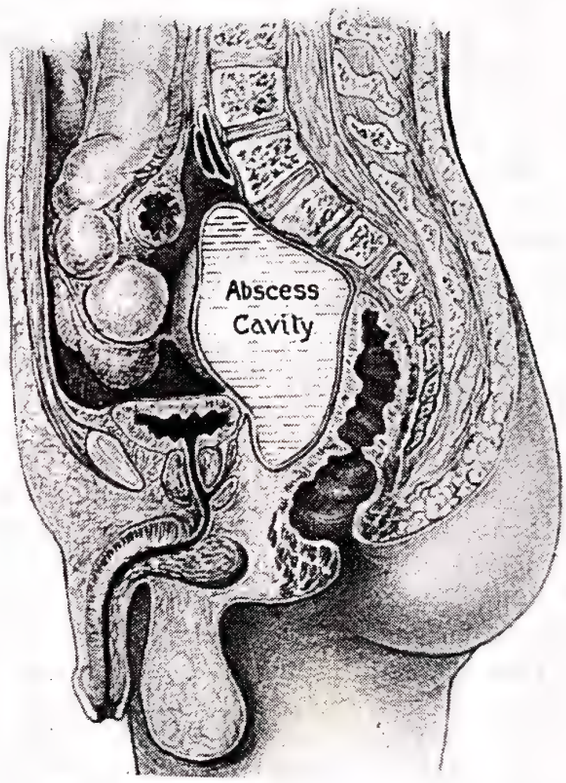

FIG. 1178.—Appendix abscess invading the pelvis. Note the relationship to the rectum.

form appendix. By the fourth or fifth day the mass becomes more circumscribed. As the rigidity passes off its periphery can be defined clearly and should be outlined with a skin pencil. During the ensuing days (fifth to tenth day) the swelling either becomes larger, and an appendix abscess results, or it becomes smaller, and subsides slowly as the inflammation resolves.

Appendix Abscess.—Accompanying an abscess there is variable pyrexia, but the pulse-rate is usually under 100. There is an increased leucocyte count with a relative increase of polymorphonuclear cells. To a great extent the location of the abscess is governed by the position of the appendix. Thus

the commonest site of the abscess is in the lateral part of the iliac fossa (extension of retrocæcal suppuration) (fig. 1177) and the second most common is in the pelvis (fig. 1178). Notwithstanding, an abscess centred beneath McBurney's point is not so unusual as the percentages of the anatomical positions of the appendix would indicate. This is because perforation often implicates the proximal half of an inflamed appendix.

Differential Diagnosis of an Appendix Mass

Carcinoma of the Cæcum.—Here the lump is rarely tender, it has appeared slowly and there is usually a secondary anæmia with occult blood in the stools. There is often progressive deterioration in health over months.

Crohn's Disease.—The diarrhœa, loss of weight, and a lump nearer the midline merits careful barium studies of the small bowel in order to make a firm diagnosis which may otherwise be difficult. Occult blood in the stools and a raised erythrocyte sedimentation rate may help, especially in a young adult.

Parametritis.—Here there is usually a history of recent parturition, the lump is over the medial third of the inguinal ligament and appears to be continuous with it.

Actinomycosis (p. 984).

Tuberculosis (p. 983).

FIG. 1179.—Tender mass connected with suppurating deep iliac lymph nodes.

Twisted Ovarian Cyst (p. 1034).—The essential step in diagnosis is the bimanual examination.

Iliac Lymphadenitis.—When right-sided, this condition sometimes simulates an appendix abscess. In the early stage psoas spasm is often in evidence. There is tenderness, some rigidity, and a palpable swelling above the inguinal ligament (fig. 1179). Often the inguinal lymph nodes are unaffected. Suppuration of the iliac lymph nodes leads to an extraperitoneal abscess. There is usually a focus of infection, e.g. a scratch or a blister on the skin of the lower limb.

TREATMENT OF ACUTE APPENDICITIS

The treatment of acute appendicitis is appendicectomy.[1] If the diagnosis is made at an early stage in the attack, and particularly in the absence of a localised mass, all are agreed that the appendix should be removed urgently.

Appendicectomy.—When the diagnosis is certain the grid-iron incision is the best one to be employed. When the diagnosis is in doubt the lower right paramedian incision is preferable because it gives good access to the pelvic organs in the female and, if necessary, it can be readily extended upwards to deal with a perforated duodenal ulcer.

The Grid-iron[2] Incision.—An adequate incision, according to the age, musculature, or obesity of the patient, is made with its centre over McBurney's point, at

[1] The first surgeon to perform deliberate appendicectomy for acute appendicitis was Lawson Tait, in May 1880. The patient recovered. It is recorded in 1736 that Claudius Amyand successfully removed an acutely inflamed appendix from the hernial sac of a boy.

[2] Grid-iron — a frame of cross-beams to support a ship during repairs. The grid-iron incision was described first by McArthur.

Burrill Bernard Crohn, Contemporary. Gastro-enterologist, Mount Sinai Hospital, New York, U.S.A.
Robert Lawson Tait, 1845–1899. Surgeon, Hospital for Diseases of Women, Birmingham, England.
Claudius Amyand, ?1685–1740. Surgeon, St. George's Hospital, London.
James Rutherford Morison, 1853–1939. Professor of Surgery, Durham, Ennland.
Lewis Linn McArthur, 1858–1934. Surgeon, St. Luke's Hospital, Chicago, U.S.A.

right angles to a line joining the anterior superior iliac spine to the umbilicus. In the subcutaneous tissues an arterial twig from the superficial circumflex iliac artery usually requires ligation. The external oblique is incised in the length of the incision. The fibres of the internal oblique and transversus abdominis are separated, and after suitable retraction the peritoneum is opened. If it is found that more room is required, it is better to cut the deeper muscles in the line of the incision thus converting the grid-iron into a Rutherford Morison incision (vide infra). The lowest mortality following appendicectomy for acute appendicitis is associated with the grid-iron incision.

FIG. 1180.—Grid-iron incision and paramedian incision.

The paramedian incision is a vertical incision lying parallel to and 1·25 to 2·5 cm. to the right of the middle line. It commences 2·5 cm. below the level of the umbilicus and ends just above the pubis. The anterior rectus sheath is incised in the line of the incision and the rectus muscle is retracted laterally. Branches of the inferior epigastric vessels may require ligation. The transversalis fascia and the peritoneum are incised together, the peritoneal cavity being opened through the length of the incision. Care must be taken not to injure the bladder inferiorly. The advantages of the incision have been referred to already. Its disadvantages are (*a*) that it gives poor access to a retrocæcal appendix (it should be possible to diagnose retrocæcal appendicitis pre-operatively); (*b*) if the incision becomes infected its 'trap-door' nature harbours infection.

Rutherford Morison's incision is useful if the appendix is para- or retrocæcal and fixed. It is essentially an oblique muscle-cutting incision with its lower end over McBurney's point and extending obliquely upwards and laterally as necessary. All layers are divided in the line of the incision.

Removal of the Appendix.—It will be assumed that the abdomen has been opened by a grid-iron incision. A retractor is placed under the medial side of the peritoneum and the abdominal wall is lifted up. After removing any pus or serous exudate with a sucker, a pack is inserted into the wound on the medial side. Using a swab, the cæcum is withdrawn. A finger may be inserted into the wound to aid delivery of the appendix. Once the appendix has been delivered the cæcum is grasped by an assistant. A tissue-holding forceps (e.g. Lane's) are applied around the appendix in such a way as to encircle the organ and yet not damage it (fig. 1181). The base of the mesoappendix is clamped in a hæmostat, tied and severed. Sometimes only one such manœuvre frees the whole of the mesoappendix. When the mesoappendix is broad, the procedure must be repeated with a second, or rarely, a third hæmostat. The appendix, now completely freed, is crushed near its junction with the cæcum in a hæmostat, which is removed and reapplied just distal to the crushed portion. A catgut ligature is tied around the crushed portion close to the cæcum and

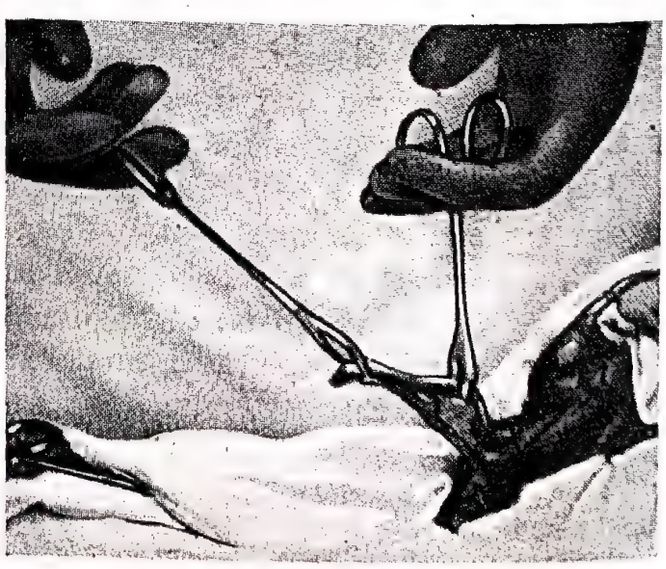

FIG. 1181.—Showing the appendix delivered and the mesoappendix displayed.

an atraumatic catgut purse-string suture is inserted into the cæcum about 1·25 cm. from the base. This stitch passes through the muscle coat, especially picking up the tæniæ coli. It is left untied until the appendix has been amputated with a scalpel below the hæmostat. The stump is invaginated (fig. 1182) while the purse-string suture is tied, thus burying the appendix stump.

Methods to be Adopted in Special Circumstances.—When the cæcal wall is œdematous, the purse-string suture is in danger of cutting out. If the œdema is of limited extent, this can be overcome by inserting the purse-string suture into more healthy cæcal wall at a greater distance from the base of the appendix. Occasions may arise when, because of extensive œdema of the cæcal wall, it is better not to attempt invagination, in which case the stump of the appendix should be ligated and the cut surface touched with the diathermy in an attempt to reduce infection.

When the base of the appendix is inflamed, it should not be crushed, for fear of distributing infection by way of the lymphatics or blood-stream. It should be ligated close to the cæcal wall just tightly enough to occlude the lumen, after which the appendix is amputated and the stump invaginated.

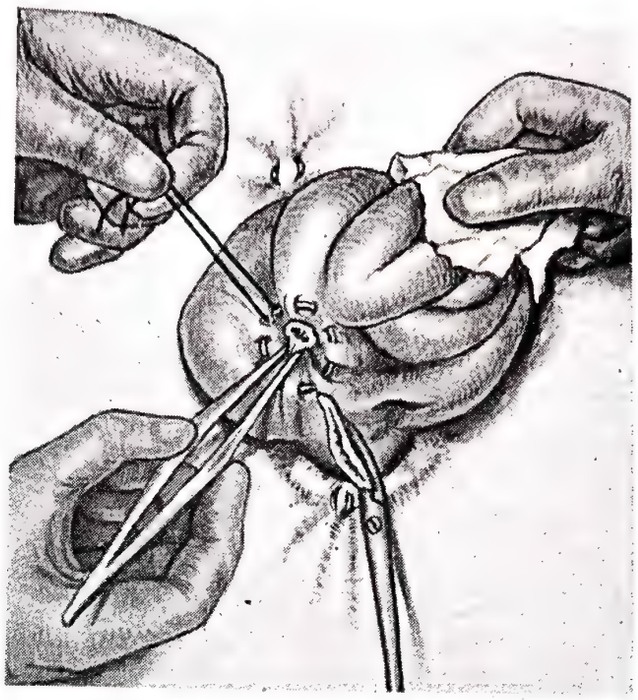

FIG. 1182.—Appendicectomy. Inverting the stump of the appendix.

Should the base of the appendix be gangrenous, neither crushing nor ligation must be attempted. Two stitches are placed through the cæcal wall close to the base of the gangrenous appendix, which is amputated flush with the cæcal wall, after which these stitches are tied. Further closure is effected by means of a second layer of interrupted sero-muscular sutures.

Retrograde Appendicectomy.—When the appendix is retrocæcal and adherent, it is an advantage to divide the base of the organ between hæmostats. After the vessels have been dealt with and the stump has been ligated and invaginated, gentle traction on the cæcum will enable the surgeon to deliver the organ which is removed from base to tip.

Drainage of the Peritoneal Cavity.—This is usually unnecessary provided adequate peritoneal toilet has been done. If, however, there is considerable purulent fluid in the retrocæcal space or the pelvis, or if there is persistent oozing, it is wise to bring out a Penrose drain[1] through a separate stab incision.

Drainage of the Parietes.—This is indicated if there is any soiling of the wound, especially in the obese and in children.

The rule is: ' If in doubt drain, and especially the parietes '.

THE MANAGEMENT OF AN APPENDIX MASS

If an appendix mass is present and the condition of the patient is satisfactory, the standard modern treatment is conservative, i.e. the *Ochsner-Sherren* regimen. This decision is based on the fact that Nature has already

[1] Penrose drain. Extremely thin (latex) rubber tubing with a gauze wick.

Sir William Arbuthnot Lane, 1856–1943. Surgeon, Guy's Hospital, London.
Charles Bingham Penrose, 1862–1925. Professor of Gynæcology, University of Pennsylvania, Philadelphia, U.S.A.
Albert John Ochsner, 1858–1925. Professor of Clinical Surgery, University of Illinois, Chicago, U.S.A.
James Sherren, 1872–1945. Surgeon, The London Hospital.

localised the lesion and it is foolish to disturb these barriers. Inadvertent surgery at this time is difficult, bloody, and dangerous. It may be impossible to find the appendix and, occasionally, a fæcal fistula may form. For these reasons it is wise to observe a rigid non-operative programme, but to be prepared to operate at any time should Nature fail to control the infection.

The treatment is not merely a postponement of operation; it is not a substitute for operation, but a preparation for it—essentially a surgeon's treatment, to be undertaken only in a hospital, or a correspondingly equipped nursing home. Although the treatment should be conducted on the threshold of an operating theatre, there are circumstances—for instance, in an ill-equipped ship at sea—where conservative treatment would be less dangerous than to attempt operation.

The history is taken, and particular note is made of the number of hours since the onset. The history begins ' ten, twenty-six, fifty-five *hours* ago ', not ' last Thursday ' or ' three days ago '. The physical signs are then recorded in the clinical notes in diagrammatic form. The extent of the rigidity is marked by shading; the presence of a lump is drawn as near as possible to scale.

In this connection it should be noted especially that sometimes when a patient is first admitted overlying muscular rigidity renders an appendix mass indefinite, or even impalpable. In the majority of such instances, should a lump be present, if the patient is re-examined in two hours' time, lessened apprehension and the warmth of being in bed will reduce guarding of the abdominal wall sufficiently to permit the lump to be felt.

Charts.—As a routine, the pulse is recorded every hour on a special chart. Temperature is recorded every four hours. Instructions are given to the nurse to report if the patient vomits and to save the specimen for inspection. Unless the vomitus is a small quantity of clear fluid, no time should be lost in passing and retaining a transnasal gastric aspiration tube, in order to keep the stomach empty.

Diet.—Water, 30 ml. hourly, may be given by mouth. Mouth-washes are given frequently. Desire for food, usually about the fourth or fifth day, is an indication that satisfactory progress is being made and that oral feeding may be started. The first feeds should be fluids only and progression to solid food can take place over the next few days.

Intravenous fluids with fluid balance chart and daily assay of electrolytes must be instituted.

Drugs.—It should be particularly noted that no morphine or its derivatives are given in border-line cases that are being watched closely for a few hours in order to observe whether the pulse-rate and other signs are tending to settle. Once it has been decided definitely to treat the patient by conservative measures, morphine may be given. Pain, as opposed to tenderness, is very seldom complained of after the first twelve hours of the treatment.

Antibiotic therapy is, of course, employed by both schools. Penicillin, 500,000 units, and streptomycin, 0·5 g, are given intramuscularly twelve-hourly. Alternatively, by adding 1·0 g of oxytetracycline (terramycin) to the intravenous fluid given over a period of each twelve hours, the patient is spared the pain of repeated intramuscular injections. When the patient is permitted to receive nourishment by mouth, the antibiotic therapy is changed to the oral route.

Bowels.—If the bowels are not opened naturally by the fourth or fifth day, a glycerine suppository will encourage normal evacuation. No purgatives of any kind are given until resolution is complete—that is, until the temperature and pulse have been normal for a week and pain and physical signs are absent.

Criteria for Stopping 'Delayed' Treatment

(1) a rising pulse-rate, (2) vomiting or copious gastric aspirate, (3) increasing or spreading abdominal pain, and, increasing size of the abscess.

A rising pulse-rate in the early stages is the most reliable single sign that it is dangerous to proceed with the delayed method.

Vomiting (or copious gastric aspirate) after the first few hours should always be regarded seriously, and this by itself may be a sufficient indication to operate.

A patient undergoing delayed treatment should not complain of pain, as opposed to tenderness, after the first six hours of such treatment. If he does, there is usually something amiss, and there is a strong indication for operation.

Contraindications to the 'Delayed' Treatment

1. The diagnosis cannot be made between acute appendicitis and some other intra-abdominal catastrophe normally requiring immediate operation.

2. The signs indicate that the inflammation is still confined to the appendix.

3. When the patient is under ten years of age (poor development of the greater omentum and early perforation of the appendix), (p. 1032).

4. When the patient is over the age of sixty-five years more than ordinary bias is directed towards immediate operation, because of the frequency of peritonitis with minimum clinical signs.

The outcome

Under the delayed treatment about 90 per cent. of cases resolve without incident. The appendix, however, must be removed later to avoid further attacks. The originators of this treatment suggested that this should be done after an interval of three months. Present-day practice, however, favours appendicectomy as soon as convenient after *complete* resolution of the mass.

FIG. 1183.—This fourteen-year-old boy had symptoms for three days. The confines of the mass are outlined. He responded to conservative treatment and returned three months later for appendicectomy.

THE TREATMENT OF APPENDIX ABSCESS

Failure of resolution of an appendix mass usually indicates that there is pus within the mass (p. 1036).

Indications for Opening an Appendix Abscess.[1]—(1) When the swelling is not diminishing in size after the fifth day of treatment; (2) when the temperature is swinging above 37·8° C on several successive days; (3) a pelvic abscess seldom resolves—repeated rectal examinations are required to determine when it is ready for opening into the rectum (p. 940).

Opening an Appendix Abscess. — The swelling is palpated under the anæsthetic.

A retrocæcal appendix abscess should be opened extraperitoneally. An incision from 2·5 to 5 cm long, depending on the thickness of the abdominal wall, is

[1] The first recorded operation for an appendix abscess was by Henry Hancock (1809–1880) of Charing Cross Hospital, London, in 1848.

made over the centre of the swelling, rather nearer the lateral than the medial aspect. The external oblique is incised and the fibres of the deeper muscles are divided, instead of being separated, so as to give freer exit to the contents of the abscess. When the peritoneum has been reached the extraperitoneal tissues are separated in an outward and backward direction, until the abscess cavity is entered. In cases where the abscess cavity lies at some distance from the incision, more direct drainage is afforded by a counter-incision in the flank, in which case the original incision is closed.

A subcæcal abscess can be opened in the same manner, the incision being placed nearer the anterior superior iliac spine.

A pre- or post-ileal abscess can be reached only through the peritoneal cavity. When the peritoneum has been opened, gauze packing is inserted so as to isolate the region from the general peritoneal cavity before opening the abscess.

A pelvic abscess is opened into the rectum as described on p. 940.

When it is necessary to drain an appendix abscess, no prolonged attempt should be made to perform appendicectomy unless the appendix is lying free in the abscess cavity; usually the appendix is incorporated in the walls of the abscess.

Interval Appendicectomy.—Following successful drainage of an appendix abscess, arrangements should be made for the patient to return for appendicectomy three months after the wound has healed. It is highly important to explain to the patient that drainage of an appendix abscess is no safeguard against future attacks of appendicitis.

THE PERILS OF PROLONGED ANTIBIOTIC THERAPY IN INTRA-ABDOMINAL SEPSIS

In addition to the general danger of antibiotics (p. 18) there are certain dangers peculiar to their use in intra-abdominal sepsis. These are:

1. The masking of the general signs (especially the raised temperature) of an intra-abdominal abscess behoves the clinician to make a daily abdominal and pelvic examination, lest an enlarging abscess bursts its confines, perhaps into the general peritoneal cavity.

2. Pus that has been sterilised by antibiotics remains and behaves as a foreign body, and as an irritant. For instance, cases have been reported where one or more sterile abscesses lay among the coils of small intestine, causing obscure subacute intestinal obstruction.

3. Cases have been reported whereby a pelvic abscess, by reason of antibiotic therapy, has been converted into granulation tissue, leading to a 'frozen' pelvis with consequent stricture of the rectum (Stammers).

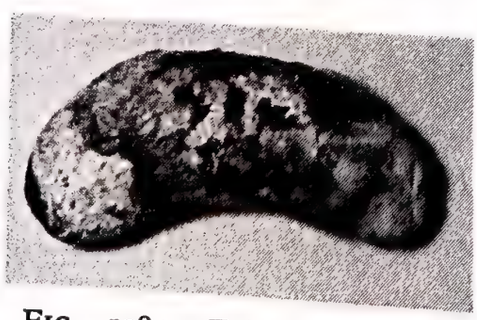

FIG. 1184.—Following appendicectomy a sinus persisted for 6 months until this faecolith appeared on the dressing. (*Roger Mitchell, F.R.C.S.*)

COMPLICATIONS ARISING AFTER APPENDICECTOMY FOR ACUTE APPENDICITIS

The complications following appendicectomy for acute appendicitis vary with the degree of peritonitis that was present, and with the resistance of the patient to the infection. These complications include:

Early.—Ileus (p. 1022), Wound sepsis, Residual abscess (local, fig. 1184, pelvic, paracolic, subphrenic, pp. 940 to 942), Intestinal obstruction from adhesions (p. 1017), Fæcal fistula (p. 994), Pylephlebitis (p. 854), Post-operative throm-

Francis Alan Roland Stammers, Contemporary. Emeritus Professor of Surgery, Birmingham, England.

bosis and embolism (pp. 162 and 141), Actinomycosis (p. 984), Pulmonary complications (pulmonary collapse or pneumonitis) (p. 723).

Late.—Intestinal obstruction from adhesions (p. 1017), Incisional hernia, Right inguinal hernia following the grid-iron incision (especially if a drain is brought through the wound) (p. 1126). Sterility in the female from 'frozen' pelvis.

★ ★ ★

It is advisable to include the following practical problem :

After an operation for acute appendicitis the condition of the patient is unsatisfactory. The temperature is swinging and the pulse rate is elevated—signs which foretell pocketing of pus. How would you investigate the case ?

1. *Examine the wound and the abdominal wall* for an abscess.
2. *Consider a pelvic abscess, and perform a rectal examination* (p. 940).
3. *Palpate the left iliac fossa* for an abscess in this situation.
4. *Examine the loin* for retrocæcal swelling and tenderness.
5. *Examine the legs*—to exclude the possibility of phlebitis.
6. *Examine the conjunctivæ for an icteric tinge and the liver for enlargement, and enquire if the patient has had rigors*—pylephlebitis.
7. *Examine the lungs*—pneumonitis or collapse.
8. *Examine the urine for organisms* (*pyelonephritis*).
9. *In children consider tonsillitis and otitis media.*
10. *Ensure that the i.v. apparatus is sterile. If you can't be sure, change it, needle and all.*
11. Lastly, *suspect the possibility of a subdiaphragmatic abscess* (p. 941).

SUBACUTE APPENDICITIS

Subacute appendicitis is but a mild form of acute appendicitis, and requires no detailed consideration.

RECURRENT ACUTE APPENDICITIS

Appendicitis is notoriously recurrent. This is perhaps the commonest form of appendicitis—mild subacute attacks which are so often attributed to 'biliousness' or a 'chill on the liver'. The attacks vary in intensity, may occur every few months, and the majority of cases ultimately culminate in severe acute appendicitis. If careful histories are taken from patients with acute appendicitis, over two-thirds remember having had milder but similar attacks of pain. The appendix in these cases shows obliterative appendicitis (fig. 1185).

FIG. 1185.—Recurrent attacks of appendicitis lead to fibrosis spreading from the tip with gradual obliteration of the lumen.

CHRONIC APPENDICITIS

Chronic appendicitis, *per se*, does not exist. Patients labelled thus are usually examples of the recurrent form of the disease.

APPENDICULAR DYSPEPSIA

This is an important form of presentation of recurrent appendicitis in which the upset of gastric function predominates over the local signs. These patients are often thought to have a duodenal ulcer because of the reflex pylorospasm. They complain of attacks of anorexia, dirty tongue, flatulence, and a dyspepsia which gives little response to alkalis. They do not

notice any pain in the right iliac fossa but on careful and repeated examination localised tenderness will be found. Appendicectomy should be done through a right paramedian incision so that other organs can be examined.

Radiology as an Aid to Diagnosis.—In the case of the vermiform appendix, radiology is not a great diagnostic aid. If the appendix cannot be visualised after an opaque meal, it suggests that its lumen is obstructed; certainly such an appendix should be removed. If it fills and empties, it is indicative that at least part of the organ is healthy—but as nobody can tell the length of a given appendix until the organ has been displayed, there must always be uncertainty in the radiological diagnosis of appendicitis.

LESS COMMON PATHOLOGICAL CONDITIONS OF THE APPENDIX

Mucocele of the appendix may occur when the proximal end of the lumen slowly becomes completely occluded, usually by a fibrous stricture, and the pent-up secretion remains sterile. The appendix is greatly enlarged; sometimes it contains several ounces of mucus. The symptoms produced are those of mild subacute appendicitis unless infection supervenes, when the mucocele is converted into an empyema. Rupture of a mucocele of the appendix is a cause of pseudomyxoma peritonei (p. 951).

Diverticula of the Appendix.—Diverticulosis occurs once in about 200 appendices removed by operation (Edwards). These diverticula are not merely extensions of diverticulosis of the colon; some are congenital (all coats); most are acquired (no muscularis layer). Diverticula of the appendix can occur in conjunction with a mucocele. The intramural pressure rises sufficiently to cause herniation of the mucous membrane through the muscle coat at several points. More often diverticula (fig. 1186) are not found in association with a mucocele, and often there is no demonstrable obstruction to the lumen. Usually the patient gives a history of previous recurrent attacks of appendicitis. If encountered during the course of an operation for another condition, a diverticula-bearing appendix should always be removed, because if perchance such an appendix becomes the seat of inflammation, perforation will occur very easily.

FIG. 1186.—Appendicular diverticulosis.

Intussusception of the appendix is a rare condition, occurring most often in childhood. It can be diagnosed only at operation. The symptoms usually are not acute. Untreated, the condition may pass on to an appendiculo-colic intussusception. The appendix may slough, and this accounts for most of the very rare cases in which the appendix is absent (p. 1026). The treatment is appendicectomy. Cæcectomy may be necessary.

Endometriosis of the Appendix.—About 150 cases have been reported. The tumour—a miniature uterus in so far as endometrium is concerned—gives rise to monthly melæna. The loss of blood per rectum may be severe.

Neoplasms of the Appendix

Carcinoid tumour (*syn.* Argentaffinoma), which arises in argentaffin tissue (Kulchitsky cells of the crypts of Lieberkühn) can occur anywhere in the gastro-intestinal tract, but most commonly it is situated in the vermiform appendix; indeed, the tumour is found once in about 300 to 400 appendices subjected to histological examination. Carcinoid tumours are distributed evenly among appendices removed from patients between the ages of sixteen and sixty years. Most of the patients are females (80 per cent.).

In many instances the appendix is removed because of symptoms of subacute or recurrent appendicitis. The tumour can occur in any part of the

Harold Clifford Edwards, Contemporary. Consulting Surgeon, King's College Hospital, London.
Nicholas Kulchitsky, 1856–1925. Professor of Histology, Kharkov, Ukraine, U.S.S.R.

appendix, but it frequently does so in the distal third of the organ. The neoplasm feels moderately hard, and on slitting up the appendix it can be seen between the intact mucosa and the peritoneum, replacing the muscular coats. There is no mistaking it, because it is of a bright yellow colour, due to contained lipoid. Microscopically the chief cells are spheroidal in type and contain granules that stain with ammoniacal silver salts. Unlike carcinoid tumours arising in other parts of the intestinal tract (p. 986) in only 4 per cent. of cases does the tumour give rise to metastases, and it is most exceptional for metastases from an argentaffin carcinoma of the vermiform appendix to secrete sufficient hormone to produce the characteristic symptomatology described on p. 986. Carcinoid tumour is ten times more common than other forms of carcinoma of the vermiform appendix.

Primary Adenocarcinoma.—Less than 200 cases are recorded. These are mostly of the colonic type and should be treated by right hemicolectomy; as a second stage procedure if the condition is not recognised at the first operation. Less frequently, a malignant mucocele occurs and here appendicectomy alone is probably sufficient if the tumour is in the distal part of the viscus and is confined to the submucosa; otherwise right hemicolectomy is again indicated. The five-year survival rate after right hemicolectomy is of the order of 60%.

CHAPTER 50

THE ANAL CANAL AND RECTUM

Surgical Anatomy

The anal canal commences at the level where the rectum passes through the pelvic diaphragm and ends at the anal verge.[1] The muscular junction between the rectum and anal canal can be felt with the finger as a thickened ridge—the 'ano-rectal bundle' or 'ring'.

Anal Canal Musculature:

The internal sphincter is a thickened continuation of the circular muscle coat of the rectum. This involuntary muscle commences where the rectum passes through the pelvic diaphragm, and ends at the anal orifice, where its lower border can be felt. The internal anal sphincter is 2·5 cm long and 2 to 5 mm thick. When exposed during life, it is pearly-white in colour, and its individual transversely placed fibres can be seen clearly. Spasm and contracture of this muscle play a major part in fissure and other anal affections.

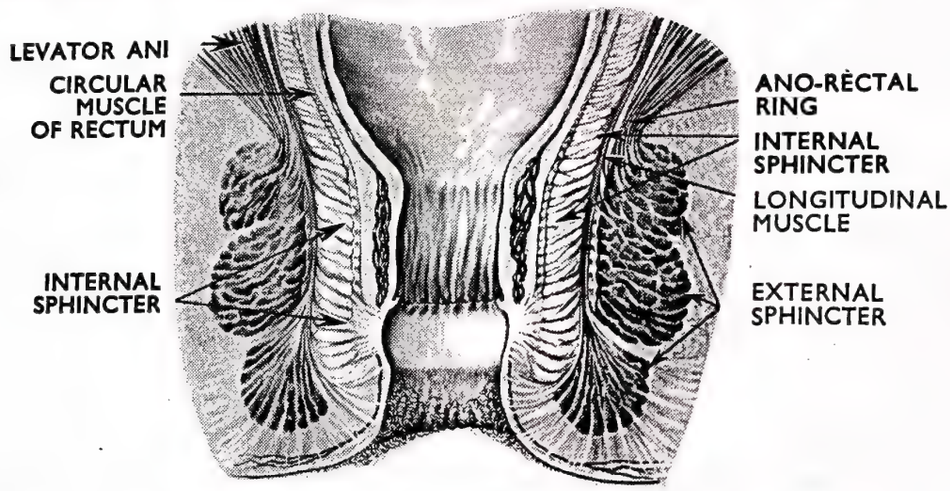

FIG. 1187.—The musculature of the anal canal. *(After Sir Clifford Naunton Morgan, F.R.C.S., London.)*

The longitudinal muscle is a continuation of the longitudinal muscle coat of the rectum intermingled with fibres from the pubo-rectalis. Its fibres fan out through the lowest part of the external sphincter, to be inserted into the true anal and perianal skin, thus constituting the **corrugator cutis ani of Ellis.**

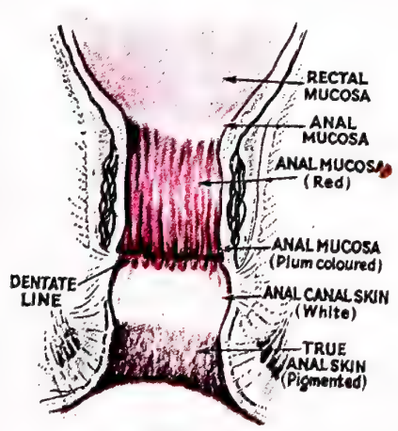

FIG. 1188. — The lining membrane of the anal canal. *(After Sir Clifford Naunton Morgan, F.R.C.S., London.)*

The external sphincter, formerly subdivided into a deep, superficial, and subcutaneous portion is now considered to be one muscle (Goligher). Some of its fibres are attached posteriorly to the coccyx, while anteriorly they are inserted into the mid-perineal point in the male, whereas in the female they fuse with the sphincter vaginæ. In life the external sphincter is pink in colour, and homogeneous. Unlike the pale internal sphincter muscle, which is involuntary, the red external sphincter is composed of voluntary (somatic) muscle.

The longitudinal muscles, by traversing the internal and external sphincters to reach their insertions, serve to brace these sphincters.

---

[1] Anal verge = the external or distal boundary of the anal canal.

George Viner Ellis, 1812–1900. Professor of Anatomy, University College, London.
John Cedric Goligher, Contemporary. Professor of Surgery, Leeds, England.

The Mucous Membrane.—The *pink* columnar epithelium lining the rectum extends through the ano-rectal ring into the surgical anal canal. The mucosa of the surgical anal canal is attached loosely to the underlying structures, and covers the internal rectal plexus. Passing downwards where it clothes the series of 8 to 12 longitudinal folds known as the columns of Morgagni, the mucous membrane becomes cubical, and *red* in colour (fig. 1188); above the anal valves the mucous membrane becomes *plum coloured*. Just below the level of the anal valves there is an abrupt, albeit wavy, transition to squamous epithelium, which is *parchment colour*. This wavy junction constitutes the dentate line. The squamous epithelium lining the anatomical anal canal is thin and shiny, and is known as the anoderm. This squamous epithelium differs from true skin in that it has no epidermal appendages, i.e. hair, sweat glands. The anoderm passes imperceptibly into the pigmented skin of the anus. At the dentate line the anoderm is attached very firmly indeed to deeper structures.

The dentate line is a most important landmark both morphologically and surgically It represents (1) the site of fusion of the proctodæum and post-allantoic gut, and (2) the position of the anal membrane, remnants of which may frequently be seen as anal papillæ situated on the free margin of the anal valves. The dentate line separates:

Above	*Below*
Cubical epithelium	from squamous epithelium
Autonomic nerves (insensitive)	from spinal nerves (very sensitive)
Portal venous system	from systemic venous system

The anal valves of Ball are a series of transversely placed semilunar folds linking the columns of Morgagni. They lie along and actually constitute the waviness of the dentate line. They are functionless remnants of the fusion of the post-allantoic gut with the proctodæum.

The crypts of Morgagni (*syn.* anal crypts) are small pockets between the inferior extremities of the columns of Morgagni. Into several of these crypts, mostly those situated posteriorly, opens one **anal gland** by a narrow duct. This duct bifurcates, and the branches pass outward to enter the internal sphincter muscle, in 60 per cent. of people (fig. 1189). Issuing from this ampulla there are three to six tubular subbranches that extend into the inter-muscular connective tissue, where they end blindly. In some lower animals these glands secrete an odoriferous substance during the rutting season; in man their function, if any, is obscure. Some of their cells have been shown to give a positive staining reaction for mucin, but as the lining epithelium is mainly cubical, the mucus-secreting propensity of the anal glands must be extremely small. Infection of an anal gland can give rise to an abscess, and in the opinion of a number of surgeons, infection of an anal gland is the most common cause of ano-rectal abscesses and fistulæ.

FIG. 1189.—Anal gland with duct opening into a crypt of Morgagni.

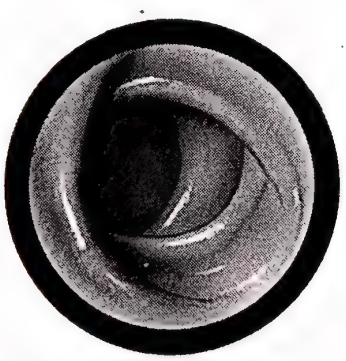

FIG. 1190.—Houston's valves as seen through a sigmoidoscope.

The Rectum[1].—The rectum begins above at the junction of the sigmoid colon with the rectum and ends at the ano-rectal bundle. The recto-sigmoid junction usually lies in front of the lumbar-sacral junction. It describes three lateral curves, two concave to the left (hence the *left* lateral position for sigmoidoscopy) and one concave to the right. The

FIG. 1191.—The disposition of the pubo-rectalis muscle.

[1] The word rectum means 'straight'. It is straight only in infants and the elderly.

Giovanni Battista Morgagni, 1682–1771. Professor of Anatomy, Padua, Italy.
Sir Charles Bent Ball, 1851–1916. Regius Professor of Surgery, Dublin.
John Houston, 1802–1845. Physician, City of Dublin Hospital and Lecturer in Surgery, Dublin.

relative shortness of the longitudinal muscle coat forms the **valves of Houston** that are so much in evidence in sigmoidoscopy (fig. 1190).

The ano-rectal ring marks the junction between the rectum and the anal canal. It is formed by the fusion of the pubo-rectalis muscle (fig. 1191), external sphincter, conjoined longitudinal muscle, and internal sphincter. The ano-rectal ring can be clearly felt digitally, especially on its posterior and lateral aspects. Division of the ano-rectal ring results in permanent incontinence of fæces.

THE BLOOD SUPPLY OF ANAL CANAL AND RECTUM

The superior rectal artery (fig. 1192) is the direct continuation of the inferior mesenteric artery and constitutes the chief arterial supply to the rectum. Opposite the third sacral vertebra the artery divides into a right and a left branch. About half-way down the rectum the right branch subdivides into an anterior and posterior branch. The terminal branches run straight downwards, each in a column of Morgagni.

FIG. 1192.—The arterial supply of the ano-rectum. S.H., superior rectal artery; M.H., middle rectal artery; I.H., inferior rectal artery.

The middle rectal artery arises on each side from the internal iliac artery and passes in close proximity to the lateral ligament of the rectum to supply the muscle coat and mucosa of the mid-rectum. Often it is a comparitively small vessel. After division of the inferior mesenteric artery, in the operation of anterior resection, the middle and inferior rectal arteries can maintain an adequate blood supply as high as the recto-sigmoid junction.

The inferior rectal artery arises on each side as a branch of the internal pudendal artery, as this artery enters Alcock's canal. Crossing the upper part of the ischio-rectal fossa, it breaks up into branches which supply the anal sphincters, anal canal, and the skin of the anal margin.

The internal rectal venous plexus lies in the loose submucosa of the anal canal and extends from the level of the dentate line to that of the ano-rectal ring. The plexus drains into about six collecting veins which are situated in the submucosa of the rectum. About half-way up the rectum these branches pass through the rectal wall, and having reached the outside of the rectum, they unite to form the **superior rectal vein,** an important tributary of the portal vein. The **middle rectal veins** are small and drain into the internal iliac veins.

The external rectal venous plexus lies under the skin of the anal canal below the dentate line and beneath the skin of the anal margin. Communicating veins pass from the external rectal plexus to the internal rectal plexus beneath the anoderm. The lower part of the external rectal plexus drains into the internal pudendal veins and thence into the internal iliac veins, thus providing a link between the portal and systemic venous systems.

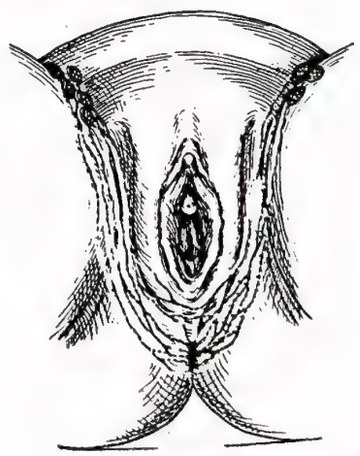

FIG. 1193.—Lymphatic trunks from the anus and the lower part of the anal canal draining into the inguinal lymph nodes. *(After M. P. C. Sappey.)*

LYMPHATIC DRAINAGE OF ANAL CANAL AND RECTUM

The lymphatics of the mucocutaneous lining intercommunicate freely with those of the muscle coats. This free anastomosis accounts for the occasional spread of malignant cells of the rectum into the inguinal lymph nodes. There are, however, three main sets of lymph nodes:

1. **Superior Rectal Lymph Nodes.**—The lymph vessels and nodes keep close to the superior rectal vessels. A special group lie just above the levator ani and close to the rectal wall in the region of the ampulla—they are the pararectal lymph nodes of Gerota. There are larger lymph nodes at the bifurcation of the superior rectal artery and also up to the origin of the inferior mesenteric artery from the aorta.

Benjamin Alcock. Professor of Anatomy, Cork, Ireland (1849–1855). He was dismissed from his post for a breach of the Anatomy Acts, and disappeared in America.
Dumitru Gerota, 1867–1939. Professor of Surgery, Bucharest, Rumania.

2. **Middle Rectal Lymph Nodes.**—Along the lateral ligaments of the rectum lie lymph vessels and nodes close to the middle rectal vessels. From here they pass to the lymph nodes around the internal iliac vessels, which are frequently involved in malignant lesions so that wide excision of the lateral ligaments is indicated.

3. **Inguinal Lymph Nodes.**—The anus and lower portion of the anal canal are drained by lymphatics which pass up to the inguinal lymph nodes (fig. 1193).

There is seldom, if ever, metastasis along the lateral or inferior lymphatic pathways from a carcinoma situated *above* the ampulla of the rectum. This justifies restorative resection in cases of carcinoma high in the rectum.

RECTAL 'FASCIAS

The rectum is separated in front from the bladder and prostate in the male by a condensation of connective tissue—the rectovesical fascia—known as Denonvilliers Fascia.

In both sexes the rectum is separated posteriorly from the last two sacral vertebræ by another condensation of connective tissue known as Waldeyer's Fascia.

These fascial layers are important in that they provide a temporary barrier to the direct invasion of the bladder and prostate in front and the sacrum behind by rectal carcinomas.

SYMPTOMS OF ANO-RECTAL DISEASE

In every case, careful enquiry should be made for pain, prolapse, pruritus, bleeding, discharge, alteration in bowel habit, and loss of weight.

EXAMINATION OF THE ANUS AND RECTUM

Rectal examination should be conducted systematically as follows:

Inspection, e.g. prolapsed hæmorrhoids, sentinel pile, fistula, pruritus ani.

Digital examination.—Intraluminal, e.g. polyp, fæcal impaction.
Intramural, e.g. carcinoma.
Extramural: Male, e.g. prostate.
Female, e.g. contents of pouch of Douglas.

Discharge.—On wiping the fingerstall mucus, pus, or blood may be seen.

Proctoscopy.—(fig. 1194) is of great importance and value. The key to good visualisation is to examine the patient in the knee-elbow position (fig. 1195) or in the left lateral position with the buttocks elevated on a small cushion. This permits air to distend the rectum and causes the pelvic colon to drop away from the proctoscope so that a good view can be obtained.

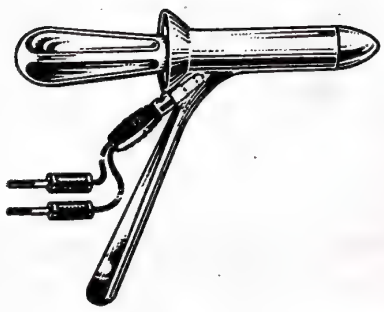

FIG. 1194.—An illuminated proctoscope.

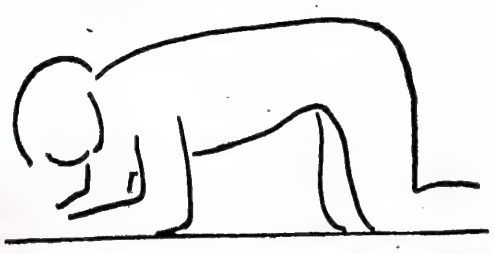

FIG. 1195.—Knee-elbow position for proctoscopy.

Charles Pierre Denonvilliers, 1808–1872. French Surgeon.
Heinrich Wilhelm Gottfried Waldeyer-Hartz, 1836–1921. Professor of Pathological Anatomy, Berlin.
James Douglas, 1675–1742. Anatomist and Obstetrician, London.

Sigmoidoscopy is necessary to visualise the whole length of the rectum and the recto-sigmoid junction. It can be carried out either in the knee-elbow or in the left lateral position.

EMBRYOLOGY

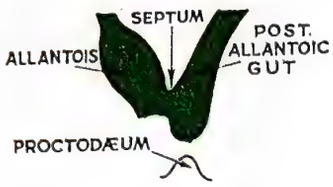

FIG. 1196.

Early in embryonic life there is a common chamber—the cloaca—into which open the hind gut and the allantois. The cloaca becomes separated into the bladder and post-allantoic gut (rectum) by the down-growth of a septum (fig. 1196). About this time an epiblastic bud, the proctodæum, grows in towards the rectum. Normally fusion between these two structures occurs during the third month of intrauterine life.

CONGENITAL ABNORMALITIES

Imperforate Anus[1].—One infant in 4,500 is born with an imperforate anus, or with imperfect fusion of the post-allantoic gut with the proctodæum. The condition is divided into two main groups—the high and the low, depending on whether the termination of the bowel is above or below the pelvic floor. The low varieties are easy to diagnose, simple to treat, and the outlook is good. The high varieties often have a fistula into the urinary tract together with a deficient pelvic floor and the prognosis is not good.

Low Abnormalities (fig. 1197).—(*a*) The *covered anus*: the underlying anal canal is covered by a bar of skin with a track running forward to the perineal raphe. The track should be opened with scissors, followed by routine

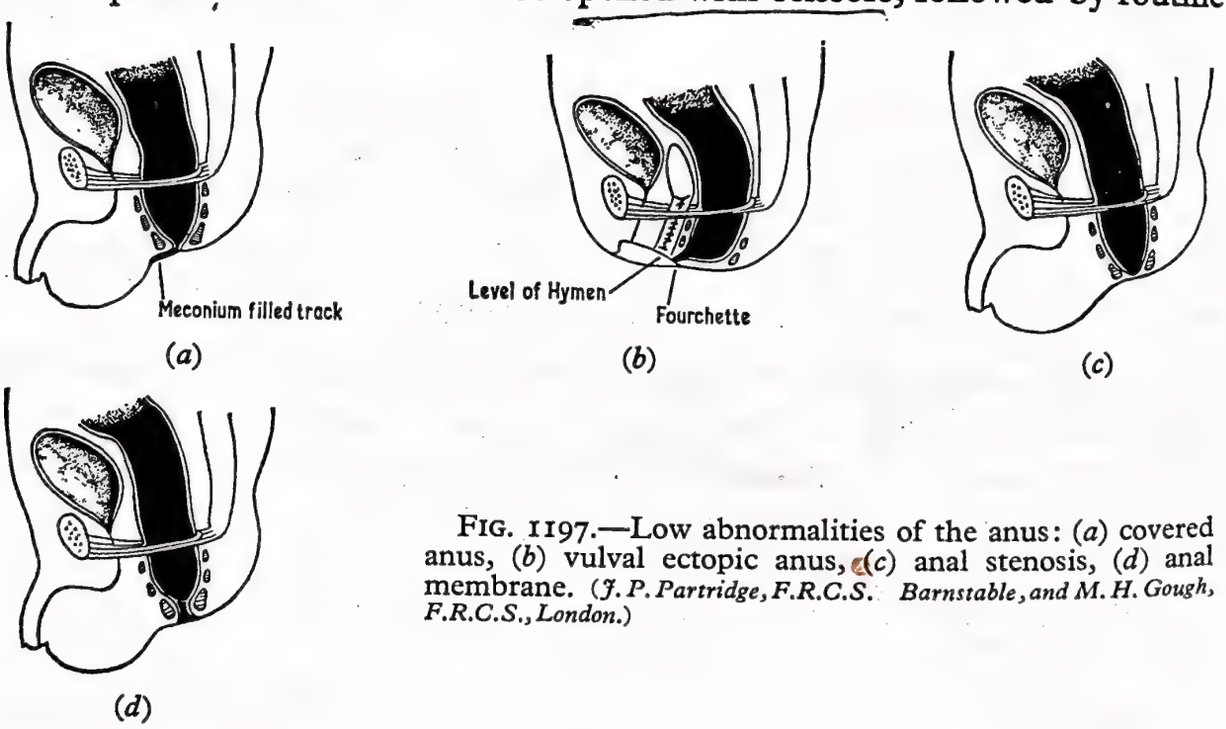

FIG. 1197.—Low abnormalities of the anus: (*a*) covered anus, (*b*) vulval ectopic anus, (*c*) anal stenosis, (*d*) anal membrane. (*J. P. Partridge, F.R.C.S. Barnstable, and M. H. Gough, F.R.C.S., London.*)

dilatation of the anus. (*b*) The *ectopic anus*: the anus is situated anteriorly and may open in the perineum in boys or more commonly in the vulva in girls, or rarely into the vagina. A plastic 'cut-back' operation is required. (*c*) The *stenosed anus*: the anus is microscopic but careful examination usually reveals a minute opening which responds to regular dilatation. (*d*) *Membranous stenosis*: here the anus is normally sited but is covered with a thin membrane

[1] The term imperforate anus is used as a well-recognised description. Strictly it should be 'agenesis' and 'atresia' of the rectum and anus.

which bulges with retained meconium. It is rare, and an incision will cure the condition.

High Abnormalities (fig. 1198).—These are often associated with a fistulous connection between the blind rectal stump and the bladder, or other abnormalities of the pelvic structures. (1) *Ano-rectal Agenesis.*—A blind rectal pouch lies just above the pelvic floor—its anterior aspect in the male is attached to the bladder and often there is a recto-vesical fistula manifested by the passage of gas or meconium in the urine. In the female the fistula is usually into the posterior fornix. (2) *Rectal Atresia.*—The anal canal is normal but ends blindly at the level of the pelvic floor. The bowel also ends blindly above the pelvic floor without a fistulous opening. This anomaly is rare but must be treated by mobilisation of the rectum and excision of the stricture. After that, end-to-end anastomosis of the anus and rectum must be attempted. More conservative measures are followed by an intractable stricture. (3) *Cloaca.*—This occurs only in females and here the bowel, urinary and genital tracts all open into a common wide cavity (fig. 1196). Commonly severe malformations of the area are associated with other developmental abnormalities (e.g. tracheo-bronchial fistula).

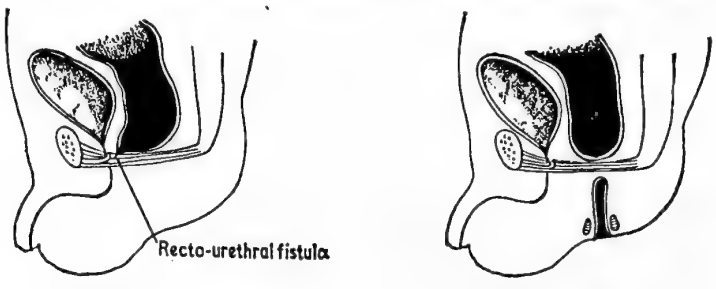

FIG. 1198.—High abnormalities: (*a*) ano-rectal agenesis with recto-urethral fistula, (*b*) rectal atresia. (*J. P. Partridge, F.R.C.S., Barnstaple, and M. H. Gough, F.R.C.S., London.*)

Clinical Management.—As congenital abnormalities are frequently multiple, very careful general examination of the baby must be made to exclude any other anomalies. It is urgent and important to determine whether the abnormality is high or low and an X-ray will help.

FIG. 1199.—X-ray of neonate while held upside down to show gas in rectum. Anal dimple marked by piece of lead shot. (*Graham Airth, Bristol.*)

X-ray Examination.—Six hours after birth sufficient air may have collected in the large intestine to cast an X-ray shadow. With a metal button or a coin strapped to the site of the anus, or a metal bougie inserted into the blind anal canal, the infant is held upside down for three to four minutes and radiographed in the inverted position (fig. 1199). The gas in the rectum will rise to the top and indicate the distance between the site of the metal indicator and the blind end of the rectum. If the distance is over 2·5 cm, the abnormality is 'high'. This method, though useful, is sometimes vitiated by a plug of meconium in the rectum causing an apparent gap far in excess of that actually present. It may be necessary to wait till the baby is twenty-four hours old before rectal gas appears.

Where a 'high' lesion is suspected an effort must be made to obtain a specimen of urine—the presence of *proteus* or *pyocyaneus* usually signifies that a fistula is present. An excretory radiograph is recommended by some, even though there is a definite radiation risk. There may be gas in the bladder. A diagnostic perineal exploration is usually unwise—it may prejudice the chances of further surgery.

Treatment.—In the *low* abnormalities this is usually simple and has been outlined when each condition was described above. The *high* abnormalities present a very difficult problem and each case must be considered on its merits. On the whole, newborn babies stand surgery very well, provided compatible blood is available and a clear airway is maintained post-operatively and inhalation of vomit prevented by naso-gastric suction. The presence of other congenital abnormalities is also a most important factor to consider. The possibilities are:

1. Laparotomy, division of recto-urethral fistula, and transverse colostomy. A rectal 'pull-through' operation can be done later.
2. Laparotomy, division of fistula, and 'pull-through' operation in one stage.
3. Division of the fistula and rectal 'pull-down' operation through the (*a*) perineal or (*b*) sacral route (this method is now rarely used).
4. Colostomy only (for the cloacal variety).

For the 'pull-through' operation the lower bowel is mobilised, and a new passage is created through the pelvic floor by passing a pair of curved forceps through it, keeping close to the urethra, to the site of the future anus. This is dilated by Hegar's dilators so that the bowel can be pulled down and its mucosa stitched to the skin of the newly formed anus. (For details the reader is referred to the standard textbooks of operative surgery.)

In general, daily dilatation will be required for at least three months and it may be necessary for years.

In a high percentage of cases, imperforate anus is associated with other congenital abnormalities, especially of the urinary organs, and nearly half the deaths in cases of imperforate anus are due to other malformations.

Sacro-coccygeal teratoma, although rare, is among the most common of the large tumours seen during the first three months of life. The frequency of the pre-coccygeal region for the development of a teratoma is explained by the fact that this area is the site of the 'primitive knot', a group of totipotent cells that retain their totipotentiality longer than any others save the sex anlage. Females are more often affected than males.

FIG. 1200.—Congenital sacro-coccygeal teratoma. The tumour was excised successfully.

The tumour, which arises between the sacrum and the rectum, is firmly attached to the coccyx, and occasionally to the last piece of the sacrum. At the time of birth some of these tumours are huge, and in 20 per cent. of cases the infant is still-born. In most instances the tumour is large (fig. 1200), but in a few it is small enough to pass unnoticed until it enlarges or a complication ensues. It is this variety that is prone to become malignant, usually at about ten months of age.

Treatment.—Removal soon after birth; delay is liable to result in fatal ulceration, infection, rectal or urinary obstruction, or a malignant change.

Alfred Hegar, 1830–1914. Professor of Obstetrics and Gynæcology, Freiburg, Germany.

Operation.—Excision is undertaken through a longitudinal elliptical incision, the coccygeal attachment being left until the last. The coccyx must always be excised; occasionally the last piece of the sacrum must be removed also. There may be a fistula between the tumour and the rectum but as a rule this is small, and can be closed safely without performing a colostomy. The dead space in the pelvis is drained, the skin is united, and a pressure dressing applied.

When the operation is undertaken soon after birth, the prognosis is good.

Post-anal Dermoid.—The space in front of the lower part of the sacrum and coccyx is occupied by a soft, cystic swelling—a post-anal dermoid cyst—which is regarded as a simple form of teratoma. Hidden in the hollow of the sacrum, it is unlikely to be discovered unless a sinus communicating with the exterior is present, or develops as a result of inflammation. Such a cyst usually remains symptomless until adult life, when it is prone to become infected. Exceptionally, by its very size, it gives rise to difficulty in defæcation. The cyst is easily palpable on rectal examination.

Differential Diagnosis.—Especially in a child, an anterior sacral meningocele must be excluded. The latter enlarges when the child cries, and is frequently associated with paralysis of the lower limbs, and incontinence. When a discharging sinus is present, a post-anal dermoid will probably be mistaken for a pilonidal sinus, unless pressure over the sacro-coccygeal region with a finger in the rectum causes a flow of sebaceous material, and/or injection of lipiodol and radiography reveals a bottle-necked cyst in front of the coccyx (fig. 1201).

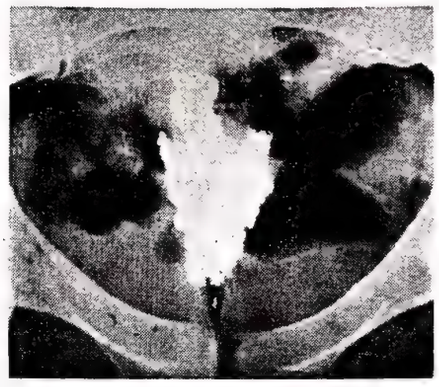

FIG. 1201.—Post-anal dermoid cyst with sinus. Injected with lipiodol. Sinus and cyst excised.

Treatment is complete excision of the cyst, and sinus if present. In the case of large cysts it is necessary to remove the coccyx in order to gain access.

Post-anal Dimple (*syn.* Fovea Coccygea).—A dimple, sometimes amounting to a short, blind pit, in the skin beneath the tip of the coccyx is noticed from time to time in the course of a clinical examination; Klass observed it in 9 per cent. of a large number of recruits. A dimple in this situation has the same significance as a dimple at other sites; it represents nothing more than a local fixation of skin by collagen fibres to underlying structures. Such a dimple is a possible starting-point of a pilonidal sinus.

PILONIDAL[1] SINUS

Ætiology.—The army of supporters of the congenital theory of the origin of pilonidal sinus has become reduced to a corporal's guard.

That, in rare instances, a sinus in the ano-coccygeal area *is* congenital must be allowed, but in these cases of proven congenital origin the sinus is not necessarily pilonidal. It could be (*a*) a sinus connected with a post-anal dermoid, referred to above, or (*b*) a sinus resulting from a persistent caudal remnant of the original neural canal. The latter occurs in the sacral rather than the coccygeal region, and is definitely connected with the spinal theca. On this account, meningitis from an extradural abscess may occur in a child.

The reasons which support the acquired theory of origin of pilonidal sinus can be summarised thus:

1. Interdigital pilonidal sinus is an occupational disease of men's hairdressers, the hair within the interdigital cleft or clefts being the customers'. Also pilonidal sinuses of the axilla and umbilicus have been reported.

2. The age incidence of the appearance of pilonidal sinus (82 per cent.

[1] Appertaining to a nest of hair. (Latin—*pilus* = hair, *nidus* = nest.)

Alan Arnold Klass, Contemporary. Surgeon, Winnipeg General Hospital, Canada.

occur between the ages of twenty and twenty-nine years) is at variance with the age of onset of congenital lesions.

3. Hair follicles have never been demonstrated in the walls of the sinus.

4. The hairs projecting from the sinus are dead hairs, with their pointed ends directed towards the blind end of the sinus.

5. The disease mostly affects men, and hairy men most frequently.

6. Recurrence is common, even though adequate excision of the track is carried out.

The mode of origin of a pilonidal sinus is now believed to be as follows:

On sitting, the buttocks take the weight of the body, and move independently, or together. Hairs broken off by friction against clothing also shed short hairs, whether originating from the nape of the neck, back, or buttocks, tend to collect in the cleft of the nates and/or a post-anal dimple. Furthermore, it is suggested that the use of toilet paper may contribute to hair entangled in fæcal matter being swept into the cleft; pilonidal sinus is extremely rare in those races that employ ablution after defæcation. By reason of the shearing action of the buttocks, which is increased by sitting on a hard seat, and especially by vibration of a vehicle, loose hair travels down the intergluteal furrow, to penetrate the skin or the open mouth of a sudoriferous gland, such glands being more active in early manhood. It is not yet clear whether the initial entry of hairs through the skin is a primary event, or follows the softening of the skin due to pustular or other forms of dermatitis. Once a sinus has formed, intermittent negative pressure of the area may suck other loose hairs into the pit. So common was pilonidal sinus among jeep[1] riders in the 1939–45 war that it became known as ' jeep bottom '.

Pathology.—The sinus extends into the subcutaneous planes as an infected track. Branching side channels are not infrequent. A stratified squamous epithelial lining, of varying degrees of integrity, is found in about half the cases. Hair shafts are found either (*a*) lying loose in the sinus, (*b*) embedded in granulation tissue, or (*c*) deep in mature scar tissue in three-quarters of the cases. Foreign body giant cells are common.

Clinical Features.—There is a chronic or recurring sinus in the middle line about the level of the first piece of the coccyx (fig. 1202). Typically a tuft of hairs projects from its mouth. The discharge from the sinus or sinuses is often blood-stained, contains foul sebum, and sometimes hairs. Secondary openings may be present on either side of the midline, often far out on to the buttocks or in the perineum.

FIG. 1202.—Pilonidal sinus. (*R. S. Lawrie, F.R.C.S., London.*)

As has been indicated already, symptoms usually commence during the third decade; patients presenting later in life nearly always give a history dating back to this period.

Males with this condition outnumber females by four to one, the females being on an average three years younger than the males; this corresponds to the earlier maturation of the female. The condition rarely occurs in blondes; many of the patients are exceptionally hairy and are usually obese. In spite of the preponderance in dark-haired persons, whose hair is stiffer than the silky blonde (Oldham), the condition is practically confined to white races.

[1] Jeep—U.S. Army reconnaissance motor vehicle.

James Bagot Oldham, ?–1977. Surgeon, United Liverpool Hospitals, Liverpool, England.

The complaint is of a discharge, pain, or a tender swelling at the bottom of the spine. Even at the height of an attack of inflammation the constitutional symptoms are slight. Often there is a history of repeated abscesses in the region that have discharged spontaneously or have been incised. The primary sinus may have one, or as many as six openings, all of which are strictly in the middle line between the level of the sacrococcygeal joint and the tip of the coccyx. Unlike a fistula-in-ano, the sinus passes upwards and forwards towards the sacrum. It does not reach bone, but ends blindly near the bone. When an abscess forms it may discharge through a primary sinus; more frequently it points and bursts, or is incised to one side of the middle line (usually the left), thus forming a secondary sinus.

Conservative Treatment.—Patients reporting for the first time with mild symptoms can sometimes be cured by conservative measures, which consist of cleaning out the track, removing all hairs from the area, followed by frequent washing of the parts with a detergent and water, and applying equal parts of witch hazel (Liq. Ext. Hamamelis) and alcohol. Long sitting, e.g. driving a car, is avoided if possible. These measures, tried on a large scale in the U.S. Army, proved tolerably successful—more successful than similar attempts in civil life, because the sufferer could be relegated to duties that were unlikely to aggravate the condition.

Treatment of an Acute Exacerbation.—If rest, baths, local antiseptic dressings, and the administration of a broad spectrum antibiotic fail to bring about resolution, the abscess should be opened through a comparatively small incision. Provided all hairs and granulation tissue are removed from the abscess cavity, there is some prospect of curing the lesion (Millar). After it has been cleaned out, the track can be destroyed by careful installation of pure phenol solution (Maurice). In all other circumstances an elective operation must be planned.

Operation should be performed only when the inflammation has been controlled by the measures indicated already.

The patient is placed on the operating table, for preference in the 'jack-knife' position. Methylene blue is injected into the sinus to colour all the tracts, the nozzle of the syringe being pressed against the opening to obtain some pressure. Variations in operative technique include the following:

1. Lay open the tracts, remove all debris and hair, and suture the edges to the skin, thus marsupializing the sinus. This procedure yields a good hairless scar.
2. Excise all the tracts as stained by the blue dye and, after securing haemostasis by diathermy and catgut ligature, pack the wound. The following day the whole dressing is removed, and daily baths and moist dressings are instituted until the wound heals by granulation. Epithelialisation can sometimes be speeded up by skin grafting.
3. Excise all the tracts, secure haemostasis as above, and, using sutures coapt the subcutaneous fat and skin very accurately and institute a drain and suction (i.e. Redivac) for 48 hours to remove blood and serum. In cases of extensive sinus formation primary cover may be achieved by rotating a flap of skin and fat.

Immediately after operation the patient should avoid sitting on the wound. Subsequently, the scar may require protection from further incursions of hair by selective hair-trimming.

Recurrent Pilonidal Sinus.—Three possibilities account for this disappointment. (1) A diverticulum of the main channel has been overlooked

Douglas Malcolm Millar, Contemporary. Surgeon, Essex County Hospital, Colchester.
Brian Armstead Maurice, Contemporary. Surgeon, Tunbridge Wells, Kent.

at the primary operation. (2) New hairs enter the skin or the scar. (3) When the natal fold is deformed by scarring, the least trauma causes tearing of the scar, and the resulting crevice becomes contaminated with coliform and cutaneous bacteria.

FIG. 1203.—Rectal impalement by a broken shooting-stick.

INJURIES

The rectum or anal canal may be injured in a number of ways, all uncommon.

1. By falling in a sitting posture on to a spiked or blunt-pointed object. The up-turned leg of a chair, handle of a broom, floor-mop, pitch-fork, or a broken shooting-stick (fig. 1203) have all resulted in rectal impalement.
2. By the fœtal head during childbirth.
3. During the administration of an enema by a syringe fitted with a bone, glass, or vulcanite nozzle.
4. During sigmoidoscopy, usually when examining a patient suffering from ulcerative procto-colitis or amœbic dysentery. Sigmoidoscopy performed under general anæsthesia is especially dangerous.
5. ' Split Perineum '. A lacerated wound of the perineum, involving the anal canal, is an occasional pillion-riding accident.
6. Compressed-air rupture (p. 965).

Diagnosis.—When there is a history of rectal impalement, the first interrogation should be, ' Has the patient passed urine since the accident? ' The anus having been inspected, the abdomen should be palpated. If rigidity or tenderness is present, early laparotomy is imperative. Prior to the operation an urethral catheter is passed. If the urine is blood-stained and/or the quantity recovered is unexpectedly small, it is wise to suspect ruptured bladder or urethra (pp. 1196 and 1260).

Treatment.—After the patient has been anæsthetised, the rectum is examined with a finger and a speculum, especial attention being directed to the anterior wall. Left lower laparotomy is then performed. If an intraperitoneal rupture of the rectum is found, the perforation is closed with sutures. Should blood be present beneath the pelvic peritoneum, it is necessary to mobilise the recto-sigmoid, which allows the rectum to be drawn upwards, thus permitting the perforation below the pelvic diaphragm to be closed securely. A perforation in the bladder also can be sutured *via* this avenue. After closing the laparotomy wound, a left iliac colostomy is performed through a separate grid-iron incision. In cases where the bladder has been injured a self-retaining urethral catheter is placed in position.

If the rectal injury is below the pelvic floor, wide drainage from below is indicated. A 'protective' colostomy is advisable. Care must be taken to preserve sphincter function during the debridement of the perineal wounds. Antibiotic cover should be provided against both aerobic and anaerobic organisms.

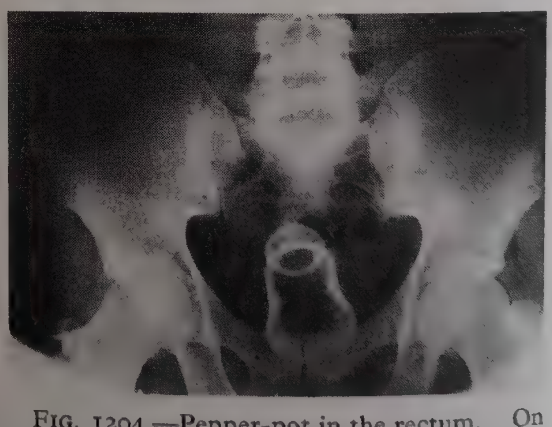

FIG. 1204.—Pepper-pot in the rectum. On removal it was found to be inscribed ' A present from Margate '| *(Dr. L. S. Carstairs, Royal Northern Hospital, London.)*

FOREIGN BODIES IN THE RECTUM

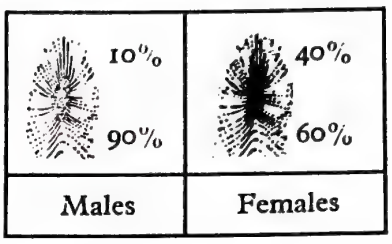
The variety of foreign bodies which have found their way into the rectum is hardly less remarkable than the ingenuity displayed in their removal (fig. 1204). A turnip has been delivered *per anum* by the use of obstetric forceps. A stick firmly impacted has been withdrawn by inserting a gimlet into its lower end. A tumbler, mouth looking downwards, has been extracted by filling the interior with a wet plaster of Paris bandage, leaving the end of the bandage protruding, and allowing the plaster to set.

If insurmountable difficulty is experienced in grasping any foreign body in the rectum, a left lower laparotomy is necessary, which allows that object to be pushed from above into the assistant's fingers in the rectum. If there is considerable laceration of the mucosa a temporary colostomy is advisable.

ANAL FISSURE (*syn.* FISSURE-IN-ANO)

Definition.—An elongated ulcer in the long axis of the lower anal canal.

Location.—The site of election for an anal fissure is the mid-line posteriorly. The next most frequent situation is the mid-line anteriorly. The relative distribution of fissure in these two sites is ——————→



Ætiology.—The cause of anal fissure, and particularly the reason why the midline posteriorly is so frequently affected, is not completely understood. A probable explanation is as follows: the posterior wall of the rectum curves forwards from the hollow of the sacrum to join the anal canal, which then turns sharply backwards. During defæcation the pressure of a hard fæcal mass is mainly on the posterior ano-rectal angle (fig. 1205) in which event the overlying epithelium is greatly stretched, and, being relatively unsupported by muscle, is placed in a vulnerable position when a scybalous mass is being expelled. Possibly some cases are due to tearing down of an anal valve of Ball. As shown by the above percentages, an anterior anal fissure is much more common in women, particularly in those who have borne children. This can be explained by the lack of support of the anal mucous membrane by a damaged pelvic floor.

One cause of anal fissure is certain—an incorrectly performed operation for hæmorrhoids in which too much skin is removed. This results in anal stenosis and tearing of the stricture when a hard motion is passed.

FIG. 1205.—Probable mechanism of tearing of the anal mucosa in the case of a posterior fissure.

Pathology.—An anal fissure is either acute or chronic. The upper internal end of the fissure stops at the dentate line. Because the fissure occurs in the stratified sensitive epithelium of the lower half of the anal canal, pain is the most prominent symptom (*vide infra*).

Acute anal fissure is a deep tear through the skin of the anal margin extending into the anal canal. There is little inflammatory induration or œdema of its edges. There is always spasm of the anal sphincter muscle.

Chronic anal fissure is characterised by inflamed indurated margins, and a base consisting of either scar tissue or the lower border of the internal sphincter muscle. The ulcer is canoe-shaped, and at the inferior extremity frequently there is a tag of skin, usually œdematous. This tag is known picturesquely as a sentinel pile—'sentinel' because it guards the fissure. There is usually spasm of the involuntary musculature of the internal sphincter. In long-standing cases this muscle becomes organically contracted by infiltration of fibrous tissue. Infection is common and may be severe, ending in abscess formation. A cutaneous fistula may follow.

Chronic fissure-in-ano may have a specific cause—often a granulomatous infection, *e.g.* Crohn's disease or syphilis. Biopsy examination is advisable of any tissue removed at operation for a chronic fissure. Specific fissures

of this type are often less painful than the appearances of the lesion would suggest.

Clinical Features.—The condition is more common in women, and generally occurs during the meridian of life. It is uncommon in the aged, because of muscular atony; on the other hand anal fissure is not rare in children, is sometimes encountered during infancy, and may cause acquired mega-colon (p. 964).

Pain is *the* symptom—sharp agonising pain starting during defæcation, often overwhelming in intensity and lasting an hour or more. As a rule it ceases suddenly, and the sufferer is comfortable until the next action of the bowel. Periods of remission occur for days or weeks. The patient tends to become constipated rather than go through the agony of defæcation.[1]

Stools are frequently streaked with blood.

Discharge.—A slight discharge accompanies fully established cases.

On Examination.—In cases of some standing, a sentinel skin tag can usually be displayed. This, together with a typical history and a tightly closed, puckered anus, is almost pathognomonic of the condition. By gently parting the margins of the anus, the lower end of the fissure can be seen.

Because of the intense pain it causes, digital examination of the anal canal should not be attempted at this stage unless (*a*) the fissure cannot be seen or (*b*) it seems imperative to exclude some intrarectal condition. In these circumstances the local application of a surface anæsthetic such as 5 per cent. xylocaine on a pledget of cotton-wool, left in place for about five minutes, will enable the necessary examination to be made. In early cases the edges of the fissure are impalpable; in fully established cases a characteristic crater which feels like a vertical buttonhole can be palpated. Proctoscopy is necessary. A general anæsthetic may be needed.

Differential Diagnosis:

Carcinoma of the anus in its very early stages easily simulates a fissure. If real doubt exists, the lesion must be excised under general anæsthesia and submitted to histological examination.

FIG. 1206.—Anal chancre.

Multiple fissures in the peri-anal skin are seen as a complication of pruritus ani (p. 1068) and procto-colitis (p. 1073).

Anal chancre (fig. 1206) is becoming more common and may present as a *painful* rather than a painless ulcer (p. 40). The serous discharge contains spirochætes. A glass pipette is used to aspirate a few drops which are placed on a slide for examination by dark-ground illumination. Lubricating gel from the finger-stall may prevent adequate aspiration of serum from a chancre.

Tuberculous ulcer (p. 61) has an undermined edge.

Proctalgia Fugax (p. 1060) causes severe episodic pain.

Treatment.—The pain of an anal fissure is so great that usually the patient demands relief, and consequently many patients with an acute fissure present

[1] One patient accustomed himself to take a generous dose of senna on Saturday night, and retire to the toilet on Sunday morning with a bottle of whisky and the newspaper.

early. The object of all treatment for this condition is to obtain *complete relaxation* of the internal sphincter. Provided the complications are dealt with, the fissure will slowly heal as soon as all spasm has disappeared.

Conservative Treatment.—In cases where the fissure is acute and superficial and where the inflammation is minimal, simple conservative measures will usually give relief. Xylocaine 5 per cent. in a water-soluble lubricant is introduced with a fine nozzle into the anal canal. After waiting a few minutes for the surface anæsthetic to act, relaxation may be sufficient to permit the passage of a well-lubricated finger into the canal. Following this a small anal dilator (fig. 1207) may be passed and, if the anæsthesia is adequate, it may be possible to introduce the largest dilator. Anal dilators are commonly made in three sizes and it may not be possible to use the largest dilator until several days have passed. The patient is supplied with xylocaine lubricant and instructed to pass a dilator twice a day for a month, by which time the fissure is usually healed. Laxatives are prescribed to ensure that the motions are soft, but the stools should not be made watery: Celevac 10 ml b.d. gives a soft stool of good bulk, which is ideal.

FIG. 1207.—St. Mark's Hospital (London), anal dilator.

Operative Measures

The simplest procedure is wide dilatation of the sphincter. Under general anæsthesia the index and middle finger of each hand are inserted simultaneously into the anus and pulled apart to give maximal dilatation. The patient can go home the same day but should be warned that there may be some fæcal incontinence lasting possibly for a week or ten days.

Should these measures prove ineffective, or if the fissure is chronic with fibrosis, a skin tag, or a mucous polypus, then operative measures are advisable. General anæsthesia is best, though some surgeons use a local anæsthetic in the form of xylocaine or proctocaine introduced into the ischio-rectal fossa on each side, in order to anæsthetise the nerves passing towards the rectum.

(i) *Dorsal fissurectomy and sphincterotomy.* With the patient in the lithotomy position a well greased Sims' speculum is introduced. This will permit a very good view of the fissure which becomes stretched to show the fibres of the internal sphincter running transversely in its floor. The essential part of the operation is to divide all of these transverse fibres so that the floor of the fissure is completely smooth. If a sentinel pile is present, this is excised. The ends of the divided muscle retract and a smooth wound is left. The after-treatment consists of attention to bowels, a daily bath, and the passage of an anal dilator until the wounds have healed, which usually takes about three weeks. Despite the presence of the wound there is little or no pain and the final results are excellent. The disadvantage of this operation is the prolonged healing time—usually not less than three weeks and often longer—and occasionally a mild, persistent and permanent mucus discharge.

(ii) *Lateral anal sphincterotomy* (Notaras). In this operation, the internal sphincter is divided away from the fissure itself—usually either in the right or the left lateral positions. The procedure can be done by an open or a closed method. Healing is usually complete within three weeks. The operation is more successful for acute than chronic fissures. 75% of cases are suitable for treatment by this method. The patients are able to leave hospital within three or four days, and the procedure can be done as an Out-Patient under local anæsthesia by an experienced surgeon.

HYPERTROPHIED ANAL PAPILLA

Anal papillæ occur at the dentate line, and are remnants of the ectodermal membrane that separated the hind-gut from the proctodæum. As these papillæ are present in

James Marion Sims, 1813–1883. Gynæcological Surgeon, State Hospital for Women, New York, U.S.A.
Mitchell James Notaras, Contemporary. Surgeon, Barnet General Hospital, London.

fully 60% of patients examined proctologically, they should be regarded as normal structures. Anal papillæ can become elongated, as they frequently do in the presence of an anal fissure. Occasionally an elongated anal papilla may be the cause of pruritus. An elongated anal papilla associated with pain and/or bleeding at defæcation, is sometimes encountered in infancy. Hæmorrhage into a hypertrophied anal papilla can cause sudden rectal pain. A prolapsed papilla may become nipped by contraction of the sphincter mechanism after defæcation. Occasionally a red œdematous papilla is encountered with local pain and a purulent discharge from the associated crypt. This condition of 'cryptitis' is more frequently seen abroad, but may be cured by laying open the mouth of the infected anal gland and removing the papilla.

Treatment.—Using a slotted proctoscope, elongated papillæ without hæmorrhoids should be crushed and excised after injecting the base with local anæsthetic. When elongated papillæ complicate internal hæmorrhoids, this is an indication for operative treatment of the hæmorrhoids, as well as excision of the elongated papillæ.

PROCTALGIA FUGAX

This disease is characterised by attacks of severe pain arising in the rectum, recurring at irregular intervals and apparently unrelated to organic disease. The pain is described as cramp-like, often occurs when the patient is in bed at night, lasts only a few minutes, and disappears spontaneously. It may follow straining at stool, sudden explosive bowel action or ejaculation. It seems to occur more commonly in patients suffering from anxiety or undue stress and also it is said to afflict young doctors. The pain may be unbearable—it is possibly due to segmental cramp in the pubo-coccygeus muscle. It is unpleasant, incurable, but fortunately harmless and gradually subsides.

HÆMORRHOIDS[1, 2] (*syn.* PILES[3])

Hæmorrhoids are dilated veins occurring in relation to the anus, and originating in the subepithelial plexus formed by radicles of the superior, middle, and inferior rectal veins.

FIG. 1208.—Carcinoma of the rectum associated with hæmorrhoids. A not infrequent diagnostic pitfall.

Such hæmorrhoids may be **external** or **internal**—external or internal to the anal orifice. The external variety are covered by skin, while the internal variety lie beneath the mucous membrane. When the two varieties are associated, they are known as **intero-external** hæmorrhoids.

Hæmorrhoids may be '*symptomatic*' of some other condition, and this important fact must be remembered when they are found. Symptomatic hæmorrhoids may appear (*a*) in *carcinoma of rectum*. This, by compressing or causing thrombosis of the superior rectal vein, gives rise to hæmorrhoids (fig. 1208) sufficiently often to warrant examination of the rectum and the recto-sigmoid junction for a neoplasm in every case of hæmorrhoids. (*b*) During *pregnancy*. Pregnancy piles are due to compression of the superior rectal veins by the pregnant uterus and the effect of progesterone on the smooth muscle in the walls of the veins. (*c*) From *straining at micturition* consequent upon a stricture of the urethra—or an enlarged prostate. (*d*) From chronic constipation.

N.B. Contrary to the usual belief, in one hundred and twenty-eight consecutive cases of portal hypertension,

---

[1] 'The common people call them piles, the aristocracy call them hæmorrhoids, the French call them figs—what does it matter so long as you can cure them?'—John of Arderne, 1370.

[2] Greek—*haima* = blood, *rhoos* = flowing. [3] Latin—*pĭla* = a ball.

John of Arderne, ?1306–?1390. The first English surgeon. He practised in Newark and later in London.

Macpherson did not encounter a single example of hæmorrhoids that could be attributed to portal cirrhosis, although bleeding œsophageal varices often complicate portal hypertension (p. 868).

The great majority of hæmorrhoids are not symptomatic, and the description that follows concerns hæmorrhoids that are *not* a manifestation of some underlying cause.

INTERNAL HÆMORRHOIDS

Internal hæmorrhoids, which include intero-external hæmorrhoids, are exceedingly common. Essentially the condition is a varicosity of the internal rectal plexus, but because of the communication between the internal and external rectal plexuses, if the former becomes varicose, the latter is liable to become involved also.

Ætiology: *Hereditary.*—The condition is so frequently seen in members of the same family that there must be a predisposing factor, such as a congenital weakness of the vein walls or an abnormally large arterial supply to the rectal plexus.

Varicose veins of the legs and hæmorrhoids often occur concurrently.

Morphological.—In quadrupeds, gravity aids, or at any rate does not retard, return of venous blood from the rectum. Consequently venous valves are not required. In man, the weight of the column of blood unassisted by valves produces a high venous pressure in the lower rectum, unparalleled in the body. Such a pressure may be resisted by a cushioning effect of the columns of mucous membrane (Thomson). Except in a few fat, old dogs, hæmorrhoids are exceedingly rare in animals.

Anatomical.—(1) The collecting radicles of the superior rectal vein lie unsupported in the very loose submucous connective tissue of the rectum. (2) These veins pass through muscular tissue and are liable to be constricted by its contraction during defæcation. (3) The superior rectal veins, being tributaries of the portal vein, have no valves.

Exciting Causes.—Straining accompanying constipation or that induced by over-purgation is considered to be a potent cause of hæmorrhoids. Less often the diarrhœa of enteritis, colitis, or the dysenteries aggravates latent hæmorrhoids.

Pathology.—Internal hæmorrhoids in association with the terminal divisions of the superior rectal artery are arranged in three groups at 3, 7, and 11 o'clock with the patient in the lithotomy position (fig. 1209).[1] This distribution is due to the arterial supply of the anus whereby there are two subdivisions of the right branch of the superior rectal artery, but the left branch remains single. In between these three primary hæmorrhoids there may be smaller secondary hæmorrhoids. Each principal hæmorrhoid can be divided into three parts:

FIG. 1209.—Proctoscopy third-degree hæmorrhoids. Note their 3, 7, and 11 o'clock positions. (*E. T. C. Milligan, F.R.C.S., London.*)

The pedicle is situated in the rectum just above the ano-rectal ring. As seen through a proctoscope, it is covered with pale pink mucosa through which large tributaries of the superior rectal vein can be seen. Occasionally a pulsating artery can be felt in this situation.

The internal hæmorrhoid, which commences at the ano-rectal ring and ends at the dentate line. It is bright red or purple, and covered by mucous membrane.

[1] Lithotomy position = the position in which patients used to be put for the classical operation of 'cutting' for bladder stone via the urethral or the perineal route.

Archibald Ian Stewart Macpherson, Contemporary. Surgeon, Royal Infirmary, Edinburgh.
William Hamish Fearon Thomson, Contemporary. Surgeon, Gloucestershire Royal Hospital, Gloucester, England.

An external associated hæmorrhoid lies between the dentate line and the anal margin. It is covered by skin, through which blue veins can be seen, unless fibrosis has occurred. This associated hæmorrhoid is present only in well-established cases.

Entering the pedicle of each internal hæmorrhoid is a terminal branch of the superior rectal artery. Very occasionally there is a hæmangiomatous condition of this artery—an ' arterial pile '.

Clinical Features.—*Bleeding*, as the name hæmorrhoid implies, is the principal and earliest symptom. At first the bleeding is slight; it is bright red and occurs during defæcation (a ' splash in the pan '), and it may continue thus for months or years. Hæmorrhoids that bleed but do not prolapse outside the anal canal are called *first-degree hæmorrhoids*.

Prolapse is a much later symptom. In the beginning the protrusion is slight and occurs only at stool, and reduction is spontaneous. As time goes on the hæmorrhoids do not reduce themselves, but have to be replaced digitally by the patient. Hæmorrhoids that prolapse on defæcation but return or need to be replaced manually and then stay reduced are called *second-degree hæmorrhoids*. Still later, prolapse occurs during the day, apart from defæcation, when the patient is tired or exerts himself. Hæmorrhoids that are permanently prolapsed are called *third-degree hæmorrhoids*. By now, the hæmorrhoids have become a source of great discomfort and cause a feeling of heaviness in the rectum.

Discharge.—A mucoid discharge is a frequent accompaniment of prolapsed hæmorrhoids. It is composed of mucus from the engorged mucous membrane, sometimes augmented by leakage of ingested liquid paraffin. *Pruritus* will almost certainly follow this discharge.

Pain is absent unless complications supervene.

Anæmia can be caused very rarely by persistent profuse bleeding from hæmorrhoids.

On inspection there may be no evidence of internal hæmorrhoids. In more advanced cases redundant folds or tags of skin can be seen in the position of one or more of the three primary hæmorrhoids. When the patient strains, internal hæmorrhoids may come into view transiently, or if they are of the third degree they prolapse and remain prolapsed.

Digital examination.—Internal hæmorrhoids cannot be felt unless they are thrombosed.

Proctoscopy.—A proctoscope is passed to its fullest extent and the obturator is removed. The instrument is then slowly withdrawn. Just below the ano-rectal ring internal hæmorrhoids, if present, will bulge into the lumen of the proctoscope.

Complications:

Profuse hæmorrhage is not rare. Most often it occurs in the early stages of the second degree. The bleeding occurs mainly externally, but it may continue internally after the bleeding hæmorrhoid has retracted or has been returned. In these circumstances the rectum is found to contain blood.

Strangulation.—One or more of the internal hæmorrhoids prolapse and become gripped by the external sphincter. Further congestion follows because the venous return is impeded. Second-degree hæmorrhoids are most often complicated in this way. Strangulation is accompanied by considerable pain, and is often spoken of by the patient as an 'acute attack of piles'.[1] Unless the internal hæmorrhoids can be reduced within an hour or two, strangulation is followed by thrombosis.

FIG. 1210. — An attack of piles. Prolapsed strangulated piles, as commonly seen, on the left. A less common mass on the right with a fibro-fatty covering.

Thrombosis.—The affected hæmorrhoid or hæmorrhoids become dark purple or black (fig. 1210) and feel solid. Considerable œdema of the anal margin accompanies thrombosis. Once thrombosis has occurred the pain of strangulation largely passes off, but tenderness persists.

Ulceration.—Superficial ulceration of the exposed mucous membrane often accompanies strangulation with thrombosis.

Gangrene occurs when strangulation is sufficiently tight to constrict the arterial supply of the hæmorrhoid. The resulting sloughing is usually superficial and localised. Occasionally a whole hæmorrhoid sloughs off, leaving an ulcer which heals gradually. Very occasionally massive gangrene extends to the mucous membrane within the anal canal and rectum.

Fibrosis.—After thrombosis, internal hæmorrhoids sometimes become converted into fibrous tissue. The fibrosed hæmorrhoid is at first sessile, but by repeated traction during prolapse at defæcation, it becomes pedunculated and constitutes a fibrous polypus that is readily distinguished by its white colour from an adenoma, which is bright red. Fibrosis following transient strangulation commonly occurs in the subcutaneous part of a primary hæmorrhoid. Fibrosis in an external hæmorrhoid favours prolapse of an associated internal hæmorrhoid.

Suppuration is uncommon. It occurs as a result of infection of a thrombosed hæmorrhoid. Throbbing pain is followed by perianal swelling, and a perianal or submucous abscess results.

Pylephlebitis (*syn.* Portal Pyæmia).—Theoretically, infected hæmorrhoids should be a potent cause of portal pyæmia and liver abscesses (p. 854). Although cases do occur from time to time, this complication is surprisingly infrequent.

TREATMENT OF INTERNAL HÆMORRHOIDS

Non-operative treatment is recommended when the hæmorrhoids are a symptom of some other condition or disease except, of course, when a carcinoma is present. The bowels are regulated by Isogel, and if necessary a small dose of Senokot at night. Various proprietary creams can be inserted into the rectum from a collapsible tube fitted with a nozzle, at night and before defæcation. Suppositories are also useful. **In cases of inflamed and permanently prolapsed hæmorrhoids** with a patulous anus, once the œdema has been reduced by repeated dressings of glycerine and tannic acid B.P. (Eisenhammer) or Lotio Plumbi B.P., surgery offers the only hope of permanent cure. However, a severe stretching of the anal sphincter ('manual dilatation of the anus') is frequently successful in relieving symptoms even in advanced cases of piles, probably by preventing congestion of the hæmorrhoidal veins (Lord). This procedure is unsuitable for cases with a patulous sphincter. It requires a general anæsthetic and after-care by

[1] An 'acute attack of piles' also embraces a thrombotic pile (p. 1067) or an inflamed anal skin tag.

Stephen Eisenhammer, Contemporary. Rectal Surgeon, Johannesburg, South Africa.
In 1871, Mitchell of Clinton, Illinois, first used carbolic acid for injecting hæmorrhoids. Itinerant irregular practitioners exploited the method.
Peter Herent Lord, Contemporary. Surgeon, Wycombe General Hospital, High Wycombe, Bucks, England.

passing a special dilator to maintain sphincter relaxation; but the patient is usually hospitalised for less than 24 hours.

Active Treatment.—This consists of injection or treatment by elastic band applications to the base of each hæmorrhoid or formal operation, each with specific indications. Treatment should not be withheld because the patient is elderly or infirm.

Injection Treatment.—*Indications.*—This is ideal for first-degree internal hæmorrhoids which bleed. Early second degree hæmorrhoids are often cured by this method but a proportion relapse.

FIG. 1211.—Correct site for injecting a hæmorrhoid. (*After W. B. Gabriel, F.R.C.S., London.*)

Technique.—The patient should have an empty rectum, but no special preparation is necessary. A proctoscope is introduced, and the hæmorrhoids are displayed. The proctoscope is introduced farther in until the hæmorrhoid has almost disappeared from the lumen and only its upper end is visible. The injection is made at this point above the main mass of each hæmorrhoid (fig. 1211) into the submucosa at or just above the ano-rectal ring. Using Gabriel's syringe (fig. 1212) with the bevel of the needle directed towards the rectal wall, from 3 to 5 ml. of 5 per cent. phenol in almond oil is injected. The injection should produce elevation and pallor of the mucosa. The solution spreads in the submucosa upwards to the pedicle, and downwards to the internal hæmorrhoid and to secondary hæmorrhoids if present, but it is prevented by the intermuscular septum from reaching the external hæmorrhoid. There is a slight, transient bleeding from the point of puncture. The injection is painless, but a dull ache is common for a few hours. There is no special after-treatment. If there is only one hæmorrhoid present, it may be cured by one injection; if all three hæmorrhoids are equally enlarged, each is injected at the same session. Often three sessions at six-weekly intervals are required. Care should be taken not to inject into the prostate anteriorly, for the resulting prostatitis can be crippling.

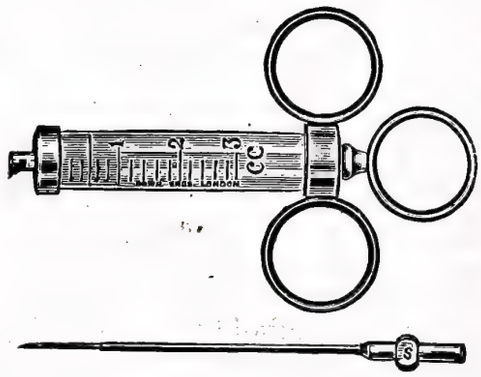


FIG. 1212.—Gabriel's syringe for injecting hæmorrhoids.

Banding Treatment (Barron).—For second-degree hæmorrhoids which are too large for successful handling by injections, treatment is available by slipping tight elastic bands on to the base of the pedicle of each hæmorrhoid with a special instrument (fig. 1213). The bands cause ischæmic necrosis of the piles, which slough off within a few days. The procedure should be painless if done properly, and can be performed in the Out-Patient Department. Not more than two hæmorrhoids should be banded at each session and three weeks at least should elapse between each treatment.

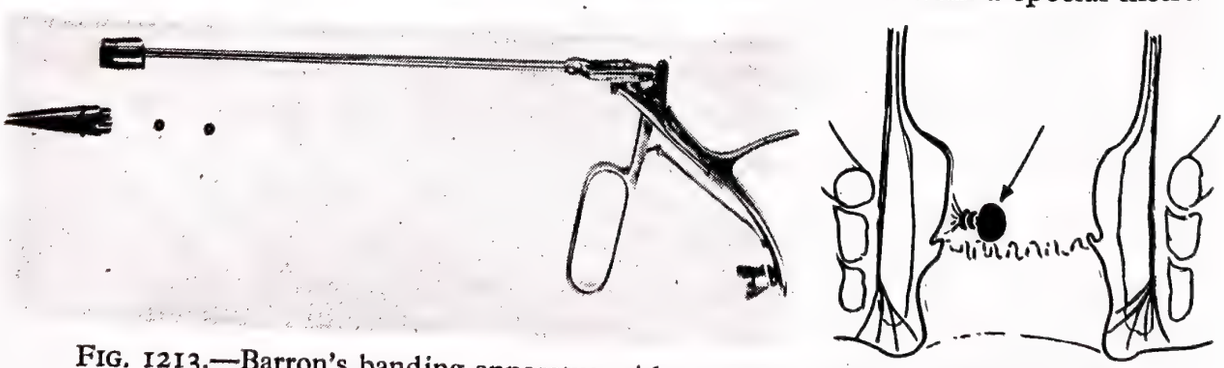

FIG. 1213.—Barron's banding apparatus with appearance of a typical 'banded' hæmorrhoid.

William Bashall Gabriel, 1893–1975. Surgeon, Royal Northern Hospital, London.
John Barron, Contemporary. Surgeon, Chicago, Illinois, U.S.A.

Cryosurgery.—The application of *liquid nitrogen* is currently under active evaluation in some centres. The extreme cold (−196° C) of the application causes coagulation necrosis of the piles which subsequently separate and drop off. The procedure is painless and can be done in the Out-Patient Department. Some encouraging early reports have been issued (K. Lloyd-Williams).

Operation.—*Indications.*—The following cases are unsuitable for injection or banding treatment. (1) Third-degree hæmorrhoids; (2) failure of conservative treatments of second-degree hæmorrhoids; (3) fibrosed hæmorrhoids; (4) intero-external hæmorrhoids when the external hæmorrhoid is well defined. These are indications for hæmorrhoidectomy.

HÆMORRHOIDECTOMY

Forty-eight hours' pre-operative treatment is necessary. An aperient, a little more than the patient usually takes, or, if none is habitually taken, 2 ml. of cascara evacuant, is given on the evening forty-eight hours prior to the operation. On the following morning a small dose of effervescent saline is given before breakfast. On the evening before the operation a soap-and-water enema is administered, and the anal region is shaved. On the morning of the operation the rectum is washed out with water by means of a funnel and tube attached to a catheter.

Ligation and Excision.—With the patient in the lithotomy position the sphincter is widely stretched, a manœuvre which greatly reduces post-operative pain. The internal hæmorrhoids are then prolapsed by traction on the skin tags, or on the skin of the anal margin. Each hæmorrhoid is dealt with as follows: It is picked up with dissecting forceps and traction is exerted. Traction displays a longitudinal fold (the pedicle) above the hæmorrhoid. Each pedicle is grasped in a fine-pointed hæmostat, as also is each external hæmorrhoid or skin tag connected with each internal hæmorrhoid. These pairs of hæmostats, when held out by the assistants, form a triangle.

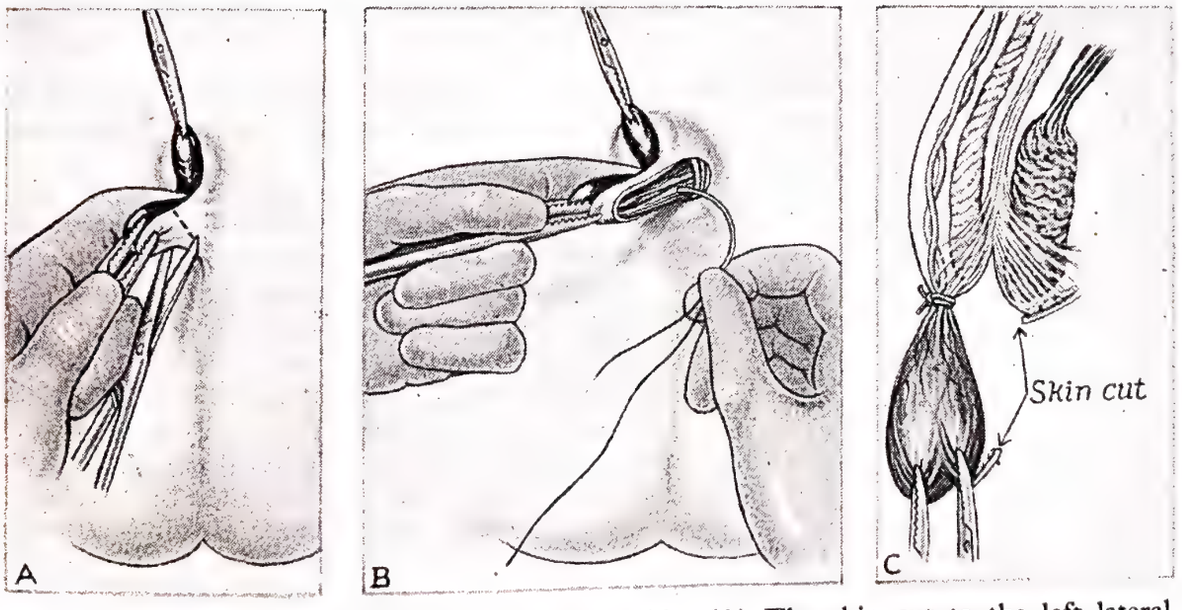

FIG. 1214.—Ligation and excision of hæmorrhoids: (A) The skin cut to the left lateral hæmorrhoid; (B) Transfixion of the pedicle; (C) Ligation.

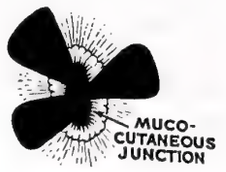
The operator takes the left lateral pair of hæmostats in the palm of his hand and places the extended forefinger in the anal canal to support the internal hæmorrhoid. In this way traction is applied to the skin of the anal margin. With scissors, a V-shaped cut is made (fig. 1214 (A)), each limb of which is placed on either side of the skin-holding hæmostat. This cut traverses the skin and the corrugator cutis ani. Exerting further traction a little blunt dissection exposes the lower border of the internal sphincter. A transfixion ligature of No. 3 chromic catgut is applied to the

K. Lloyd-Williams. Contemporary. Surgeon, Royal United Hospitals, Bath, England.

pedicle at this level (fig. 1214 (B)). Each hæmorrhoid having been dealt with in this manner (fig. 1214 (C)), they are excised 1·25 cm distal to the ligature, the ends of which are cut about 1 cm from the knot. The stumps of the ligated hæmorrhoids are returned to the rectum by tucking a piece of gauze into the anal canal with closed scissors.



The margins of the skin wounds are trimmed so as not to leave overhanging edges, viz.——————————[1]. Bleeding subcutaneous arteries having been secured, the corners of three pieces of petroleum-jelly gauze are tucked into the anus so as to cover the areas denuded of skin. A pad of gauze and wool, and a firmly applied T-bandage complete the operation.

Post-operative Treatment.—Twice daily baths are started from the first day and liquid paraffin in the evenings. The dressings float off in the bath; if not, they can be removed. An enema is rarely necessary as the bowels usually move on the fourth or fifth day. The baths and dry dressings (a sterile sanitary towel is best for this purpose) held in position by a T-bandage keep the area clean. On the seventh day a finger is passed into the rectum to assess the degree of spasm. If there is risk of stricture formation, a St. Mark's Hospital dilator (fig. 1160) is passed daily. The patient can leave hospital on the tenth to fourteenth day when the risk of secondary hæmorrhage has passed. In the later stages a dry dressing is employed during the day and a zinc and castor oil dressing at night. The paraffin should be stopped after the tenth day and the patient encouraged to pass solid motions in order to dilate the anal canal. The wounds heal in three to six weeks. Modifications of the hæmorrhoidectomy operation have been described by Ferguson and Parks. In these modifications, the anal wound is closed completely or partly to reduce pain and healing time.

Post-operative complications may be early or late.

Early. *Pain* may demand repeated pethidine. Xylocaine jelly introduced through a fine nozzle into the rectum, as necessary, is of considerable value.

Retention of urine is not unusual after hæmorrhoidectomy in male patients, and frequently it is precipitated by the presence of a rectal tube, or pack, or both. Before resorting to catheterisation, the patient should be reassured, given an analgesic, allowed to stand at the side of the bed in privacy or be assisted to a hot bath into which he may be able to void urine.

Reactionary hæmorrhage is much more common than secondary hæmorrhage. The hæmorrhage may be mainly or entirely concealed, but will become evident on examining the rectum.

Treatment.—A suitable dose of morphine is given intravenously. If the bleeding persists, the patient must be taken to the operating theatre and the bleeding-point secured by diathermy or under-running with a ligature on a needle. Should a definite bleeding-point not be found, suspected areas are under-run in this way.

Late.—Secondary hæmorrhage is uncommon; when it occurs, it does so about the seventh or eighth day after operation. It is usually controlled by morphia but if the hæmorrhage is severe, an anæsthetic should be given and a catgut stitch inserted to occlude the bleeding vessel.

Anal stricture.—This must be prevented at all costs. A rectal examination at the tenth day will indicate if stricturing is to be expected. It may then be necessary to give a general anæsthetic and dilate the anus to take four fingers. After that daily use of the dilator should give a satisfactory result.

Anal fissure (p. 1057) and submucous abscess (p. 1077) may also occur.

TREATMENT OF COMPLICATIONS OF HÆMORRHOIDS

In cases of strangulation, thrombosis, and gangrene, it was formerly believed that surgery would cause pylephlebitis. If an adequate antibiotic cover is given from the start, this is not found to be so. Bed rest with frequent hot sitz baths, warm saline compresses with firm pressure usually cause the

[1] If it looks like a clover, the trouble is over,
If it looks like a dahlia, it's surely a failure.

James A. Ferguson, Contemporary. *Ferguson Clinic, Grand Rapids, Michigan, U.S.A.*
Alan Guyatt Parks, Contemporary. *Surgeon, St. Mark's Hospital, London.*

pile mass to shrink considerably in three or four days when ligation and excision of the piles can be carried out. Some surgeons consider that the operation at this stage increases the risk of post-operative stenosis and delay surgery for a month or so. They then review the situation and only carry out hæmorrhoidectomy if necessary.

In cases where the patient has been admitted because of severe hæmorrhage the cause usually lies in a bleeding diathesis or the use of anticoagulants (p. 142). If such are excluded, a local compress containing adrenaline solution, with an injection of morphine and blood transfusion if necessary, will usually control the hæmorrhage. After blood replacement is adequate, ligation and excision of the piles may be required.

EXTERNAL HÆMORRHOIDS

Unlike internal hæmorrhoids, external hæmorrhoids comprise a conglomerate group of distinct clinical entities.

1. **A thrombosed external hæmorrhoid** is commonly termed a perianal hæmatoma. It is a small clot occurring in the perianal subcutaneous connective tissue, usually superficial to the corrugator cutis ani muscle. The condition is due to back pressure on an anal venule consequent upon straining at stool, coughing, or lifting a heavy weight.

The condition appears suddenly and is very painful, and on examination a tense, tender swelling which resembles a semi-ripe blackcurrant is seen (fig. 1215). The hæmatoma is usually situated in a lateral region of the anal margin. Untreated it may resolve, suppurate, fibrose, and give rise to a cutaneous tag or burst and extrude the clot or continue bleeding.

In the majority of cases resolution or fibrosis occurs. Indeed, this condition has been called ' a five-day, painful, self-curing lesion ' (Milligan).

Provided it is seen within thirty-six hours of the onset, a perianal hæmatoma is best treated as an emergency. Under local anæsthesia the hæmorrhoid is bisected and the two halves are excised together with 1·25 cm. of adjacent skin. This leaves a pear-shaped wound which is allowed to granulate. The relief of pain is immediate and a permanent cure is certain. On the rare occasions in which a perianal hæmatoma is situated anteriorly or posteriorly, it should be treated conservatively because of the liability of a skin wound in these regions to become an anal fissure.

FIG. 1215.—' Thrombotic ' pile.

2. **Associated with internal hæmorrhoids** = intero-external hæmorrhoids. These have been discussed (p. 1060).

3. **Dilatation of the veins of the anal verge** becomes evident only if the patient strains, when a bluish cushion-like ring appears. This

Edward Thomas Campbell Milligan, 1886–1972. Surgeon, St. Mark's Hospital, London.

variety of external hæmorrhoid is almost a perquisite of those who lead a sedentary life. The only treatment required is an adjustment in habits of the patient.

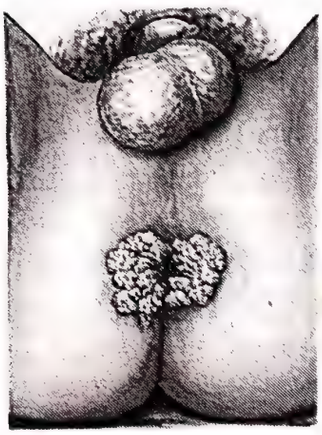


FIG. 1216.—Anal condylomas.

4. A 'sentinel' pile is associated with an anal fissure, and has been discussed on p. 1057.

SOME CONDITIONS THAT SIMULATE EXTERNAL HÆMORRHOIDS

Anal warts are usually multiple and present the same characteristics as warts elsewhere. Occasionally they accompany gonococcal proctitis. Simple warts respond well to treatment by precise applications at weekly intervals of 25 per cent podophyllin in liquid paraffin. Large or residual warts require diathermy.

Condylomas (fig 1216) have a smoother surface and are more pedunculated than the foregoing. Also they are usually moist, with a glairy discharge. Immediate examination of the discharge by 'dark ground' illumination establishes the diagnosis.

Hypertrophic tuberculide of the anus is rare. These are multiple yellowish-brown papillomatous excrescences. The diagnosis is seldom established until microscopic examination has been undertaken.

PRURITUS ANI

This is intractable itching around the anus. Usually the skin is reddened hyperkeratotic and may become cracked and moist. The causes are numerous.

1. *Lack of cleanliness, excessive sweating, and wearing rough or woollen under-clothing* are common causes.

2. *An anal or perianal discharge* which renders the anus moist. The causative lesions include an anal fissure, fistula-in-ano, prolapsed internal or external hæmorrhoids, and excessive ingestion of liquid paraffin. A mucous discharge is an intense pruritic agent.

3. *A vaginal discharge*, especially due to the trichomonas vaginalis.

4. *Parasitic causes.* Threadworms should be excluded, especially in young subjects.[1] Scabies and pediculosis pubis may infest the anal region.

5. *Epidermophytosis* is a common cause especially if the skin between the toes is infected also. Microscopic and cultural examinations are essential. Half-strength Whitfield's ointment quickly gives relief and is the sheet anchor of treatment.

6. *Allergy* is sometimes the cause, in which case there is likely to be a history of other allergic manifestations, such as urticaria, asthma, or hay-fever. Antibiotic therapy may be the precipitating factor.

7. *Skin diseases localised to the perianal skin*—psoriasis, lichen planus and contact dermatitis.

8. *Bacterial infection.*—Intertrigo due to a mixed bacterial infection. Erythrasma due to *Corynebacterium minutissimum* is responsible for some cases and its presence is detected by ultra-violet light which induces a pink fluorescence.

9. *A psychoneurosis.*—It is alleged that in a few instances neurotic individuals become so immersed in their complaint that a pain-pleasure complex develops, the pleasure being the scratching. Possibly this is true, but such a syndrome should not be assumed without firm grounds for coming to this conclusion.

Treatment.—The cause is treated. Other methods include :

Hygienic Measures.—Cotton-wool should be substituted for toilet paper. Soap is avoided, and replaced by a detergent. These measures alone, combined with wearing cotton cellular underwear and applications of calamine lotion, are all that is necessary to cure some cases. If there is much anal hair trapping the moisture and discharge, shaving can be very helpful.

[1] Children suffering from thread worms should wear gloves at night, lest they scratch the perianal region and are reinfested with ova by nail biting—'Parasites lost, Parasites regained'.

Arthur Whitfield, 1868–1947. Professor of Dermatology, King's College Hospital, London.

The following measures are directed mainly to those frequent instances where no obvious reason for the itching can be demonstrated. The best sedative appears to be the alkaloid reserpine, 0·25 mg. daily. This has a tranquillising effect on many anxious patients, but is without direct effect on the pruritus itself.

Hydrocortisone.—In cases with dermatitis, *and only in cases with dermatitis,* prednisolone, applied topically in a cream of 1 per cent. is often beneficial; sometimes after discontinuation of the therapy the pruritus is liable to return, in which event 5 per cent. Xylocaine ointment can be substituted for a time.

Strapping the buttocks apart (fig. 1217) is a most useful procedure, especially when the pruritus is acute, and in chronic cases when the opposing surfaces are moist. The strapping is worn so long as the patient finds it beneficial.

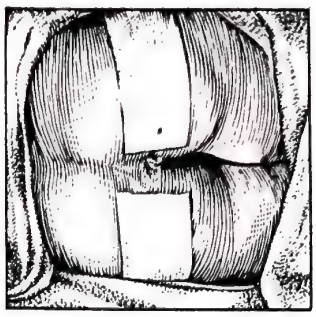

FIG. 1217.—Strapping the buttocks apart.

Operative Treatment.—This may be necessary for a concomitant lesion of the ano-rectum which is thought to initiate or contribute to the pruritus. Otherwise, surgery is not indicated and the older operations described for this condition are no longer performed.

PROLAPSE OF THE RECTUM < Partial / Complete

Partial Prolapse.—The mucous membrane and submucosa of the rectum protrude outside the anus for not more than between 1·25 and 3·75 cm. When the prolapsed mucosa is palpated between the finger and thumb, it is evident that it is composed of no more than a double layer of mucous membrane (cf. complete prolapse). The condition occurs most often at the extremes of life—in children between one and three years of age, and in elderly people.

In Infants.—The direct downward course of the rectum, due to the as yet undeveloped sacral curve (fig. 1218) predisposes to this condition, as does the reduced resting anal tone which offers diminished support to the mucosal lining of the anal canal (Mann).

FIG. 1218.—The absence of the normal sacral curve predisposes to rectal prolapse in an infant (cf. fig. 1205).

In children, partial prolapse often commences after an attack of diarrhœa, as a result of severe whooping cough, or from loss of weight and consequent diminution in the amount of fat in the ischio-rectal fossæ.

In adults the condition is usually associated with third-degree hæmorrhoids or a complete prolapse. In the female a torn perineum predisposes to prolapse, and in the male straining from urethral obstruction. In old age, both partial and complete prolapse are due to atony of the sphincter mechanism.

Partial prolapse may follow an operation for fistula-in-ano where a large portion of muscle has been divided. Here the prolapse is usually localised to the damaged quadrant and is seldom progressive.

Charles Victor Mann, Contemporary. Surgeon, St. Mark's Hospital for Diseases of the Colon and Rectum, London.

Prolapsed mucous membrane is pink (fig. 1220); prolapsed internal hæmorrhoids are plum coloured, and more pedunculated.

Treatment :

In Infants and Young Children : (1) *Digital Reposition.*—The mother must be taught to replace the protrusion. The distal two-thirds of the index finger is wrapped in Kleenex tissue. The finger is inserted into the protrusion, and the mass is eased into place. Gently the finger is withdrawn, leaving the Kleenex tissue to disintegrate. In cases of malnutrition, dietetic adjustments are necessary.

2. *Submucous Injections.*—If digital reposition fails after six weeks' trial, injections of 5 per cent. phenol in almond oil are carried out under general anæsthesia.

Technique.—The submucosa at the apex of the prolapse is injected circularly, so as to form a raised ring, up to 10 ml. of the solution being injected. A similar injection is made at the base of the prolapse. Alternatively, if the prolapse cannot be brought down, the injections are given through a proctoscope.

As a result of the aseptic inflammation following these injections, the mucous membrane becomes tethered to the muscle coat.

3. *Thiersch's Operation.*—When the prolapse persists in spite of these measures, Thiersch's operation (p. 1071) is almost certain to succeed. In infants, insertion of the little finger into the anus before the stitch is tied is recommended. In infants and young children, strong chromic catgut should be used for the stitch instead of silver wire: if wire were employed (or any other retained unabsorbable material) as growth proceeded the stitch would have to be removed or anal stenosis would result. Since the procedure is designed only as a *temporary* measure in the young, chromic catgut is adequate for the purpose.

In Adults : (1) *Submucous injections* of phenol in almond oil occasionally are successful in cases of early partial prolapse.

(2) *Excision of the Prolapsed Mucosa.*—When the prolapse is unilateral the redundant mucosa can be excised after inserting and tying Goodsall's ligature (fig. 1219) which, after the needles have been cut off, permits the base of the prolapsed mucous membrane to be ligated in three portions lying in juxtaposition. When necessary, the operation is combined with hæmorrhoidectomy, and if the pedicle of one or more of the hæmorrhoids is broad, Goodsall's ligature is applied.

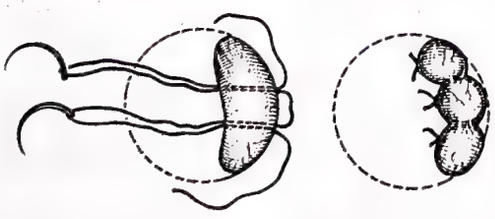

FIG. 1219.—Goodsall's ligature.

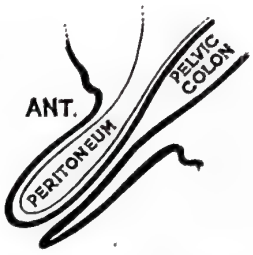
Complete prolapse (*syn.* procidentia) is less common than the partial variety. The protrusion consists of all layers of the rectal wall and is a descending hernia-en-glissade of the rectum downward through the levator ani. As the rectum descends it intussuscepts upon itself. The process starts with the anterior wall of the rectum where the supporting tissues are weakest, especially in women. It is more than 3·75 cm. and commonly as much as

Karl Thiersch, 1822–1895. Professor of Surgery, Leipzig, Germany.
David Henry Goodsall, 1843–1906. Surgeon, St. Mark's Hospital for Diseases of the Rectum and Colon, London.

10 to 15 cm. in length. On palpation between the finger and the thumb the prolapse feels much thicker than a partial prolapse, and obviously consists of a double thickness of the entire wall of the rectum. Any prolapse over 5 cm in length contains anteriorly between its layers a pouch of peritoneum, viz. ——→ When large, the peritoneal pouch contains small intestine which returns to the general peritoneal cavity with a characteristic gurgle when the prolapse is reduced. The prolapsed mucous membrane (fig. 1220) is often arranged in a series of circular folds. The anal sphincter is characteristically patulous and gapes widely on straining to allow the rectum to prolapse. Complete prolapse is uncommon in children. In adults it can occur at any age, but is more common in the elderly. Women are six times more often affected than men. In women, prolapse of the rectum is commonly associated with prolapse of the uterus, or a past history of a gynæcological operation, e.g. hysterectomy.

FIG. 1220.—Complete rectal prolapse. (*G. D. Adhia, F.R.C.S., Bombay.*)



Differential Diagnosis.—In the case of a child with abdominal pain, prolapse of the rectum must be distinguished from **ileo-cæcal intussusception** protruding from the anus. Figures 1221 and 1222 make the differential diagnosis clear. In **recto-sigmoid intussusception** in the adult there is a deep groove (5 cm or more) between the emerging protruding mass and the margin of the anus.

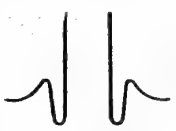


FIG. 1221.—Partial prolapse of the rectum.

FIG. 1222.—Intussusception protruding from the anus.

Treatment.—The Thiersch operation can be recommended in elderly patients, in those suffering from injury or disease of the spinal cord, and in the feeble-minded, in whom the condition is relatively common, as well as in very early life p. 1070).

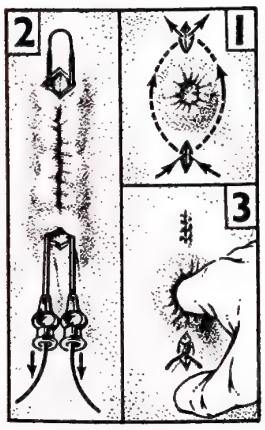

FIG. 1223.—The Thiersch operation (Dodd's modification.)

The Thiersch Operation.—A short incision is made in the midline anteriorly and posteriorly about 1·25 cm. from the anal verge. Large-bore hollow needles are inserted one at a time through the posterior wound, in such a way as to encircle the anus 1 cm. from the orifice (fig. 1223 (1)), until their points emerge from the anterior wound (fig. 1223 (2)). A malleable silver wire, gauge 19 or 20, is introduced through the points of the needles. The needles are withdrawn. The assistant introduces his index finger into the anal canal (fig. 1223 (3)), and the surgeon tightens the wire around the finger by twisting the ends of the wire. The finger is withdrawn and the ends of the wire are clipped short, and bent back. Monofilament O nylon can be used instead of wire, and passed round the rectum two or three times to produce a 'watch-spring' effect when the stitch is tightened. The wounds are then closed.

Harold Dodd, Contemporary. (*See footnote p. 172.*)

A glycerol suppository or a low-pressure enema is given as required post-operatively. Confinement to bed is unnecessary.

By and large, the results of Thiersch's operation are remarkably successful, but in about 50 per cent. of cases the wire breaks; it is, however, easily removed and the operation can be carried out several times, at intervals, on the same patient. Its main disadvantage is that spurious incontinence of fæces caused by fæcal impaction (p. 1024) is wont to occur in all age groups. Constipation must, therefore, be guarded against vigilantly.

Operative Suspension of the Prolapsed Bowel.—Of many operations designed to cure complete prolapse of the rectum, the following procedures are relatively simple. They are recommended in patients with complete prolapse who are otherwise in good health. All are abdominal procedures designed to replace and hold the rectum in its proper position. Many other procedures have been described incorporating the same principles illustrated by these operations, some of which are carried out through a perineal approach.

Wells' Operation.—In this operation the rectum is fixed firmly to the sacrum by inserting a sheet of polyvinyl alcohol sponge between them. The rectum is separated from the sacrum in the usual way. The sponge is fixed by a series of sutures to the periosteum over the midline of the sacrum and is then wrapped loosely about the rectum covering all except the anterior wall. The free margins of the polyvinyl sponge are sutured to the lateral margins of the anterior wall of the rectum. The peritoneal floor is resutured so that the sponge is excluded from the peritoneal cavity. Polyvinyl sponge does not give rise to a foreign body reaction but it does produce very marked fibrous tissue formation. Many proctologists regard this as the method of choice. The results are excellent.

Ripstein's Operation.—In this operation, the recto-sigmoid junction is hitched up by a Teflon sling to the front of the sacrum just below the sacral promontory. The operation is very safe and simple and the results are good.

Lahaut's Operation.—This operation depends entirely upon mobilising the rectum and lower sigmoid colon and holding it up by extraperitonealising it through the rectus sheath. The results are moderate.

ANAL INCONTINENCE

Congenital.—(*a*) In cases of imperforate anus, partial or complete lack of the sphincter mechanism is the exception rather than the rule; (*b*) patulous anus associated with mental deficiency.

Traumatic.—By far the most frequent cause is a complication of a complete perineal tear during parturition. Other injuries resulting in a torn anal sphincter are extremely rare.

Post-operative.—(*a*) After the ano-rectal ring has been severed during an operation for a high fistula-in-ano; (*b*) following conservative perineal resection of the rectum for carcinoma, an operation that cannot be recommended.

Associated with advanced complete prolapse due to atony of the sphincter.

Interruption of the reflex arc responsible for sphincter control in diseases of the nervous system, notably neuro-syphilis (e.g. tabes dorsalis).

Carcinoma of the Anus involving the Sphincter (p. 1094).

Treatment of Anal Incontinence:

Partial incontinence often can be remedied by the Thiersch operation (p. 1071). This also is the operation of choice in cases of complete incontinence associated with mental deficiency.

Partial and often complete incontinence due to parturition is particularly amenable to operative treatment. Posterior perineorrhaphy with repair of the torn edges of the sphincter often cures the condition.

Charles Alexander Wells, Contemporary. Professor Emeritus of Surgery, Liverpool, England.

Jules Lahaut, Contemporary. Surgeon-in-Chief, Hôpital du Pont Canal, Jemappes (Hainaut), Belgium.

PROCTITIS

Inflammation is sometimes limited to the rectal mucosa; in others it is associated with a similar condition in the colon (procto-colitis). The inflammation can be acute or chronic. The symptoms are tenesmus, the passage of blood and mucus and, in severe cases, of pus also. Although the patient has a frequent intense desire to defæcate, the amount of fæces passed at a time is small. Acute proctitis is usually accompanied by malaise and pyrexia. On rectal examination the mucosa feels swollen and is often exceedingly tender. Proctoscopy is seldom sufficient and sigmoidoscopy is the more valuable method of examination. Skilled pathological assistance is required to establish or exclude the diagnosis of specific infection by bacteriological examination and culture of the stools, examination of scrapings or swabs from ulcers, and serological tests. When early carcinoma cannot be excluded, biopsy is necessary.

Non-specific proctitis is an inflammatory condition affecting the mucosa, and to a lesser extent the submucosa, confined to the terminal rectum and anal canal. It is the most common variety.

Ætiology is unknown. The concept that the condition is a mild and limited form of ulcerative colitis (although actual ulceration is not present) is the most accepable hypothesis. Approximately 10% of cases of limited procto-sigmoiditis eventually proceed to total ulcerative colitis.

Clinical Features.—The patient is usually middle-aged, and complains of slight loss of blood in the motions. Often the complaint is one of diarrhœa, but on closer questioning it transpires that usually one relatively normal action of the bowels occurs each day, although it is accompanied by some blood. During the day the patient attempts to defæcate, with the passage of flatus and a little blood-stained fæcal matter; which is mistakenly interpreted as diarrhœa. On rectal examination the mucosa feels warm and smooth. Often there is some blood on the examining finger. Proctoscopic and sigmoidoscopic examination shows inflamed mucous membrane of the rectum, but no ulceration. The inflammation extends for only 12·5 or 15 cm from the anus, the mucosa above this level being quite normal.

Treatment.—Although, fortunately, the condition is self-limiting, much relief may be obtained from the use of Salazopyrin, Acetarsol suppositories or Prednisolone retention enemas. Milk should be rigidly excluded from the diet and the motions kept soft with Isogel or Celevac.

Ulcerative Procto-colitis.—Proctitis is present in a high percentage of cases of ulcerative colitis, and the degree of severity of the rectal involvement may influence the type of operative procedure (p. 976).

Proctitis Due to Specific Infections:

Bacillary Dysentery.—The appearance is that of an acute purulent proctitis with multiple small shallow ulcers. The examination of a swab taken from the ulcerated mucous membrane is more certainly diagnostic than is a microscopical examination of the stools. Proctological examination is painful; agglutination tests may render it unnecessary.

Amœbic Dysentery.—The infection is more liable to be chronic, and exacerbations after a long period of freedom from symptoms often occur. Proctoscopy and sigmoidoscopy are not painful. The appearance of an amœbic ulcer is described on p. 978. Scrapings from the ulcer should be immersed in warm normal saline solution and sent to the laboratory for immediate microscopical examination.

Amœbic granuloma presents as a soft mass, usually in the recto-sigmoid region. This lesion is frequently mistaken for a carcinoma. Sigmoidoscopy shows an ulcerated surface, but the mass is less friable than a carcinoma. A scraping should be taken, preferably with a small sharp spoon on a long handle, and the material sent for

immediate microscopical examination, as detailed above. If doubt exists, a provocative dose of emetine may cause cysts of the amœbæ to appear in the stools. A biopsy is also required. Treatment is as described on p. 979.

Amœbic granuloma of the rectum is from time to time encountered in a patient who has never visited a country in which the disease in endemic. Persons living in old people's institutions are liable to harbour this deceptive lesion.

Tuberculous proctitis is nearly always associated with active pulmonary tuberculosis, and is often complicated by a tuberculous fistula-in-ano or tuberculous ulceration of the anus. Submucous rectal abscesses burst and leave ulcers with an undermined edge. A hypertrophic type of tuberculous proctitis occurs in association with tuberculous peritonitis or tuberculous salpingitis. This type of tuberculous proctitis requires biopsy for confirmation of the diagnosis.

Gonococcal proctitis occurs in both sexes as the result of rectal coitus, and in the female from direct spread from the vulva. In the acute stage the mucous membrane is hyperæmic and thick pus can be expressed as the proctoscope is withdrawn. In the early stages the diagnosis can be readily established by bacteriological examination, but later, when the infection is mixed, it is more difficult to recognise. Specific treatment is so effective that local treatment is unnecessary.

Lymphogranuloma Inguinale.—The modes of infection are similar to those of gonococcal proctitis, but in the female infection spreading from the cervix uteri via lymphatics to the pararectal lymph nodes is common. The proctological findings are similar to those of gonococcal proctitis. The diagnosis of lymphogranuloma inguinale should be strongly suspected when the inguinal lymph nodes are greatly enlarged, although the enlargement may be subsiding by the time proctitis commences. Frei's intradermal test is positive in 95 per cent. of cases, and the complement-fixation test is even more accurate (p. 42).

Primary Syphilis.—A primary chancre may occur inside the anus (p. 1058).

'Strawberry' lesion of the recto-sigmoid is due to an infection by *Spirochæta vincenti* and *Bacillus fusiformis*. The leading symptom is diarrhœa, often scantily blood-stained. Occasionally the diagnosis can be made by the demonstration of the specific organisms in the stools. More often sigmoidoscopy is required. The characteristic lesion is thickened, somewhat raised mucosa with superficial ulceration in the region of the recto-sigmoid. The inflamed mucous membrane oozes blood at numerous pin-points, giving the appearance of an over-ripe strawberry. A swab should be taken from the lesion and examined for Vincent's and fusiform organisms. Swabs from the gums and the throat are also advisable.

Treatment.—Acetarsol suppositories together with vitamin C is almost specific.

Rectal bilharziasis is caused by the *Schistosoma mansoni*, which is endemic in many tropical and subtropical countries, and particularly in the delta of the Nile.

Stage 1.—A cutaneous lesion develops at the site of entrance of the cercariæ.[1]

Stage 2 is characterised by pyrexia, urticaria, and a high eosinophilia.

Both these stages are frequently overlooked.

Stage 3 is due to deposition of the ova in the rectum (much more rarely in the bladder) and is manifested by bilharzial dysentery. On examination in the later stages papillomas are frequently present. The papillomas, which are sessile or pedunculated (fig. 1224), contain the ova of the trematode, the life-cycle of which resembles that of *Schistosoma hæmatobium* (fig. 1225).

Untreated, the rectum becomes festooned, and prolapse of the diseased mucous membrane is usual. Multiple fistulæ-in-ano are prone to develop.

FIG. 1224.—Bilharzial papilloma. (*The late Dr. H. P. Keatinge, Cairo.*)

Wilhelm Siegmund Frei, 1885–1943. Professor of Dermatology, Berlin, who later settled in New York, U.S.A.
Jean Hyacinthe Vincent, 1862–1950. (See footnote p. 540.)
Theodor Maximilian Bilharz, 1825–1862. Professor of Zoology, Cairo.
Sir Patrick Manson, 1844–1922. (See footnote p. 843.)

emetic (potassium antimony tartrate) is given intravenously on alternate days, 30 mg at the first injection, increasing by 30 mg until a dose of 130 mg has been reached, the total dose being 1,360 mg. For this treatment the patient must be in fairly good condition, i.e. a hæmoglobin not below 60 per cent. Alternatively:

(*b*) *Fouadin, Stibophen, or Repodral* (all of which are preparations of antimony) is given intramuscularly. A robust adult receives a daily injection of 5 ml. for ten days. In long-standing cases the dose is reduced by half, and given on alternate days. These preparations deteriorate and should not be used after six months from the date of manufacture.

(*c*) *Miracil D or Nilodin* is given by mouth, one 200 mg tablet t.d.s. for twenty days. These are drugs of great promise, and are safer than antimony (Halawani).

The *British National Formulary* (*1976–78*) describes the use of niridazole (Ambilhar) in cases of infestation with *S. haematobium* or *S. mansoni* (**not** *S. japonicum*).

Local Treatment.—When the papillomas persist in spite of general treatment, they must be treated in the same manner as other papillomas (p. 1084).

Proctitis due to herbal enemas is a well-known clinical entity to those practising in tropical Africa. Following an enema consisting of a concoction of ginger, pepper, and tree-bark administered by a witch doctor, a most virulent proctitis sets in. Pelvic peritonitis frequently supervenes. Not infrequently a complete gelatinous cast of the mucous membrane of the rectum is extruded. Very large doses of morphine, together with streptomycin, often prevent a fatal issue if commenced early (Bowesman). Temporary colostomy is often advisable.

Treatment of severe proctitis necessitates confinement to bed. It will be appreciated that in most instances specific treatment can be given once the cause has been elucidated. The stools should be kept soft with Isogel. Local instillations of 150 ml. of olive oil are soothing. Suppositories of succinyl-sulphathiazole are often beneficial. The specific treatment for the dysenteries, tuberculosis, gonorrhœa, lymphogranuloma inguinale, and syphilis are described in the appropriate sections of this book.

SOLITARY ULCER

This is a rare condition that takes the form of an ulcer on the anterior wall of the rectum. It is thought to be traumatic in origin, either by sexual malpractises from below, or by intussusception of the anterior rectal wall into the anal sphincter from above. It is a benign condition that is clinically very easily confused with a carcinoma until repeated biopsies are performed. The clinico-pathological features have been well documented by Morson. The condition, although benign, is difficult to cure. The symptoms of bleeding and discharge can sometimes be ameliorated by topical hydrocortisone applications or by diathermy destruction of the ulcer (which usually returns).

ANO-RECTAL ABSCESSES

In 60 per cent. of cases the pus from the abscess yields a pure culture of *Esch. coli*; in 23 per cent. a pure culture of *Staphylococcus aureus* is obtained. In diminishing frequency, pure cultures of *Bacteroides*, a streptococcus, or *B. proteus* are found. In many cases the infection is mixed. In a high percentage of cases—some estimate it as high as 90 per cent.—the abscess commences as an infection of an anal gland (figs. 1226 and 1227). Other causes are penetration of the rectal wall, e.g. by a fish bone, a blood-borne infection, or an extension of a cutaneous boil.

A large percentage of ano-rectal abscesses coincide with a fistula-in-ano. For this reason, ano-rectal abscess becomes a highly important subject.

Ahmed Halawani, Contemporary. Director of the Institute of Tropical Medicine, Cairo.
Charles Bowesman, Contemporary. Formerly Surgical Specialist, Colonial Medical Service, Kumasi, Ghana.
Basil Clifford Morson, Contemporary. Pathologist, St. Mark's Hospital, London.

Moreover, as antibiotics cannot reach the contents of an abscess in adequate concentration, no reliance can be placed on antibiotic therapy alone.

Differential Diagnosis—The only conditions with which an ano-rectal abscess is likely to be confused are an abscess connected with a pilonidal sinus, Bartholin's gland, or Cowper's gland (p. 1255).

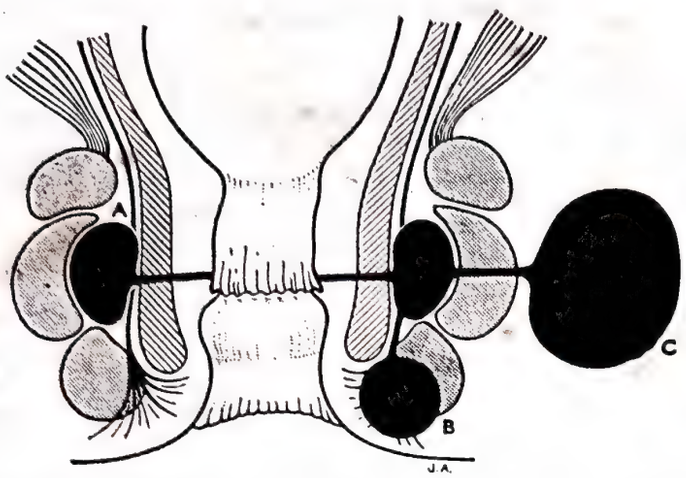

FIG. 1226.—To illustrate the spread of infection from the primary anal gland abscess (A) to the perianal region (B) and the ischio-rectal fossa (C). *(After Alan Parks, F.R.C.S., London.)*

Classification of Ano-rectal Abscesses.—A clear understanding of suppuration in this area is dependent on a concise knowledge of the anatomy (figs. 1226 and 1227). There are four main varieties — perianal, ischio-rectal, submucous, and pelvi-rectal.

1. **Perianal** (60 per cent.). —This usually occurs as the result of suppuration in an anal gland, which spreads superficially to lie in the region of the subcutaneous portion of the external sphincter (fig. 1227A). It may also occur as a result of a thrombosed external pile. If the hæmatoma is not evacuated, it may become infected and a perianal abscess results. This is the most common abscess of the region. Persons of all ages are affected, and the condition is not uncommon, even in infancy and childhood. The constitutional symptoms and the pain are less pronounced than in the ischio-rectal abscess because the pus can expand the walls of this part of the intermuscular space comparatively easily. Early diagnosis is made by inspecting the anal margin when an acutely tender rounded cystic lump about the size of a cherry is seen and felt at the anal verge below the dentate line (fig. 1228).

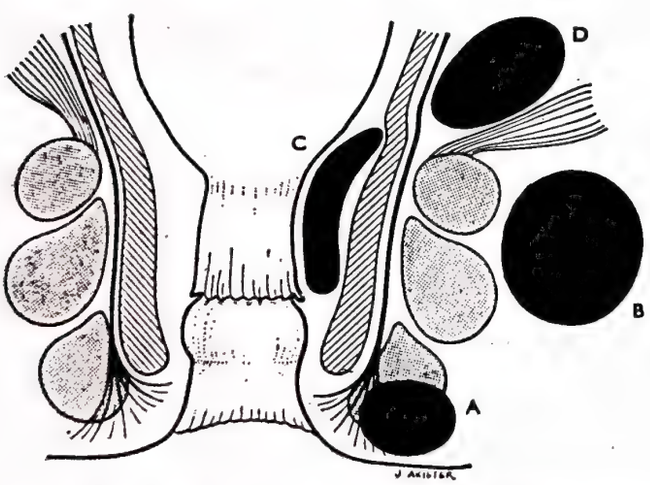

FIG. 1227.—The four types of ano-rectal abscess —(A) Perianal. (B) Ischio-rectal. (C) Submucous. (D) Pelvi-rectal. *(After W. F. W. Southwood, F.R.C.S., Bath.)*

FIG. 1228.— Perianal abscess. *(W. B. Gabriel, F.R.C.S., London.)*

Treatment.—No time should be lost in evacuating the pus.

Operation.—Thorough drainage is achieved by making a cruciate incision

Caspar Bartholin, 1655–1738. Professor of Medicine, Anatomy and Physics, Copenhagen.

over the abscess and excising the skin edges—this completely removes the 'roof' of the abscess. Healing commonly occurs within a few days.

2. **Ischio-rectal abscess** (30 per cent.).—Commonly, this is due to an extension laterally through the external sphincter of a low intermuscular anal abscess (fig. 1227B). Rarely, the infection is either lymphatic or blood-borne. The fat, which fills the ischio-rectal fossa (fig. 1229), is particularly vulnerable because it is poorly vascularised; consequently it is not long before the whole space becomes involved. The ischio-rectal fossa communicates with that of the opposite side via the post-sphincteric space, and if an ischio-rectal abscess is not evacuated early, involvement of the contralateral fossa is not uncommon.

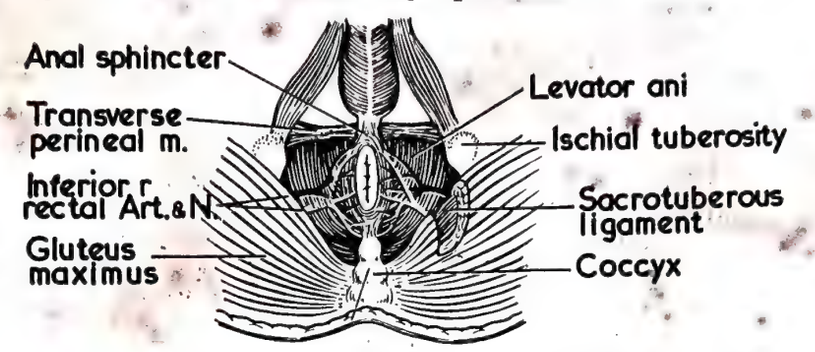

FIG. 1229.—The ischio-rectal fossa. (*After V. C. Shah and Y. V. Shah.*)

An ischio-rectal abscess gives rise to a tender, brawny induration palpable on the corresponding side of the anal canal and the floor of the fossa. Constitutional symptoms are severe, the temperature often rising to 38·9° C. Men are affected more often than women.

Treatment.—Operation should be undertaken early—as soon as it is certain that an abscess is present in this area—remembering that antibiotic therapy often masks the general signs.

Operation.—*Stage* 1.—A +-shaped incision (fig. 1230 inset) is made into the abscess. An adequate portion of skin that includes most, if not all, of the roof of the abscess is excised (fig. 1230). The cavity is explored and, if septa exist, they should be broken down gently with a finger and the necrotic tissue lining the walls of the abscess is removed by the finger wrapped in gauze. Nothing further is done at this stage.

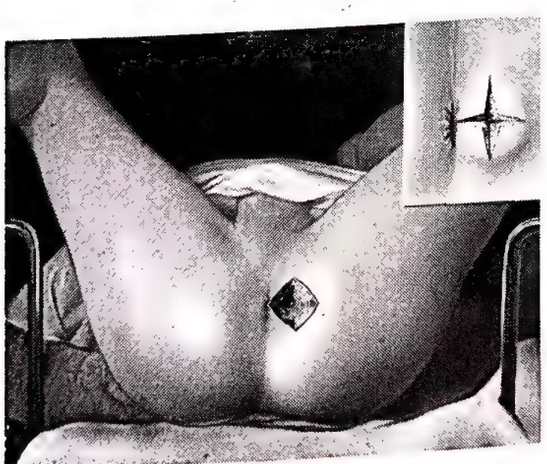

FIG. 1230.—Excision of the skin forming the floor of the ischio-rectal fossa is an essential step in the efficient treatment of an ischio-rectal abscess.

Stage 2.—As soon as the acute infection has subsided, the wound should be re-examined, preferably under general anæsthesia. A careful search is made for a fistulous opening communicating with the anal canal. If such is found, the treatment should be as for fistula (p. 1081). If no fistula is found, the cavity should be lightly packed with gauze wrung out in any weak antiseptic favoured by the operator. A T-bandage is applied. When the cavity has become covered with granulation tissue skin grafting may help to expedite final epithelialisation.

3. **Submucous abscess** (5 per cent.) occurs above the dentate line (fig. 1227C). When it occurs after the injection of hæmorrhoids it always resolves. Otherwise, it can be opened with sinus forceps when adequately displayed by a proctoscope.

4. **Pelvi-rectal abscess** is situated between the upper surface of the levator ani and the pelvic peritoneum. It is nothing more or less than a pelvic abscess and as such is usually secondary to appendicitis, salpingitis, diverticulitis, or parametritis. An important point to remember is that rarely it may be due to over-enthusiastic attempts to drain an ischio-rectal abscess or to display the site of a fistula resulting therefrom, when a probe is pushed through the levator ani from below (p. 1082). Crohn's disease is an important cause of pelvic disease that can present as peri-anal sepsis (cf. fistula-in-ano).

5. **Fissure Abscess.**—This is the name given to a subcutaneous abscess lying in immediate association with an anal fissure (p. 1057). Drainage is achieved at the same time as the fissure is treated by sphincterotomy.

FISTULA-IN-ANO

A fistula-in-ano is a track, lined by granulation tissue which opens deeply in the anal canal or rectum and superficially on the skin around the anus. It usually results from an ano-rectal abscess which burst spontaneously or was opened inadequately (fig. 1226). The fistula continues to discharge and, because of constant reinfection from the anal canal or rectum, seldom, if ever, closes permanently without surgical aid. An ano-rectal abscess may produce a sinus the orifice of which has the appearance of a fistula, but it does not communicate with the anal canal or the rectum. By definition this is *not* a fistula, but a sinus.

TYPES OF ANAL FISTULÆ

These are divided into two groups, according to whether their internal opening is below or above the ano-rectal ring.

Low Level.—These open into the anal canal below the ano-rectal ring. There are 5 varieties (fig. 1231).

High Level.—These open into the anal canal at or above the ano-rectal ring. There are 3 varieties (fig. 1232) but subvarieties are described.

As an alternative to the common anatomical classification illustrated in fig. 1231, Parks has produced another based on the origin of the fistulæ from an abscess in an anal gland situated on the plane between the internal and external sphincters (the ' anal intersphincteric plane ') fig. 1232.

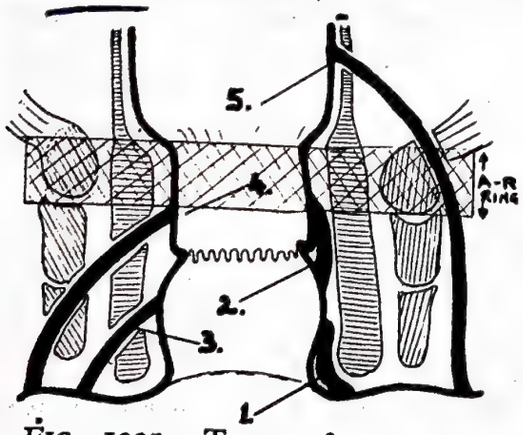

FIG. 1231.—Types of anal fistulæ (standard classification). 1. Subcutaneous, 2. submucous, 3. low anal, 4. high anal, 5. pelvi-rectal.

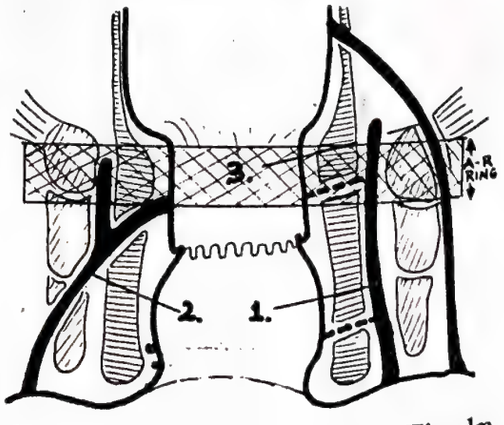

FIG. 1232.—Types of Anal Fistulæ. 1. Intersphincteric, 2. transphincteric (which may be *high* or *low*), 3. supra-levator. (*After A. G. Parks.*)

Sir Alan Guyatt Parks, Contemporary. Surgeon, St. Mark's Hospital for Diseases of the Colon and Rectum, London. For treating successfully Louis XIV's fistula-in-ano, Charles Félix, barber-surgeon to the Court, received a gift of a farm, 300,000 livres, and a title. 300,000 livres today would be worth about £25,000.

The importance of deciding whether a fistulæ is a low- or a high-level type is that a low-level fistula can be laid open without fear of permanent incontinence (from damage to the ano-rectal bundle), while a high-level fistula can be treated only by 'staged' operations, often with the use of a protective colostomy to prevent septic complications and to shorten healing time between the stages.

In probing a high fistulous track, great care must be taken not to create an internal opening into the rectum where none existed previously. Such a disaster could convert a relatively straightforward 'intersphincteric' track into a high 'pelvi-rectal' fistula that might prove very difficult to cure.

By the standard classification, a *high* fistula refers to both a high anal (No. 4, fig. 1231) and a pelvi-rectal fistula (No. 5, fig. 1231). By the Parks classification, both a high transphincteric or a supralevator fistula would qualify as high, with the intersphincteric falling into either category depending on whether an internal opening was present at all, and at what level it entered the anal canal (see No. 1, fig. 1232).

Low-level Fistulæ

Clinical Features.—Commonly, the principal symptom is a persistent sero-purulent discharge that irritates the skin in the neighbourhood and causes discomfort. Often the history dates back for years. So long as the opening is large enough for the pus to escape, pain is not a symptom, but if the orifice is occluded pain increases until the discharge recurs. Frequently there is a solitary external opening, usually situated within 3·75 cm. of the anus, presenting as a small elevation with granulation tissue pouting from the mouth of the opening. Sometimes superficial healing occurs, pus accumulates and an abscess reforms and discharges through the same opening, or a new opening. Thus there may be two or more external openings, usually grouped together on the right or left of the middle line, but occasionally, when both ischio-rectal fossæ are involved, an opening is seen on each side, in which case there is often intercommunication between them (fig. 1233). As a rule there is much induration of the skin and subcutaneous tissues around the fistula.

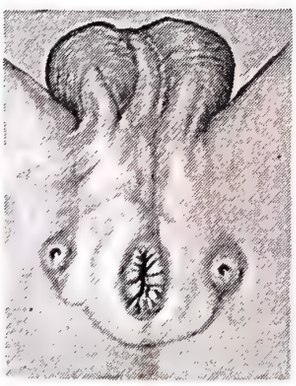

FIG. 1233.—Horse-shoe fistula-in-ano. Both ischio-rectal fossæ involved. Usually there is only one internal orifice.

Goodsall's Rule.—Fistulæ with an external opening in relation to the anterior half of the anus tend to be of the direct type (fig. 1234). Those with an external opening or openings in relation to the posterior half of the anus, which are much more common, usually have curving tracks, and may be of the horse-shoe-variety.

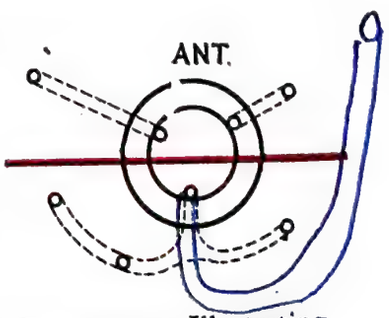

FIG. 1234.—Illustrating Goodsall's rule.

Digital Examination.—Not infrequently an internal opening can be felt as a nodule on the wall of the anal canal. Irrespective of the number of external openings, there is almost invariably but one internal opening.

David Henry Goodsall, 1843–1906. (*See footnote p. 1070.*)

Proctoscopy sometimes will reveal an internal opening of the fistula. A hypertrophied papilla is suggestive that the internal orifice lies within the crypt related to the papilla (fig. 1236).

Probing.—In the past it was the universal practice to probe a fistula in the ward or the out-patient department. Such manœuvres accomplish nothing, are painful, and are liable to reawaken dormant infection. Furthermore, if probing is performed without the utmost gentleness, or if the patient, experiencing pain, makes a sudden jerk, a false passage may result which complicates the condition still further. Probing should be postponed until the patient is under an anæsthetic in the operating theatre.

The injection of lipiodol, or other opaque medium, along the sinus, prior to radiography, has little to recommend it. The radiographs thus obtained are seldom illuminating, and the procedure is likely to cause a recrudescence of inflammation.

Radiography of the thorax should be undertaken and the possibility of pulmonary tuberculosis considered, despite the fact that today it will be found in only a very small proportion of patients with fistula-in-ano.

Special Clinical Types of Fistulæ-in-ano :

1. **Fistula connected with an Anal Fissure.**—Unlike the usual fistula-in-ano, pain (due to the fissure) is a leading symptom. The fistula is very near the anal orifice, usually posterior, and the external opening is often hidden by the sentinel pile.

2. **Fistula with an internal opening above the ano-rectal ring** is due, almost invariably, to penetration by a foreign body or simple intraluminar incision of a high intermuscular abscess erroneously thought to be submucous.

3. **Granulomatous infections.**—If induration around a fistula is lacking, if the opening is ragged and flush with the surface, if the surrounding skin is discoloured and the discharge is watery, it strongly suggests that the fistula is due to a tuberculous infection. In more than 30% of patients suffering from pulmonary tuberculosis, virulent tubercle bacilli are present in the rectum. About 2–3% of fistulæ-in-ano are tuberculous, but in sanatoria and settlements for tuberculous patients the incidence is higher. Histo-pathological examination supplies the only criterion of importance as to whether the tissue removed is tuberculous. The fistula will usually respond to anti-tuberculous drugs alone (p. 32). The differential diagnosis is from Crohn's disease. In Crohn's disease the rectal mucosa is often involved.

FIG. 1235.—Perianal fistulæ due to colloid carcinoma. No primary in the rectum. (*C. E. Dukes, F.R.C.S., London, and C. Galvin, F.R.C.S.*)

4. **Fistulæ with many external openings** may arise from tuberculous proctitis, ulcerative proctocolitis, Crohn's disease of colon or ileum, bilharziasis, and lymphogranuloma inguinale with a fibrous rectal stricture. Colloid carcinoma may complicate fistulæ-in-ano. Crohn's disease is the most frequent cause seen in this country from this group.

5. **Colloid Carcinoma arising within Perianal Fistulæ.**—Colloid carcinoma of the rectum is notoriously liable to be complicated by perianal fistulæ. In some instances the fistulous condition, with its discharge of colloid material, overshadows the primary carcinoma, and not a few unfortunate patients have had their condition diagnosed for a time as an inflammatory fistula-in-ano. If a primary tumour is present in the

Burrill Bernard Crohn, Contemporary. Gastro-enterologist, Mount Sinai Hospital, New York, U.S.A.

rectum, usually it can be detected and its nature established by biopsy. Dukes has established conclusively that colloid carcinomatous fistulæ can develop without a primary neoplasm in the rectum (fig. 1235.) He regards such cases as examples of colloid carcinoma developing in a reduplicated portion of the intestinal tract.

Hidradenitis Suppurativa.—This is a chronic infection of the apocrine glands around the anal margin giving rise to numerous sinuses discharging thin sero-purulent material. Clinically it looks like a relatively superficial inflammatory lesion with considerable fibrous tissue reaction. Treatment is excision of the area with skin grafting.

Treatment.—That the fistulous track must be laid open from its termination to its source was a rule promulgated by John of Arderne more than 500 years ago. Today, pre-operative treatment by cleansing enemas is a necessity.

The operation can best be described in stages :

Step 1.—When the patient has been anæsthetised, he is placed in the lithotomy position or in the prone jack-knife position, according to the preference of the operator. Using bidigital palpation under anæsthesia, it is often possible to obtain more information concerning a fistula than can be learned from probing; it is surprisingly easy to insert a probe through the wall of the track. Unfortunately, many inexperienced operators find it more reassuring to create a false passage than to risk criticism for not being able to demonstrate the internal opening. Careful bidigital palpation of the peri-anal tissue will often reveal a cord-like induration, representing the track, which will lead the intra-anal finger towards the proximal opening. Rather than insert a probe through the distal orifice at this stage, it is better to endeavour to find the internal opening via a proctoscope. If the internal opening still cannot be seen, the insertion of a probe retrogradely into an anal crypt, especially one with a nearby hypertrophied papilla, often reveals the internal portion of the track (fig. 1236). The injection of methylene blue or other dye into the external mouth of the fistula to establish the site of the internal opening is occasionally necessary, but is not recommended as a routine.

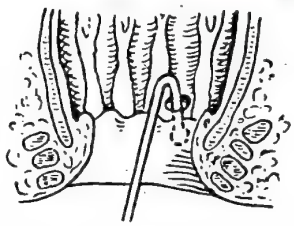

FIG. 1236.—Retrograde probing of an anal crypt sometimes reveals the internal orifice of the fistula.

Step 2.—A probe-pointed director (fig. 1237) is inserted into the distal orifice, and it is advanced delicately until it reaches a point where it does not pass readily. The track is opened along the director, and bleeding is controlled.

FIG. 1237.—A director with a probe-pointed malleable extremity is a useful instrument.

Step 3.—If it is not at once evident in which direction the track passes, granulations are wiped away with gauze (it is seldom necessary to use a curette). Often this will leave a granulation-filled spot at one site only. Gentle probing at this spot frequently will give the clue to the continuation of the fistula. The director is reinserted, and again followed with the knife for a short distance. This procedure is repeated until the entire track, and any side channels, are laid open. As far as possible, all muscle is divided at right angles to its fibres. In the rare event of the track passing above the ano-rectal ring, cutting should cease at the level of the dentate line, and from thenceforth the operation is conducted as suggested below. In most instances probing and laying open the track can be repeated until the entire track is laid open. Pursuing this course, if there is no internal opening the track will become bereft of granulations on wiping it. As a rule the internal opening can be demonstrated either by direct inspection through a proctoscope, or by a bent probe inserted into an anal crypt. In the latter circumstance, the internal portion of the track is excised in continuity.

Step 4.—The edges of the track are trimmed, 1 to 3 mm of tissue being removed —a step that makes post-operative packing unnecessary after the first twenty-four to thirty-six hours. Hughes advocates primary split skin grafting of the wound resulting from fistulotomy. The grafts are taken from the inner aspect of the thigh and applied to the anal wound, being stitched to the skin edges and to each other in the

Cuthbert Esquire Dukes, 1890–1977. Pathologist, St. Mark's Hospital, London.
Edward Stuart Reginald Hughes, Contemporary. Surgeon, Melbourne, Victoria, Australia.

depths of the wound. Tulle gras is then superimposed, and a firm pack of cotton-wool applied. The first dressing is done on the fifth post-operative day.

When skin grafting is not employed, digital dilatation of the anus, or the passage of a St. Mark's Hospital dilator, every other day prevents pocketing or bridging of the granulating wound.

High-level Fistulæ

The treatment of these cases is difficult. If the track is laid open as for low-level fistulæ, incontinence will follow. There are three types (Parks):

(1) *Supralevator fistula—secondary* to local disease (type 3, fig. 1231).—It occurs as a result of Crohn's disease, ulcerative colitis, carcinoma, foreign body perforating the rectal ampulla from above, or trauma. This fistula is quite unrelated to the ordinary type and the treatment is that of the cause. A traumatic fistula usually needs a colostomy. None of these fistulæ require to be laid open, which would in any case cause incontinence.

(2) *Transphincteric fistula* (type 2, fig. 1231) with *perforating secondary track.*—The condition starts as an *intersphincteric* fistula (type 1, fig. 1231), often with a high secondary track in the ischio-rectal fossa up to the levator ani. Here lies the danger. Although the anal opening may be low, during exploration of the high secondary track, unless great care is taken, the probe can be pushed through the levator ani into the rectal ampulla, thus converting a low fistula into a high-level type. Treatment should first of all be directed to the low transphincteric fistula and healing of the upper track may follow. If it fails to do so, or if the opening into the rectum is of any size or near the ano-rectal bundle a colostomy must be done before complete healing will take place. A seton (i.e., a ligature of silk or linen) is rarely used, but is helpful when the internal opening is near the ano-rectal ring. Insertion of a seton and subsequent re-examination of the patient without anæsthesia will establish whether the internal opening is situated so near to the ano-rectal ring that incontinence would result if the track was laid open. Under these conditions, a staged operation and a covering colostomy would be the proper treatment.

(3) *High Intersphincteric Fistula.*—The track starts as a primary anal gland abscess (type A, fig. 1226), and it runs between the internal and external sphincter along the plane of the longitudinal muscle fibres. It may have an opening into the rectum above the ano-rectal ring and below at the site of a perianal abscess (type B, fig. 1226). Providing it is recognised it is easy to treat. The internal sphincter is divided and the whole track is laid open without fear of incontinence.

NON-MALIGNANT STRICTURES

1. **Congenital:**

(*a*) A stricture at the level of the anal valves, due to incomplete obliteration of the proctodeal membrane, sometimes does not give rise to symptoms until early childhood.

(*b*) Patients who have had an operation for imperforate anus in infancy may require periodic ano-rectal dilatation.

St. Mark's Hospital for Diseases of the Rectum and Colon, London, founded in 1835 at St. Mark's Hospital for Fistula.

2. **Spasmodic :**

(*a*) An anal fissure causes spasm of the internal sphincter, which in time becomes fibrotic.

(*b*) Rarely, a spasmodic stricture accompanies Secondary Megacolon (p. 964).

3. **Organic :**

(*a*) *Post-operative stricture* sometimes follows hæmorrhoidectomy performed incorrectly, and also occurs after sleeve resection of a portion of the rectum for a neoplasm.

(*b*) *Irradiation stricture* is an aftermath of irradiation proctitis.

(*c*) *Senile Anal Stenosis.*—A condition of chronic internal sphincter contraction is sometimes seen in the aged. Increasing constipation is present with pronounced straining at stool. Fæcal impaction is liable to occur. The muscle is rigid and feels like a tight umbrella-ring. There is no evidence of a fissure-in-ano. The treatment is internal sphincterotomy or dilation at frequent intervals.

(*d*) *Lymphogranuloma Inguinale* (p. 1283).—This is by far the most frequent cause of a *tubular* inflammatory stricture of the rectum, and 80% of the sufferers are women. Frei's reaction is usually positive. This variety of rectal stricture is particularly common in Negro races, and may be accompanied by elephantiasis of the labia majora. In the early stages, antibiotic treatment may lead to cure. In advanced cases excision of the rectum is required.

(*e*) *Ulcerative Colitis.*—Stricture of the rectum also complicates ulcerative proctocolitis; in this instance the stricture is *annular*, and often more than one are present. A carcinoma should be suspected if a stricture is found.

(*f*) *Endometriosis* of the recto-vaginal septum may present as a stricture. There is usually a history of frequent menstrual periods with the appearance of severe pain during the first two days of the menstrual flow (p. 1086).

(*g*) *Neoplastic.*—When free bleeding occurs after dilatation of a supposed inflammatory stricture, carcinoma should be suspected (Grey Turner), and a portion of the stricture should be removed for biopsy. Sometimes, in these cases, repeated biopsies show inflammatory tissue only. If, however, the symptoms show a marked progression, malignancy should be strongly suspected.

Clinical Features.—Increasing difficulty in defæcation is the leading symptom. The patient finds that increasingly large doses of aperients are required, and if the stools are formed, they are ' pipe-stem ' in shape. In cases of inflammatory stricture, tenesmus, bleeding, and the passage of muco-pus are superadded. Sometimes the patient comes under observation only when subacute or acute intestinal obstruction has supervened.

Rectal Examination.—The finger encounters a sharply defined shelf-like interruption of the lumen at a varying distance from the anus. If the calibre is large enough to admit the finger, it should be noted whether the stricture is annular (fig. 1238) or tubular. Sometimes this point can be determined only after dilatation. A biopsy of the stricture should be taken.

George Grey Turner, 1877–1951. Professor of Surgery, Postgraduate Medical School, London.

Treatment:

Prophylactic.—The passage of an anal dilator during convalescence after hæmorrhoidectomy greatly reduces the incidence of post-operative stricture. Efficient treatment of lymphogranuloma inguinale in its early stages should lessen the frequency of rectal stricture from that cause.

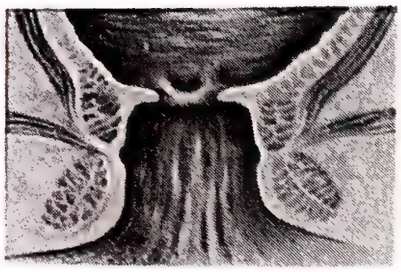

FIG. 1238.—Simple annular stricture of the rectum.

Dilatation by Bougies.—For anal and many rectal strictures dilatation by bougies at regular intervals, combined at first with lavage, is occasionally curative. When the stricture is in the lower two-thirds of the rectum, Hegar's dilators are suitable for this purpose. *Stricture of the upper third of the rectum should never be treated by dilatation* because of the risk of extra- or intra-peritoneal perforation of the bowel.

Incision and Primary Free Skin Graft.—For the post-operative and senile strictures this operation gives by far the best results.

The stricture is exposed and divided posteriorly so as to remove about 1 cm of the fibrosed ring. A 'back cut' is made and a triangular piece of skin removed with its apex above in such a way as to ensure complete and adequate enlargement of the strictured region. A split skin graft is then taken from the inner side of the thigh, laid firmly into the defect, and sutured into position with fine catgut sutures. Greasy dressings are applied to keep it firmly in position and renewed on about the fourth day when the bowels are allowed to act. The percentage 'take' is high and the results surprisingly good.

Colostomy must be undertaken when a stricture is situated in the upper third of the rectum, when it is causing intestinal obstruction, and in advanced cases of stricture complicated by fistulæ-in-ano. In selected cases this can be followed by restorative resection of the stricture-bearing area. If this step is anticipated, the colostomy is placed in the transverse colon.

Excision of the rectum is required in some resistant cases due to lymphogranuloma inguinale, especially when the associated proctitis persists in spite of general treatment.

BENIGN TUMOURS OF THE RECTUM

The rectum shares the same types of polyp as the colon, and with the sigmoid colon is the most frequent site of polyps (and cancers) in the gastro-intestinal tract. All neoplastic polyps of the colon and rectum (with rare exceptions) have a tendency to become malignant. This tendency is greatly enhanced if the polyp is more than 1 cm. in diameter, shows obvious signs of increasing size and has a sessile rather than a pedunculated shape. For these reasons, removal of all polyps is recommended, and *total* removal is mandatory. Only total removal will give complete histological examination and exclude (or confirm) localized carcinoma-in-situ, and also prevent local recurrence. For these reasons, destruction of ano-rectal tumours by fulguration is not the best treatment, and should be used for only the tiniest polyps. If one or more rectal polyps are discovered on sigmoidoscopic

examination; an air contrast barium enema should be performed as further polyps are frequently found in the colon and treatment may be influenced. *No rectal tumour should be removed until the possibility of a proximal carcinoma has been ruled out, otherwise local implantation of cancer cells may occur in the distally situated rectal wound.*

The rectum shares substantially the same spectrum of polyps as the colon. Polyps are described chiefly in terms of their tissue organisation. For further clinical details the reader is referred to Chapter 47. Certain polyps that are unique to the ano-rectum, or which have certain features relevant to the rectum, are now described:

1. **Juvenile polyp.**—This is a bright red glistening pedunculated sphere ('cherry tumour') which is found in infants and children. Occasionally it persists into adult life. It can cause bleeding, or pain if it prolapses during defæcation. It often separates itself, but can be removed easily with forceps or a snare. It has no tendency to malignant change but should be treated if it is causing symptoms. It has a unique histological structure of large mucous-filled spaces covered by a smooth surface of thin rectal cuboidal epithelium.

2. **Metaplastic polyps.**—There are small pinkish sessile polyps 2–4 mm. in diameter and frequently multiple. They are harmless.

3. **Pseudo-polyps.**—These are actually œdematous bosses of mucous membrane. They are usually associated with colitis in the United Kingdom but most inflammatory diseases (including tropical diseases) can cause them. They are more likely to cause radiological difficulty as the sigmoidoscopic appearances are usually associated with obvious signs of the inflammatory cause.

4. **Villous adenomas.**—These have a characteristic frond-like appearance. They are often of very large size, and occasionally fill the entire rectum. The large tumours have an enhanced tendency to become malignant—a change that can be detected most easily by palpation with the finger; any hard area should be assumed to be malignant and should be biopsied.

Providing cancerous change has been excluded, these tumours can be removed either by submucous dissection per anum, or by sleeve resection from above. Only very unusually is rectal excision required, and then only when malignant change has occurred.

Rarely, the profuse mucous discharge from these tumours which is high in potassium content causes dangerous electrolyte and fluid losses.

All neoplastic polyps can be solitary or multiple. Small colonic polyps (<5 cm in size) can now be snared through the colonoscope. This new instrument has revolutionised the treatment of multiple polyps.

5. **Familial polyposis coli.**—This disease usually manifests itself by the development of multiple rectal polyps around puberty (p. 987). An air-contrast barium enema will confirm the presence of multiple colonic polyps.

Differential Diagnosis.—In patients who have lived in Egypt or any country where bilharzial infestation is rife, bilharzial papilloma must be excluded (p. 1074).

Treatment.—Diathermy coagulation is satisfactory in the case of a small papilloma, but the patient must be examined at regular intervals, for recurrence is common, as in the case of the bladder. For large papillomas, especially the sessile variety, excision of the rectum is the only curative treatment. Some cases (not, as a rule, those invading the anal canal) are suitable for conservative resection of the rectum.

Benign lymphoma, which occurs as a circumscribed movable nodule, firm but not hard, and greyish-white to pink in colour, is essentially submucosal. This neoplasm, which occurs at all ages and in both sexes, has no definite capsule. Notwithstanding, complete local excision is curative.

Endometrioma is not exceedingly rare, and as a rule it is diagnosed as a carcinoma. This neoplasm produces either a constricting lesion of the recto-sigmoid, or a tumour invading the rectum from the recto-vaginal septum. The latter variety gives rise to a very tender submucous elevation of the rectal wall. Endometrioma occurs usually between twenty and forty years of age; less often at the menopause. Dysmenorrhœa with rectal bleeding are the main symptoms. On sigmoidoscopy endometriosis involving the recto-sigmoid junction usually presents as a stricture with the mucous membrane intact. Bilateral öophorectomy may be followed by regression of the tumour, rendering resection unnecessary. The contraceptive 'Pill' is also effective as it inhibits ovulation.

Hæmangioma of the rectum, which is an uncommon tumour, is a cause of serious and, if the neoplasm is large, sometimes fatal hæmorrhage. When localised in the lower part of the rectum or anal canal, a hæmangioma can be excised after applying Goodsall's ligature (p. 1070). When the neoplasm is diffuse, or lying in the upper part of the rectum, the symptoms simulate ulcerative colitis, and often the diagnosis is missed for a long period. At other times the neoplasm is mistaken for a vascular carcinoma, an error which, fortunately, is not often a cause for serious regret, because the correct treatment of an extensive hæmangioma is excision of that portion of the ano-retum bearing the neoplasm. Lesser procedures are followed nearly always by recurrence and renewed loss of blood.

Fibroma (*syn.* fibrous polypus) is not uncommon. *It is not a neoplasm*, but is due to fibrosis of a thrombosed hæmorrhoid.

CARCINOMA OF THE RECTUM

This is the fourth most common variety of malignant tumour found in women, and its frequency in men is surpassed only by carcinoma of the bronchus and stomach.

Origin.—The carcinoma commences as a nodule of atypical columnar epithelium, the rapidly proliferating cells of which extend on the surface by exuberant growth at its edges. Similar changes occur on the deep (submucosal) surface of the nodule. The less malignant varieties continue to extend towards the lumen; the more malignant varieties soon become necrotic in their centre, and give place to an ulcer with indurated, everted edges. In about 30 per cent. of cases, operation specimens show that in some part of the bowel that has been removed, in addition to the carcinoma, there are one or more adenomas or papillomas, proof indeed that adenoma and papilloma of the rectum are pre-carcinomatous conditions. In approximately 3 per cent. of cases there is more than one carcinoma present.

Pathological Histology.—Three types are recognised:

(1) Well differentiated adenocarcinoma; (2) Averagely differentiated adenocarcinoma; (3) Anaplastic, highly undifferentiated adenocarcinoma.

The more malignant varieties frequently contain large numbers of mucin producing cells. The prognosis after treatment is greatly influenced by the histological grading of the tumour (p. 1088)

Usually these carcinomas present as an ulcer, but papilliferous and infiltrating types are not uncommon.

Local spread occurs circumferentially rather than in a longitudinal direction. Usually a period of six months is required for involvement of one-quarter of the circumference, and eighteen months to two years for complete encirclement, the annular variety being common at the recto-sigmoid junction. After the muscular coat has been penetrated the growth spreads into the underlying fat, but is still limited by the fascia propria (peri-rectal fascia). Eventually the fascia propria is penetrated but this occurrence is rare before eighteen months from the commencement of the disease. If penetration occurs anteriorly, the prostate, seminal vesicles, or the bladder become involved in the male; in the female the vagina or the uterus are invaded. In either sex, if the penetration is lateral, a ureter may become implicated, while posterior penetration involves the sacrum and the sacral plexus. Downward spread for more than a few centimetres is rare except in anaplastic tumours.

Lymphatic Spread.—Enlargement of lymph nodes from bacterial infection is more frequent than enlargement from metastasis, and microscopical examination is required to detect carcinomatous involvement of the nodes. Lymphatic spread from a carcinoma of the rectum above the peritoneal reflexion occurs almost exclusively in an *upward* direction; below that level to within 1 to 2 cm of the anal orifice the lymphatic spread is still *upwards*, but the first halting place is in the para-rectal lymph nodes of Gerota. The exception to this rule is when the neoplasm lies within the field of the middle rectal artery, i.e. between 4 and 8 cm from the anus, in which case primary *lateral* spread along the lymphatics that accompany the middle rectal vein is not infrequent. *Downward* spread is exceptional, drainage along the subcutaneous lymphatics to the groins being confined, for practical purposes, to the lymph nodes draining the perianal rosette and the epithelium lining the distal 1 to 2 cm of the anal canal.

Metastasis at a higher level than the main trunk of the superior rectal artery occurs only late in the disease. A radical operation should ensure that the high-lying lymph nodes are removed by ligating the inferior mesenteric artery and vein at the highest possible level.

Atypical and widespread lymphatic permeation can occur in highly undifferentiated neoplasms.

Venous Spread.—As a rule, spread via the venous system occurs late, except in that portion of the anal canal where the anoderm is firmly adherent to deeper structures (fig. 1181). Anaplastic and rapidly growing tumours in younger patients are much more liable to spread in this way than tumours of relatively low malignancy. The principal sites for blood-borne metastases are: liver (34 per cent.), lungs (22 per cent.), adrenals (11 per cent.). The remaining 33 per cent. is divided among the many other locations where secondary carcinomatous deposits are wont to lodge.

Peritoneal dissemination may follow penetration of the peritoneal coat by a high-lying rectal carcinoma.

Stages of Progression.—As a rule carcinoma of the rectum does not metastasise early. Dukes classifies carcinoma of the rectum into three stages (fig. 1239).

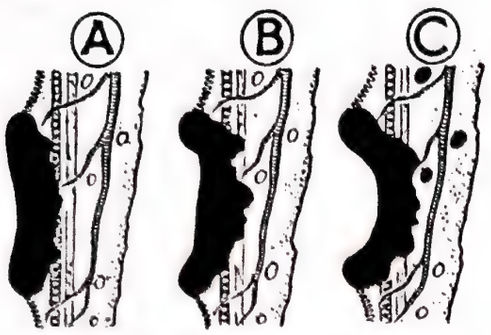

FIG. 1239.—The three cardinal stages of progression of the neoplasm. (*After Cuthbert Dukes, F.R.C.S.*)

(A) The growth is limited to the rectal wall (15 per cent.).

(B) The growth is extended to the extra-rectal tissues, but no metastasis to the regional lymph nodes (35 per cent.).

(C) There are secondary deposits in the regional lymph nodes (50 per cent.). These are subdivided into C^1 where the local para-rectal lymph nodes alone are involved, and C^2 where the nodes accompanying the supplying blood-vessels are implicated. This does not take into account cases that have metastasised beyond the regional lymph nodes or by way of the venous system.

Histological Grading.—In the great majority of cases carcinoma of the rectum is a columnar-celled adenocarcinoma. The more nearly the tumour cells approach normal shape and arrangement, the less malignant is the tumour. Conversely, the greater the percentage of cells of an embryonic or undifferentiated type, the more malignant is the tumour. Broders' histological classification (p. 48) into four grades has been simplified by Dukes into three grades :

Low grade = well-differentiated tumours	11 per cent.	Prognosis good.
Average grade	64 per cent.	,, fair.
High grade = anaplastic tumours . .	25 per cent.	,, poor.

Colloid carcinoma is present in 12 per cent. of cases. There are two forms—primary and secondary; much the more frequent is secondary mucoid degeneration of an adenocarcinoma. Histologically the glandular arrangement is preserved and mucus fills the acini. This type is of average malignancy. In a small number of cases the tumour is a primary mucoid carcinoma. The mucus lies within the cells, displacing the nucleus to the periphery, like the seal of a signet ring. Primary mucoid carcinoma gives rise to a rapidly growing bulky growth which metastasises very early and the prognosis of which is very bad. See also Colloid Carcinoma arising in a fistula-in-ano (p. 1080).

Clinical Features.—Carcinoma of the rectum is not uncommon early in life, and when the disease commences in youth, in spite of radical treatment death usually results within a year. Usually the early symptoms are so slight that the patient does not seek advice for six months or more.

Bleeding is the earliest and most constant symptom. There is nothing characteristic about the time at which it occurs, neither is the colour nor the amount of blood distinctive; often the bleeding is slight in amount, and occurs at the end of defæcation, or is noticed because it has stained underclothing. Indeed, more often than not, the bleeding in every respect simulates that of internal hæmorrhoids[1], and it is lamentable that, in spite of oft-repeated exhortations, the patient's doctor sometimes fails to examine the rectum but prescribes a salve while the growth advances to inoperability (footnote, p. 1030).

[1] Hæmorrhoids and carcinoma sometimes co-exist (fig. 1208).

Cuthbert Esquire Dukes, 1890–1977. (*See footnote p. 1081.*)

Sense of Incomplete Defæcation.—The patient has his bowels open but feels that there are more fæces to be passed. This is a very important early symptom[1] and is almost invariably present in tumours of the lower half of the rectum. The patient may endeavour to empty the rectum several times a day (spurious diarrhœa), often with the passage of flatus and a little blood-stained mucus (' bloody slime ').

Alteration in bowel habit is the next most frequent symptom, and the commonest deviation from normality is increasing constipation. The patient finds it necessary to start taking an aperient, or to supplement his usual dose, and as a result a tendency towards diarrhœa ensues. A patient who has to get up before the accustomed hour in order to defæcate, and one who passes blood and mucus in addition to fæces[2], is usually found to be suffering from carcinoma of the rectum. Usually it is the patient with an annular carcinoma at the pelvi-rectal junction who suffers with increasing constipation, and the one with a cauliflower growth in the ampulla of the rectum with early morning diarrhœa (Bruce).

Pain is a late symptom, but pain of a colicky character accompanies advanced growths of the recto-sigmoid and is due to some degree of intestinal obstruction. When a deep carcinomatous ulcer of the rectum erodes the prostate or bladder, there is severe pain. Pain in the back, or sciatica, occurs when the growth invades the sacral plexus. Weight loss is suggestive of hepatic metastases.

Abdominal examination is negative in early cases. Occasionally when an advanced annular growth is situated at the recto-sigmoid junction, signs of obstruction to the large intestine are likely to be present. By the time the patient seeks advice metastases in the liver may be palpable (fig. 1240). When the peritoneum has become studded with secondary deposits, ascites results.

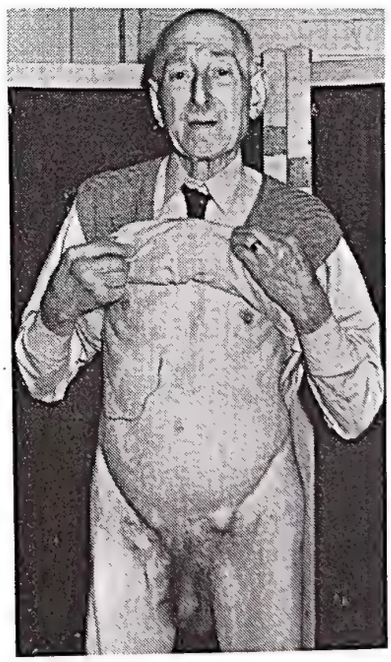

FIG. 1240.—Massive irregular enlargement of the liver. Rectal examination revealed a carcinomatous ulcer on the right side of the ano-rectal junction. Hard lymph node in right groin. The patient also has a left inguinal hernia and a right saphenous varix.

Rectal Examination.—In approximately 90 per cent. of cases the neoplasm can be felt digitally: in early cases as a plateau or as a nodule with an indurated base. When the centre ulcerates, a shallow depression will be found, the edges of which are raised and everted; this, combined with induration of the base of the ulcer, is a frequent and unmistakable finding. On bimanual examination it may be possible to feel the lower extremity of a carcinoma situated in the recto-sigmoid junction. After the finger has been withdrawn, if it has been in direct contact with a carcinoma, it is smeared with blood, or muco-purulent material tinged with blood. When a car-

[1] *Tenesmus* is painful straining to empty the bowels without resultant evacuation.
[2] ' Early morning bloody diarrhœa.'

Sir John Bruce, 1905–1975. Regius Professor of Clinical Surgery, University of Edinburgh.

cinomatous ulcer is situated in the lower third of the rectum, involved lymph nodes can sometimes be felt as one or more hard oval swellings in the extra-rectal tissues posteriorly or posterolaterally above the tumour. In females a vaginal examination should be performed, and when the neoplasm is situated on the anterior wall of the rectum, with one finger in the vagina and another in the rectum, very accurate palpation can be carried out.

Procto-sigmoidoscopy in the complete knee-elbow position (fig. 1195) will always show a carcinoma, if present.

Biopsy.—Employing biopsy forceps (fig. 1241) by way of a proctoscope, a portion of the edge of the tumour is removed. If possible another specimen from the more central part of the growth is obtained also. Expert histological examination will not only enable the diagnosis of carcinoma to be confirmed, but the tumour can be graded as to its relative malignancy.

Barium enema is required (*a*) in rare instances when sigmoidoscopy is unsatisfactory because of spasm, (*b*) in cases of suspected carcinoma of the pelvi-rectal junction when sigmoidoscopy fails to reveal the growth because of spasm of the bowel below it, (*c*) when multiple adenomatous polyposis of the colon must be excluded and (*d*) when practical, to exclude other synchronous carcinomas (5% of cases).

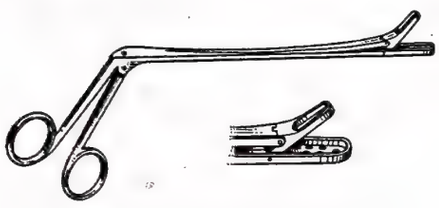

FIG. 1241.—Yeomans' biopsy forceps.

Differential Diagnosis.—When a seemingly benign **papilloma** or **adenoma** shows evidence of induration or friability, it is certain that malignancy has occurred, even in spite of biopsy findings to the contrary. On the other hand, biopsy is invaluable in distinguishing carcinoma from an **inflammatory stricture** or an **amœbic granuloma**, which simulates a carcinoma very closely. The possibility of a neoplasm being an **endometrioma** should always be entertained in patients with dysmenorrhœa. Finally, the importance of bearing in mind the possibility of a **carcinoid tumour** in atypical cases has already been emphasised. In the last four instances biopsy will frequently establish the correct diagnosis. The solitary ulcer syndrome has already been alluded to (p. 1075).

Treatment

Some form of excision of the rectum is essential, if at all possible, because of the extreme suffering entailed if the neoplasm remains.

Apart from co-existent disease or senile enfeeblement, the only prohibitions to excision of the rectum are widespread distant metastases and extensive peritoneal deposits. Many instances have been reported where a presumed solitary metastasis in the liver has been resected, either at the time of excision of the rectum, or subsequently. Even when metastases in the liver are irremovable, resection of the rectum is often justifiable, and the patient may survive in comfort for a year or two.

A combined (abdominal and perineal) excision offers the best prospect of eradicating the disease for tumours in the lower half of the rectum. For those in the upper half of the rectum a restorative type of operation (anterior resection) is usually possible. Because of the much wider degree of local spread by anaplastic tumours and the high risk of local recurrence, restorative operations are not usually done for this group of lesions.

The combined operation can be carried out as an abdomino-perineal procedure (Miles), by which is meant that the abdominal part of the operation is undertaken first, or a perineo-abdominal (Gabriel), where the perineal stage is performed before the abdominal stage, or thirdly, as a synchronised procedure, where two operating teams work simultaneously.

Five days pre-operative sterilisation of the alimentary tract by sulphasuccidine is required. The colon is cleansed by enemas or a colon wash as necessary. Blood and electrolyte deficiencies are corrected. Before commencing the operation, an indwelling catheter is inserted into the bladder. In male patients a full sized catheter is preferred as damage to the urethra is thereby made less likely during dissection anterior to the rectum.

Combined Synchronised Excision of the Rectum.—This is the operation which is now commonly performed. It combines the advantages of both the abdomino-perineal and the perineo-abdominal operations. With the patient in Trendelenburg-lithotomy position, the legs being supported in special crutches designed by Lloyd-Davies

access is afforded to the abdomen and the perineum at the same time. Two surgeons operate simultaneously, one performing the perineal dissection and the other the abdominal portion of the operation. This considerably reduces the time expended in performing the operation, and obviates turning the patient. The resectability rate is increased by this operation.

The *Abdominal Surgeon* makes a left paramedian incision, extending it well above the umbilicus. The liver and the peritoneum are examined for metastases and the degree of fixity of the growth established. The small intestine is packed away from the pelvis. A self-retaining retractor is placed in the wound and the pelvic colon freed by dividing any congenital adhesions on the left side. The peritoneum and the pelvic floor are divided with a knife by an incision which runs from the colon at the proposed site of division over the mesocolon and across the base of the bladder or near the cervix on the peritoneal floor and then upwards on the right side of the mesocolon. The peritoneum is now raised, using the points of the scissors to expose the ureters and testicular or ovarian artery. The mesocolon is now divided at the site of the proposed division on the colon and the trunk of the inferior mesenteric artery (fig. 1242) ligated and divided distal to the first branch. (Some surgeons emphasise 'flush ligation' of the artery at its origin from the aorta.) The recto-sigmoid mesentery is further divided and separated from the sacrum by blunt dissection with the fingers. In this way the sacrum is cleared almost down to the coccyx. The peritoneal incision anterior to the rectum is now deepened and the seminal vesicles or the vaginal wall is identified so that the fascia behind them is cleared by a dissection leading down to the prostate or perineal body. The middle rectal vessels usually lying anterior to the lateral ligaments on each side are now seized with clamps, divided and ligated. The site of division of the pelvic colon is cleared of fat and the colon divided between clamps with diathermy.

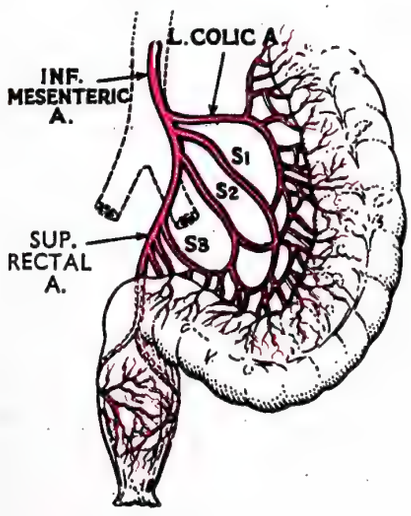

FIG. 1242.—The inferior mesenteric artery. S_1 S_2 S_3 = sigmoid branches.

By this time the perineal surgeon working from below has mobilised the anus and the lower rectum so that the whole of the bowel below together with a clamp can be passed through the perineal wound by the abdominal surgeon. Hæmostasis over the sacrum may be difficult but it is achieved by diathermy and a hot saline pack left in position for a few minutes. The pelvic peritoneum is now united by continuous catgut stitches from the bladder right back over the promontory of the sacrum (fig. 1243).

William Ernest Miles, 1869–1947. Surgeon, Royal Cancer Hospital (now the Royal Marsden Hospital), London.
Friedrich Trendelenburg, 1844–1924. Professor of Surgery, Leipzig, Germany.
Oswald Vaughan Lloyd-Davies, Contemporary. Surgeon, Middlesex Hospital, London.

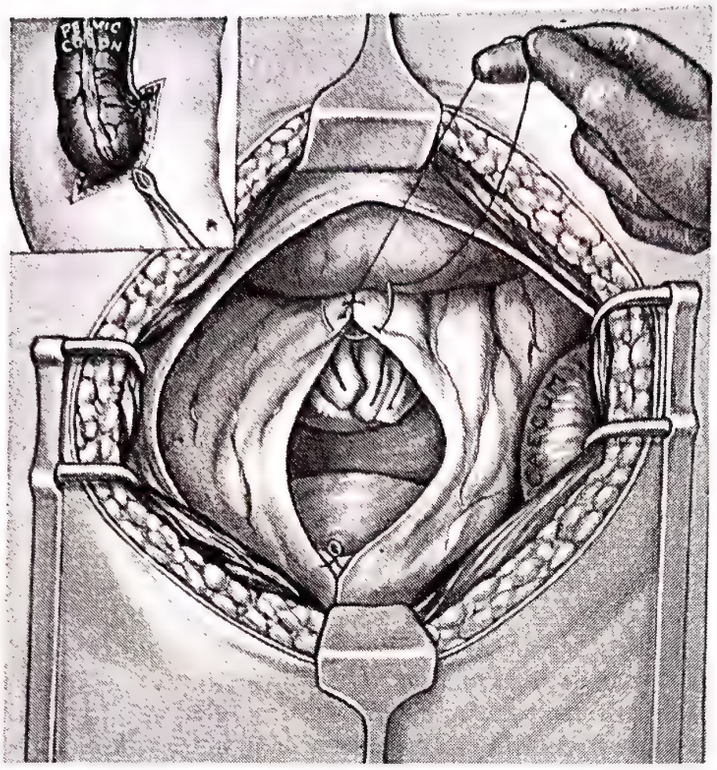

FIG. 1243.—The cut edges of the pelvic peritoneum are being united by the abdominal surgeon over the space (filled by packing) where the perineal surgeon is working. *Inset:* The rectum and pelvic colon drawn through the left iliac incision to form a terminal colostomy.

The site in the L.I.F. for the colostomy is then selected. This should be equidistant from the umbilicus and the left anterior superior iliac spine and is usually sited at the linea semilunaris about 2·5 cm above the spino-umbilical line. A circular piece of skin and fascia, about 3 cm in diameter, is incised and this hole deepened to excise similar layers of fascia and peritoneum. The protected end of the colon with the clamp is now passed through this incision and the colostomy performed by suturing the colon to the peritoneum and the mucosa directly to the skin. The paracolic gutter is closed with sutures—this will close the 'lateral space'. The abdomen is closed and the layers of the incision protected from the colostomy. An adherent plastic colostomy bag is then fitted in position and the dressings are placed on the abdominal wound.

Perineal Surgeon.—When the abdominal surgeon has made certain that the condition is operable, the perineal surgeon closes the anus with purse-string sutures of stout silk. An elliptical incision between the tip of the coccyx and the central perineal point is made around the anus and deepened. The left forefinger is insinuated into the levator ani which is divided lateral to the finger first on one side and then on the other. The dissection is deepened posteriorly by incising Waldeyer's fascia which is a thick condensation of pelvic fascia lying between the rectum and the sacrum. Contact is made with the abdominal surgeon. The apex of skin anterior to the anus is grasped in a hæmostat, which serves as a retractor, and by scissors and gauze dissection the wound is deepened, when the catheter within the membranous urethra will be felt. Both in the male and the female a plane of cleavage will be found between the rectum and the prostate or the rectum and the vagina, respectively. This plane having been carefully determined, the strong median raphé of the perineum is divided, after which the rectum can be stripped from the prostate or the vagina. The posterior wall of the vagina is frequently excised with the rectum. When the abdominal surgeon has cleared the rectum laterally, the whole of the anus and rectum can be drawn downwards and removed. Hæmostasis must be secured and the perineal wound closed anteriorly and posteriorly in layers around a large drainage tube. Large dressings of gauze and wool are applied over the area and a triangular bandage is used to keep the dressing in place. It is becoming a more common practice in some centres to employ *primary closure* of the perineal wound, and use laterally-situated suction drains brought out through each ischio-rectal fossa to keep the large perineal cavity from filling up with blood and serous exudate. These drains can be removed after 5 days.

After Treatment.—The patient is returned to bed, blood transfusion being continued as necessary. The catheter is connected to a closed catheter drainage system (fig. 1383) and left in for five days. It may have to be re-inserted if voluntary micturition is not re-established; carbachol may be necessary to establish this.

Reactionary hæmorrhage from the perineal wound may demand return to the theatre to open and pack the wound with gauze. The colour of the colostomy must be watched to make sure the blood supply is adequate. Small bowel obstruction may occur by herniation in the lateral space of the colostomy or through the pelvic peri-

Heinrich Wilhelm Gottfried Waldeyer-Hartz, 1836–1921. Professor of Pathological Anatomy, Berlin.

toneal closure line. Discharge of urine from the perineal wound demands immediate investigation for bladder or ureteric damage.

Care of the Colostomy.—This is much the same as the care of an ileostomy (p. 977). Within a very short time the colostomy acts once or twice a day. The patient soon learns which foods cause diarrhœa and he therefore avoids them.

Stenosis of the colostomy is usually avoided by the removal of the circle of skin and subcutaneous tissues at the colostomy site. Anal dilators (fig. 1207) may be necessary if there is any tendency for stenosis to occur (see also pp. 996–998).

Less Extensive Operations :

Abdominal Radical Restorative Resection (anterior resection).—In cases of carcinoma of the rectum situated above the peritoneal reflection, lymphatic spread is virtually confined to the upward paths, and wide resection of the bowel with its lymphatic field, followed by end-to-end anastomosis and preservation of the sphincter mechanism is both justifiable and highly desirable.

This apparently ideal treatment was, and still is, unpopular in many centres because it has been found that local recurrence occurred in a formidable percentage of cases. It has now been substantiated that the so-called recurrences are due, for the most part, to local implantation of free malignant cells into the distal segment that is to be preserved, the survival and rooting of these cells being favoured by disinfection of the intestine by sulphasuccidine and antibiotics. Naunton Morgan has shown that when a suitable clamp is placed at least 5 cm below the neoplasm, and the rectum is irrigated with buffered Dakin's solution (Chlorinated soda–0·5 per cent. available chlorine), and the lumen of the proximal end and the edges of both segments are swabbed with the same solution before anastomosis, the incidence of local recurrence is reduced considerably.

Restorative resection should be performed only when the tumour is high in the rectum, i.e. at least 10 cm above the anal orifice, and even then it should not be attempted if the build of the patient, and/or the anatomy of the colon and its vascular supply, makes restoration of the continuity of the alimentary canal difficult, nor in a young subject in whom these neoplasms grow rapidly and recur.

The perineal operation (Lockhart-Mummery) does not remove the lymphatic field in relation to the inferior mesenteric artery, and it is reserved mainly as a palliative for poor-risk patients when the neoplasm is situated in the lower third of the rectum.

Hartmann's Operation.—This is an excellent procedure in an old and feeble patient who would not stand an abdomino-perineal procedure. Through an abdominal incision the rectum is excised down to within an inch of the anus, a colostomy performed and the peritoneum oversewn to cover the pelvic defect in the usual way. The cavity below can be drained through the anus, which is divided posteriorly. In the old patient, where the neoplasm is usually slow growing and spread is late, this is a most useful operation.

Palliative colostomy is indicated only in cases giving rise to intestinal obstruction, or where there is gross infection of the neoplasm. It is often possible to resect the growth later.

Local Operations.—For small, low-grade mobile lesions, which are often Grade A tumours, local removal should be curative. For these tumours, especially in the unfit or patients who will not accept a colostomy, local removal has been used. Such operations are only suitable for lesions within 10 cm of the anal verge. Turnbull has advocated local diathermy removal while York-Mason has developed a trans-anal (trans-sphincteric) approach.

More Extensive Operations.—When the carcinoma of the rectum has spread to contiguous organs, the radical operation can often be extended to remove these structures. Thus in the male, where the spread is usually to the bladder, a total cystectomy and resection of the rectum can be affected. In the female the uterus acts as a barrier preventing spread from the rectum to the bladder. Accordingly, a total hysterectomy should be undertaken in addition to excision of the rectum. Should the bladder be involved, then pelvic evisceration must include that structure. Pelvic

John Percy Lockhart-Mummery, 1875–1957. Surgeon, St. Mark's Hospital, London.
Henri Albert Charles Antoine Hartmann, 1860–1952. Professor of Surgery, Paris.
R. Turnbull, Contemporary. Surgeon, Cleveland Clinic, Cleveland, Ohio, U.S.A.
Aubrey York-Mason, Contemporary. Surgeon, St. Helier Hospital, Carshalton, Surrey.

evisceration for carcinoma of the rectum is justifiable only when the surgeon is reasonably confident that the growth can be removed *in toto*.

Pelvic Evisceration (Brunschwig's operation).—The aim is to remove all the pelvic organs, together with the internal iliac and the obturator groups of lymph nodes (fig. 1244). The lithotomy-Trendelenburg position facilitates the procedure, and ligation of both internal iliac arteries diminishes the blood loss. The small intestine fills the empty pelvis. Especial care must therefore be taken to suture accurately the perineal skin, and to avoid pressure necrosis of the perineal incision by nursing the patient on alternate sides. Some form of urinary diversion is necessary (p. 1229).

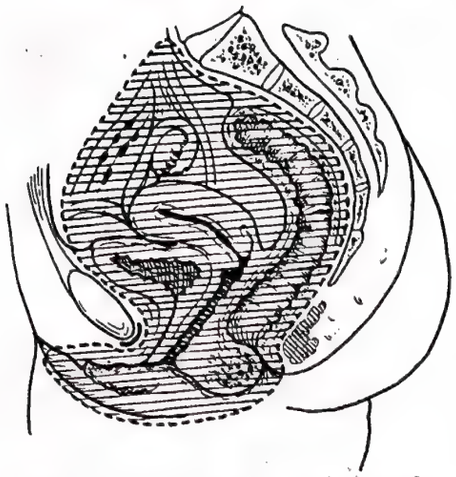

FIG. 1244.—Radical pelvic evisceration, indicating the extent of the dissection and the viscera removed.

Carcinoid Tumour.—Carcinoid tumour of the rectum, as far as its lethal properties are concerned, can be looked upon as a gradation between a benign tumour and a carcinoma. A number of carcinoid tumours of the rectum have been reported during recent years so that a latter-day aphorism is 'keep carcinoid in mind when an atypical neoplasm of the rectum is encountered'. Like benign lymphoma, carcinoid tumour originates in the submucosa, the mucous membrane over it being intact. Consequently it seldom produces evidence of its presence in the early stages, when it appears as a small plaque-like elevation. The incidence of clinical malignancy, i.e. the occurrence of metastases, is 10 per cent. This is much less than that for carcinoid tumour of the small intestine (p. 986) but it is greater than that of carcinoid tumour of the vermiform appendix (p. 1044). Multiple primary carcinoid tumours of the rectum are not infrequent. The neoplasm is slow of progression, and usually metastasises late.

Treatment.—Resection of the rectum is advisable if the growth is more than 2·5 cm. in diameter, if recurrence follows local excision, or if the growth is fixed to the peri-rectal tissues. Even when metastases are present, resection may prolong life.

Radiotherapy.—With modern techniques (MV cobalt therapy or neutron beam irradiation) some adenocarcinomas now respond to radiotherapy. Some large tumours can be shrunk as a pre-operative measure to make removal easier, and palliative irradiation can be given for inoperable primary tumours or local recurrence. Papillon claims cures of early low rectal cancer by direct intracavitary irradiation.

MALIGNANT TUMOURS OF THE ANUS

Carcinoma of the anus differs from carcinoma of the rectum in histological structure, behaviour, and the requisites for treatment. This is mainly because of its abundant lymph drainage, both superficial and deep (fig. 1193).

Squamous-celled Carcinoma.—Because of its superficial situation the presence of the lesion is recognised by the patient, who often presents early. The exception is when radiation carcinoma develops in the anal and perianal skin of a patient unwisely treated with lightly filtered X-rays for pruritus ani. The chronic radiation dermatitis becomes so familiar to the patient that too often he does not perceive the superimposition of carcinoma. Simple papillomas (anal warts) sometimes take on a carcinomatous change (fig. 1245). Anal cancer may also masquerade as an anal fissure (p. 1057). Occasionally a squamous cell carcinoma develops in the track of a long-standing fistula-in-ano.

Basal-celled Carcinoma.—Of twenty-eight cases occurring at the Mayo Clinic, seven were *basaloid* small-celled carcinomas that occurred near the dentate line, and showed a high degree of malignancy. With these exceptions, basal-celled carcinomas are found predominantly at the anal margin and are of relatively low malignancy.

Alexander Brunschwig. Formerly Surgeon, Memorial Hospital for the Treatment of Cancer, New York.
J. Papillon, Contemporary. Professor of Radiotherapy, Lyons, France.
The Mayo Clinic, Rochester, Minnesota (footnote, p. 631).

Melanoma.—Melanoma of the anus presents as a bluish-black soft mass that is apt to be confused with a thrombotic pile, and therefore unfortunately incised. Such trauma, followed by the trauma of defæcation, incites the tumour to rapid metastasis. Left undisturbed, it ulcerates, and the colour of the tumour changes from blue to black. The inguinal lymph nodes are soon involved. Unless a melanoma is excised at an early stage, it disseminates by the blood-stream.

FIG. 1245.—Neglected papillomas of the anus which have become malignant. The patient was a woman of forty-three years of age and symptoms had been present for eight years.

Treatment:

Radiotherapy.—Either low-voltage contact X-rays or interstitial gold radon seeds, 2 millicuries each, placed 1·5 cm. apart at the base of a small tumour, should be reserved for the following types of cases (Pack):

1. Early papillary or basal-celled carcinoma of low-grade malignancy.
2. Advanced lesions that have recurred after operation.
3. In an inoperable case, with the hope of converting an inoperable carcinoma into one that is resectable.

Operation.—For small squamous cell lesions at the anal verge, wide local excision leaving a margin of at least 2·5 cm of tissue all round is occasionally sufficient to effect a cure: in such cases, lymphatic dissemination will be to the inguinal nodes, which should be watched carefully. If they become involved, block dissection removal of the glands of both groins will be necessary.

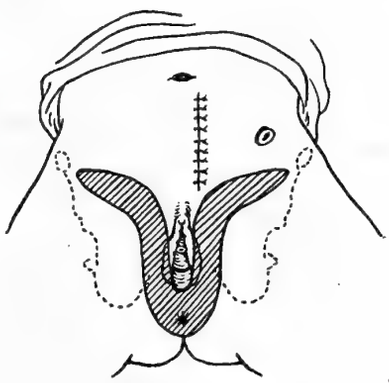

FIG. 1246.—Radical operation for carcinoma of the anus, showing the area of skin removed. In the male the lower half of the scrotum is included (*After G. T. Pack and J. C. Baldwin.*)

With the above exception (and for those suitable for treatment by radiotherapy) all other cases, including the basaloid carcinomas, should be treated by radical surgery, as described below:

Radical operation for malignant disease of the anus must be even more radical than that employed for the average case of carcinoma of the rectum. A curative operation, therefore, comprises removal of the area of skin shown in fig. 1246, together with a block dissection of the inguinal lymph nodes and a radical abdomino-perineal excision of the rectum. This operation is very formidable and causes considerable morbidity. It is usual therefore to do an abdomino-perineal excision, removing the growth and perianal area widely. If and when the inguinal lymph nodes become involved, a radical dissection of the groin is carried out. This formidable operation, which is founded on sound premises based on pathology, gives more favourable results than has been generally believed. It should be noted that dissection of the lymph nodes of the groin or groins, is carried out only when involvement of the nodes can be recognised clinically, or when a doubtful lymph node, submitted to frozen section at the time of the operation, proves to be involved. As has been emphasised already, patients with carcinoma of the anus often present early, and in many patients the inguinal lymph nodes are not involved clinically. Should they become so later, dissection of the groin is carried out.

George Thomas Pack. Formerly Clinical Professor of Surgery, New York Medical College, New York.

CHAPTER 51

THE UMBILICUS AND THE ABDOMINAL WALL (EXCLUDING HERNIA)

THE UMBILICUS

The umbilical cord, formed in the second month of fœtal life from the body stalk, is composed of Wharton's jelly, covered by ectoderm, and contains:

1. **The allantois,** a diverticulum from the yolk sac, is a narrow tube passing from the cloaca through the umbilicus and umbilical cord to end blindly at the placenta. The part within the body forms the urachus and the bladder, except the trigone. The remainder disappears.

2. **The vitello-intestinal duct** is a tubular outgrowth of yolk sac from which the gut is derived (fig. 1247). In 98 per cent. of cases by the time the embryo is six weeks old the vitello-intestinal duct disappears (p. 1098).

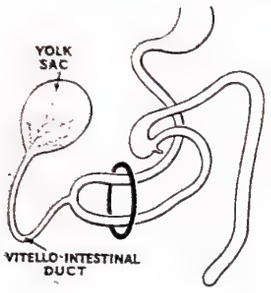

FIG. 1247.—Embryonic canal, showing the vitello-intestinal duct attached to the yolk sac.

3. **The Umbilical Vein.**—Originally two, early in fœtal life the right one atrophies and disappears. The vein carries oxygenated blood from the placenta to the fœtal liver where, having given off branches, it bifurcates (*a*) to join the left branch of the portal vein, and (*b*) to pass on as the ductus venosus to empty its contents into the inferior vena cava.

4. **The umbilical arteries** pass from the internal iliac arteries to, and through, the umbilicus, and, in a spiral fashion, traverse the umbilical cord to join the placental plexus.

The fibrous ring of the umbilicus is situated in the blended aponeurosis of the linea alba at, or below, the centre of that line. In the early days of infancy, while the umbilicus becomes a consolidated scar, the structures just referred to shrink into impervious cords (except that section of the allantois which forms part of the bladder). These cords diverge from the abdominal aspect of the umbilicus into the extraperitoneal fatty tissue, and produce peritoneal folds. Upwards, in the free edge of the falciform ligament, runs the ligamentum teres (the obliterated umbilical vein) to the longitudinal fissure of the liver. Directly downwards to the apex of the bladder runs the urachus (obliterated allantois). Obliquely downwards and outwards pass the obliterated hypogastric (umbilical) arteries to join the internal iliac arteries.

Lymphatics.—The lymphatic vessels drain into both groins and both axillæ.[1]

DISEASES OF THE UMBILICUS

Inflammations:
- Infection of the stump of the umbilical cord (omphalitis).
- Umbilical granuloma.
- Umbilical dermatitis.
- Pilonidal sinus.

Fistulæ:
- Fæcal:
  - Patent vitello-intestinal duct.
  - Neoplastic ulceration from the transverse colon.
  - Tuberculous peritonitis.
- Urinary = Patent urachus.
- Biliary.

[1] A society lady wished to be re-vaccinated ' where the scar wouldn't show '. She selected an area just beneath the umbilicus. Four days later she was confined to bed with painful adenitis of both groins and both axillæ.

Thomas Wharton, 1614–1673. Physician, St. Thomas's Hospital, London.

- Neoplasms
  - Benign
    - Adenoma (raspberry tumour).
    - Endometrioma.
  - Malignant
    - Primary Carcinoma
    - Secondary Carcinoma
      - Stomach.
      - Colon, including the rectum.
      - Ovary and uterus.
      - Breast.

Hernia (p. 1122).
Umbilical calculus.
Eversion (in ascites).

INFLAMMATIONS

Infection of the Umbilical Cord.—By the third or fourth day of life the stump of the umbilical cord is found to be carrying staphylococci in over 50 per cent. of babies born in maternity hospitals. Less commonly the stump of the cord harbours streptococci, and epidemics of puerperal sepsis in maternity hospitals have been traced to the umbilical cord of one infant in the nursery thus infected. *Esch. coli* and *Cl. Tetani* (causing neonatal tetanus) are other possible invaders. The chief prophylaxis is strict asepsis during severance of the cord, and the use of 0·1% chlorhexidine locally, for a few days.

Omphalitis.—The incidence of an infected umbilicus is much higher in communities that do not practise aseptic severance of the umbilical cord. When the stump of the umbilical cord becomes inflamed, antibiotic therapy usually localises the inflammation. By employing warm moist dressings the crusts separate, giving exit to pus. Exuberant granulation tissue requires a touch of silver nitrate. In more serious cases infection is liable to spread along the defunct hypogastric arteries or umbilical vein, when, in all probability, one or other of the following complications will supervene:

1. **Abscess of the Abdominal Wall.**—If gentle pressure is exerted below or above the navel, and a bead of pus exudes at the umbilicus, a deep abscess associated with one of the defunct umbilical vessels is present. This must be opened. A probe is passed into the sinus to determine its direction and this is followed by a grooved director on to which the skin and overlying tissues are incised in the middle line.
2. **Extensive ulceration of the abdominal wall,** due to a synergic infection, is treated in the same way as post-operative subcutaneous gangrene (p. 1102).
3. **Septicæmia** can occur from organisms entering the blood-stream via the umbilical vein. Jaundice is often the first sign. An abscess in the abdominal wall above the umbilicus should be sought. In other respects the treatment of this grave complication follows the usual lines (p. 23).
4. **Jaundice in the Newborn.**—Infection reaching the liver via the umbilical vein may cause a stenosing intrahepatic cholangiolitis, appearing some three to six weeks after birth.
5. **Portal vein thrombosis** and subsequent portal hypertension (p. 867).
6. **Peritonitis** carries a particularly bad prognosis.
7. **Umbilical Hernia** (p. 1122).

Umbilical Granuloma.—Chronic infection of the umbilical cicatrix which continues for weeks causes granulation tissue to pout at the umbilicus. There is no certain means of distinguishing this condition from an adenoma (p. 1099). Usually an umbilical granuloma can be destroyed by one application of a silver nitrate stick followed by dry dressings but an adenoma soon recurs in spite of these measures (p. 1100).

Dermatitis of and around the umbilicus is common at all times of life. Fungus and parasitic infections are more difficult to eradicate from the umbilicus than from the skin of the abdomen. Sometimes the dermatitis is

consequent upon a discharge from the umbilicus, as is the case when an umbilical fistula or a sinus is present.

A deep, tender swelling in the midline below the umbilicus signifies an abscess present in the extraperitoneal fat, and is usually due to an *infected urachal remnant*. Exploration and proper drainage is necessary.

Pilonidal sinus (a sinus containing a sheaf of hairs) is sometimes encountered. It should be excised.

Umbilical calculus (umbolith), often black in colour, is composed of desquamated epithelium which becomes inspissated and collects in a deep recess of the umbilicus. Eventually it gives rise to inflammation, and often a blood-stained discharge. The treatment is to dilate the orifice and extract the calculus, but, to prevent recurrence, it may be better to excise the umbilicus.

UMBILICAL FISTULÆ

The umbilicus being a central abdominal scar, it is understandable that a slow leak from any viscus is liable to track to the surface at this point (fig. 1248). Added to this, very occasionally, the vitello-intestinal duct or the urachus remains patent; consequently it has been remarked aptly that the umbilicus is a creek into which many fistulous streams may open.

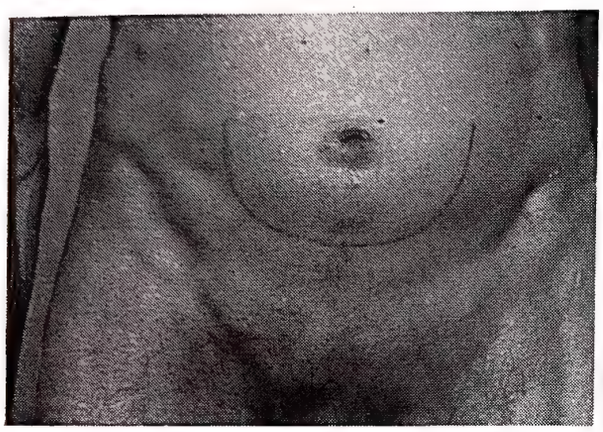

FIG. 1248.—This patient, aged sixty-two, complained only of a purulent discharge from the umbilicus. A lump could be felt in the position outlined. Perforated carcinoma of the transverse colon.

For instance, an enlarged inflamed gall-bladder perforating at its fundus may discharge gall-stones through the umbilicus. Again, an unremitting flow of pus from a fistula at the umbilicus of a middle-aged woman led to the discovery of a length of gauze overlooked during hysterectomy five years previously.

The vitello-intestinal duct occasionally persists, and gives rise to one of the following conditions:

1. It remains patent (figs. 1249 and 1250 (*a*)). The resulting umbilical fistula discharges mucus and, rarely, fæces.

(*b*) A small portion only of the duct near the umbilicus remains unobliterated. This gives rise to a sinus that discharges mucus. The epithelial lining of the sinus often becomes everted to form an adenoma (p. 1098).

FIG. 1249.—Patent vitello-intestinal duct opening at the umbilicus. (*After A. L. Taylor.*)

2. Sometimes both the umbilical and the intestinal ends of the duct close, but the mucous membrane of the intervening portion remains, and an intra-abdominal cyst develops (fig. 1250 (*c*)).

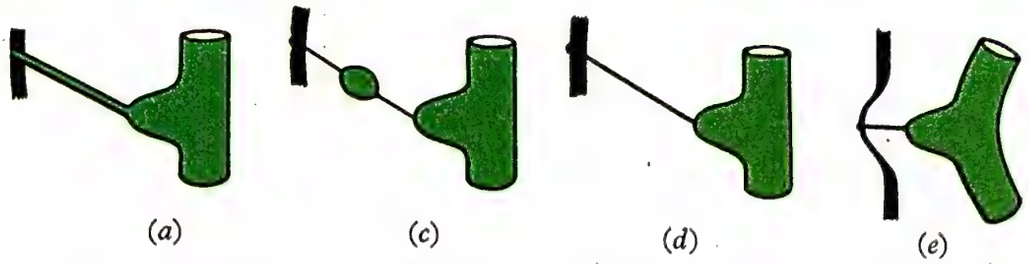

FIG. 1250.—Anomalies connected with the vitello-intestinal duct: (*a*) umbilical fistula; (*b*) umbilical sinus (not illustrated); (*c*) intra-abdominal cyst; (*d*) intraperitoneal band; (*e*) Meckel's diverticulum adherent to the sac of a congenital umbilical hernia.

3. With its lumen obliterated or unobliterated, the vitello-intestinal duct provides an intraperitoneal band (fig. 1250 (*d*)) which is a potential danger, for intestinal obstruction is liable to occur. The obstruction results from a coil of small intestine passing under or over (fig. 1251), or becoming twisted around the band.

4. Such a band may contract and pull a Meckel's diverticulum into a congenital umbilical hernia (fig. 1250 (*e*)).

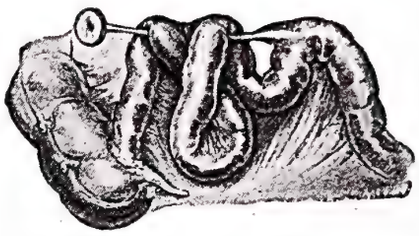

FIG. 1251.—Vitello-intestinal duct causing intestinal obstruction.

5. A vitello-intestinal cord connected to Meckel's diverticulum, but not attached to the umbilicus, becomes adherent to, or knotted around, another loop of small intestine, and so causes intestinal obstruction (fig. 1251).

6. Sometimes a band extending from the umbilicus is attached to the mesentery near its junction with a distal part of the ileum. In this case the band is probably an obliterated vitelline artery, and is not necessarily associated with a Meckel's diverticulum.

Treatment.—A patent vitello-intestinal duct should be excised, together with a Meckel's diverticulum, if such be present, preferably when the child is about six months old. When a vitello-intestinal band gives rise to acute intestinal obstruction, after removing the obstruction by division of the band, it is expedient, when possible, to excise the band and to bury the cut ends.

A patent urachus seldom reveals itself until maturity, or even old age. This is because the contractions of the bladder commence at the apex of the organ and pass towards the base. A patent urachus, because it opens into the apex of the bladder, is closed temporarily during micturition, and so the potential urinary stream to the umbilicus is cut off. Therefore the fistula remains unobtrusive until a time when the organ is overfull, usually due to some form of obstruction.

Treatment.—Usually treatment is directed to removing the obstruction to the lower urinary tract. If, after this is remedied, the leak continues or a cyst develops in connection with the urachus, umbilectomy and excision of the urachus down to its insertion into the apex of the bladder, with closure of the latter organ, is indicated.

Abscess in a urachal remnant, causing persistent umbilical dermatitis and discharge, is described on p. 1098.

NEOPLASMS OF THE UMBILICUS

Umbilical adenoma or **Raspberry tumour** is commonly seen in infants (fig. 1252), but only occasionally later in life. It is due to a partially (occasionally a completely) unobliterated vitello-intestinal duct. Mucosa

Johann Friedrich Meckel (The Younger), 1781–1833. Professor of Anatomy and Surgery, Halle, Germany.

prolapsing through the umbilicus gives rise to a raspberry-like tumour, which is moist with mucus and tends to bleed.

Treatment.—If the tumour is pedunculated, a ligature is tied around it, and in a few days the polypus drops off. Should the tumour reappear after this procedure, umbilectomy is indicated. Sometimes a patent vitello-intestinal duct, or more often a vitello-intestinal band, will be found associated with a Meckel's diverticulum. The Meckel's diverticulum and the attached cord or duct should be excised at the same time as the umbilicus. Histologically, the tumour at the umbilicus consists of columnar epithelium rich in goblet cells.

FIG. 1252.—Adenoma (raspberry tumour) of the umbilicus.

Endometrioma occurs in women between the ages of twenty and forty-five. On histological examination it is found to consist of endometrial glands occupying the same plane in the dermis as the sudoriferous glands, and opening on to the surface in the same way. The umbilicus becomes painful and bleeds at each menstruation, when the small fleshy tumour between the folds of the umbilicus becomes more apparent. Occasionally an umbilical endometrioma is accompanied by endometriomas in the uterus or ovary. When, as is usually the case, the tumour is solitary, umbilectomy will cure the condition.

Secondary carcinoma at the umbilicus[1] (fig. 1253) is not very uncommon, but it is always a late manifestation of the disease. The primary neoplasm is often situated in the stomach, colon or ovary, but a metastasis from the breast, probably transmitted along the lymphatics of the round ligament of the liver, is sometimes located here.

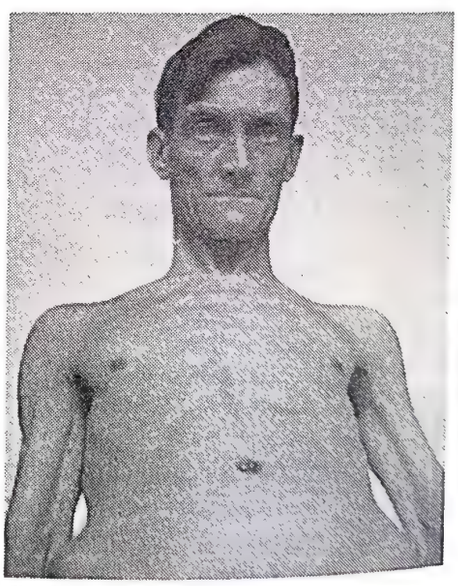

FIG. 1253.—Secondary nodule at the umbilicus in a case of carcinoma of the stomach.

THE ABDOMINAL WALL

Tearing of the inferior epigastric artery occurs in three dissimilar types of individual, viz. elderly women, often thin and feeble; athletic, muscular men, usually below middle age; and pregnant women, mainly multiparæ late in pregnancy. The site of the hæmatoma is usually at the level of the arcuate line, where the posterior sheath of the rectus abdominis is lacking.

Clinical Features.—The possibility of tearing of the epigastric vessels

[1] The neoplastic nodule so caused is known as Sister Joseph's nodule. Sister Joseph of the Mayo Clinic imparted this clinical observation to the late Dr. William Mayo.

should always be considered when, following a bout of coughing, or a sudden blow to the abdominal wall, an exquisitely tender lump appears in relation to the rectus abdominis (fig. 1254). Occasionally, a hæmatoma occurs within the muscles lateral to the rectus sheath. Unless there is bruising of the overlying skin the diagnosis may be difficult.

FIG. 1254.—Tearing of the inferior epigastric artery, showing the tell-tale swelling and bruising (see text). (*Dr. C. L. Colton, Bristol.*)

Differential Diagnosis.—The conditions for which the hæmatoma is frequently mistaken are, in the female, a twisted ovarian cyst, and in both sexes, when the lump is on the right side, an appendix abscess. The sign most likely to be of value in differentiating a hæmatoma of the abdominal wall from these conditions, namely tensing the abdominal musculature, is often unsatisfactory because of the pain it causes. Again, the differential diagnosis between the hæmatoma and a strangulated Spigelian hernia (p. 1130) may be difficult. The absence of vomiting suggests a hæmatoma, and the presence of resonance over the swelling favours a Spigelian hernia, while a plain radiograph of the abdomen sometimes gives positive evidence of the latter.

As a Complication of Pregnancy.—Rupture of the inferior epigastric artery occurs occasionally during pregnancy. Surprising to relate, the hæmorrhage into this closed space from this comparatively small artery has proved fatal.

Treatment.—With rest, a comparatively small hæmatoma may resolve, but sometimes renewed hæmorrhage causes the hæmatoma to rupture into the peritoneal cavity. Therefore it is safer to operate early, evacuate the clot, and ligate the artery.

BURST ABDOMEN (*syn.* ABDOMINAL DEHISCENCE)

In 1 to 2 per cent. of cases a laparotomy wound disrupts and viscera are eventrated. The peak incidence of the catastrophe is between the sixth and eighth day after operation. The predisposing causes are infection, persistent cough, abdominal distension, leakage of pancreatic enzymes, hypoproteinæmia, delayed healing in anæmia, jaundice, malignancy, poor suturing technique and the too early removal of deep tension sutures, which should remain in place for fourteen days. Upper abdominal incisions disrupt more frequently than lower abdominal incisions.

In most cases dehiscence of the deeper layers occurs some days before the wound actually bursts asunder; there may be a small serous discharge; the peritoneal stitches snap or become untied within the first three days of operation, though often the peritoneum at the site of the suture line tears. Sometimes the damage is done while the patient is coming round from the anæsthetic; a most potent factor in this respect is the violent coughing reflex set up if an endotracheal tube is withdrawn while the patient is but lightly anæsthetised.

Prophylaxis.—Great care should be taken in suturing the posterior as well as the anterior layer of the rectus sheath. It is all too easy to omit the suture of this layer when the peritoneum is sewn together. It may have retracted laterally and therefore needs to be sought for diligently. The insertion of deep tension sutures of braided nylon is an additional insurance. When infection of the wound has supervened, or in other conditions in which it is thought that the stitches are liable to give way, the abdominal wall should be supported by ' corsets ' of adhesive plaster. In debilitated and

aged subjects wound healing is retarded, so vitamins, particularly vitamin C, and a high protein diet are indicated.

Clinical Features.—A serosanguineous (pink) discharge from the wound is a forerunner of disruption in fully 50 per cent. of cases. It is the most pathognomonic sign of impending wound disruption, and it signifies that intraperitoneal contents are lying extraperitoneally. The patient often volunteers the information that he 'felt something give way'. If skin sutures have been removed, omentum or coils of intestine may be forced through the wound and will be found lying on the skin. Pain and shock are often absent. It is important to note that there may be symptoms and signs of intestinal obstruction.

Treatment.—An emergency operation is required to replace the bowel, relieve any obstruction, and to resuture the wound. While awaiting operation, reassure the patient and cover the wound with a sterile towel. The stomach is emptied by a gastric tube and intravenous fluid therapy commenced.

Operation.—Each protruding coil of intestine is washed gently with saline solution, and returned to the abdominal cavity. Then protruding greater omentum is treated similarly and spread over the intestine. The abdominal wall having been cleansed, all layers are approximated by through-and-through sutures of braided nylon each passed through a soft rubber or plastic tube collar. The abdominal wall may be supported by strips of adhesive plaster encircling the anterior two-thirds of the circumference of the trunk. Antibiotic therapy is started.

Contrary to what might be thought, peritonitis rarely supervenes and, though the skin wound becomes infected, healing is satisfactory. Also a second dehiscence rarely occurs. There is biochemical evidence that healing after disruption produces a stronger wound. This is due to the improvement in collagen metabolism under these circumstances.

INFECTIONS

Cellulitis can occur in any of the planes of the abdominal wall.

Superficial cellulitis is usually discovered when an abdominal wound is inspected following pyrexia. The earliest sign is when the stitches become embedded in the œdematous skin. Later there is a blush extending for a variable distance from the incision or the stitch holes. On palpation with the gloved hand usually one area is found to be more indurated and tender than the remainder. A stitch should be removed from the immediate vicinity, and if pus or sero-pus escapes it is sent for bacteriological examination, meanwhile one of the tetracyclines is administered.

Deep cellulitis is characterised by brawny œdema towards one or both flanks, and not infrequently of the scrotum or vulva as well. Antibiotic therapy is the mainstay of treatment. When tenderness persists, an anatomical incision dividing the muscles carefully, layer by layer, until pus or purulent fluid is encountered, is often advisable.

Progressive post-operative bacterial synergistic gangrene is fortunately a rare complication after laparotomy, usually for a perforated viscus (notably perforated appendicitis). It has also occurred after gall-bladder operations, colectomy for ulcerative colitis, and even after drainage of an empyema thoracis. The condition is

due to the synergic action of microærophilic non-hæmolytic streptococci and, usually, a staphylococcus. The skin in the immediate vicinity of the wound exhibits signs of cellulitis. Within a few days a central purplish zone with an outer brilliant red zone can be distinguished, and the whole region is extremely tender. Soon the purplish area becomes gangrenous and looks like suède leather. Slowly the condition advances (fig. 1255). The gangrenous skin liquefies, exposing underlying granulation tissue. If the condition persists, the general condition deteriorates.

FIG. 1255.—Bacterial synergistic gangrene of the chest and abdominal wall.

Treatment.—Identification of the organisms and a report on their sensitivity to antibiotics is essential. The usual antibiotics may be of little avail. Bacitracin can be effective (10,000 to 20,000 units I.M., every six hours with local application of 500 units per ml., 4 times daily). Without vigorous and effective treatment the gangrene spreads to the flanks and the patient may die of toxæmia. Hyperbaric oxygen (p. 80), if available, can be life-saving. Cellulitis due to bacteriodes (p. 936) may give no bacteriological growth by conventional techniques and may be missed.

Subcutaneous gas infection.—This is described on page 29.

NEOPLASMS OF THE ABDOMINAL MUSCULATURE

Desmoid tumour is a tumour arising in the musculo-aponeurotic structures of the abdominal wall, especially below the level of the umbilicus. It is a completely unencapsulated fibroma, and is so hard that it creaks when it is cut. Some cases recur repeatedly in spite of apparently adequate excision.

Ætiology.—Eighty per cent. of cases occur in women, many of whom have borne children, and the neoplasm occurs occasionally in scars of old hernial or other abdominal operation wounds. Consequently, trauma—e.g. the stretching of the muscle fibres during pregnancy or possibly a small hæmatoma of the abdominal wall—appears to be an ætiological factor.

Pathology.—The tumour is composed of fibrous tissue containing multinucleated plasmodial masses resembling foreign-body giant-cells. Usually of very slow growth, it tends to infiltrate muscle in the immediate neighbourhood. Eventually it undergoes a myxomatous change: it then increases in size more rapidly. Metastasis does not occur. Unlike fibromata elsewhere, no sarcomatous change occurs.

Treatment.—Unless the tumour is excised widely, with a surrounding margin of at least 2·5 cm of healthy tissue, recurrence commonly takes place. After removal of a large tumour, repair of the defect in the abdominal wall by tantalum gauze or nylon mesh (p. 1128) is required. These tumours are moderately radio-sensitive.

Fibrosarcoma of the abdominal wall is rare. It is resistant to radiotherapy and only in some cases can a wide excision, with tantalum or nylon net repair, offer hope of a cure.

Adenocarcinoma of the colon (fig. 1248) or of other viscera may invade the abdominal wall. In such cases the resection of this extension, along with the primary growth, may require special repair of the resulting defect.

Secondary implantation in the wound may follow any abdominal operation for carcinoma.

CHAPTER 52

HERNIA

A HERNIA is the protrusion of a viscus or part of a viscus through an abnormal opening. The external abdominal hernia is the commonest form (fig. 1256).

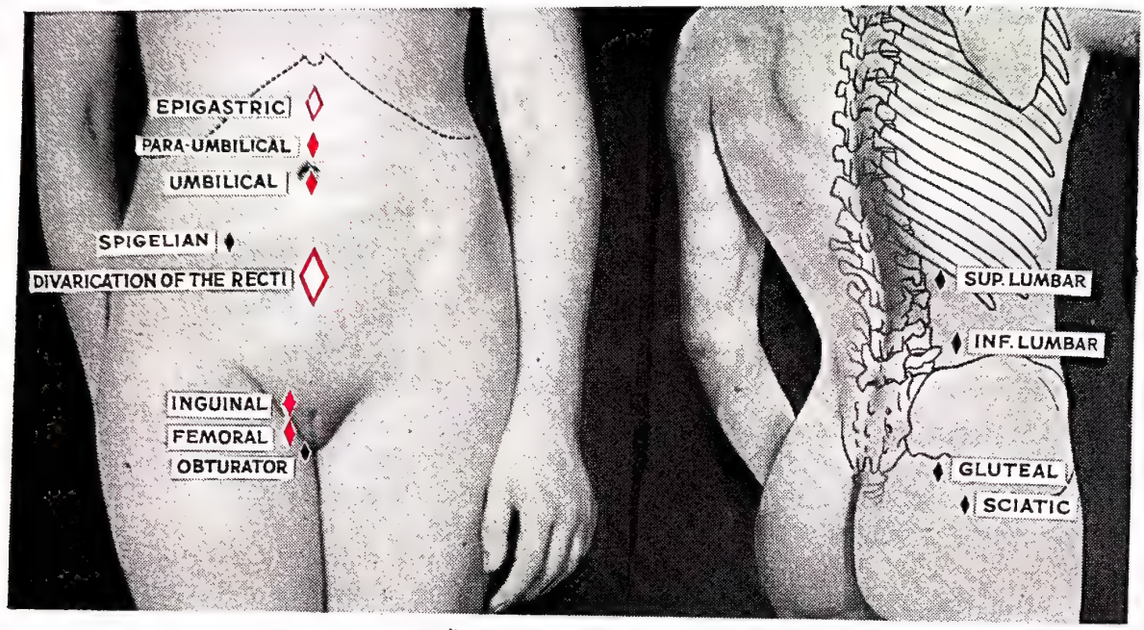

FIG. 1256.—External herniæ. Red = common. White = not unusual. Black = rare.

At least 2 per cent. of male inhabitants of Great Britain have a hernia (Keith), the common types being inguinal, femoral, and umbilical. The most frequent of these is inguinal which occurs in 73 per cent. of cases; then comes femoral, in 17 per cent. of cases, followed by umbilical, which occurs in 8·5 per cent. This leaves 1·5 per cent. for the rarer forms. Post-operative incisional hernia has not been included in these figures.

Aetiology.—In most cases no cause can be elucidated. It is probable that indirect inguinal herniæ occur in a congenital performed sac—the remains of the processus vaginalis (Hamilton Russell). Sometimes a powerful muscular effort or strain occasioned by lifting a heavy weight will cause such a hernia. Any condition which raises intra-abdominal pressure is liable to be followed by a hernia. Whooping cough is a predisposing cause in childhood, whilst a chronic cough favours the appearance of a hernia in an adult. Straining on micturition because of urethral obstruction and straining on defæcation[1] may precipitate a hernia.

Stretching of the abdominal musculature because of an increase in contents as in obesity and in pregnancy, can be another factor. Fat acts as a kind of 'pile-driver' for it separates muscle bundles and layers, weakens aponeuroses, and favours the appearance of paraumbilical, direct inguinal, and hiatus herniæ.

---

[1] If a patient over forty presents with recent hernia one should enquire particularly as to bowel habits, for rectal and colonic carcinoma may be brought to light in this way.

Sir Arthur Keith, 1866–1955. Conservator of the Hunterian Museum, Royal College of Surgeons of England, London.
Robert Hamilton Russell, 1860–1933. Surgeon, Alfred Hospital, Melbourne, Victoria, Australia.

Pathological Anatomy.—As a rule, a hernia consists of three parts—the sac, the contents of the sac, and the coverings of the sac.

The sac consists of a diverticulum of peritoneum which is divided into a mouth, neck, body, and fundus (fig. 1257). Usually the neck is well-defined, but in certain direct inguinal herniæ and in many incisional herniæ there is no actual neck. The body of the sac varies greatly in size and is not necessarily occupied. In cases occurring in infancy and childhood the sac is more delicate than the parietal peritoneum with which it is continuous. In old-standing cases, especially after years of pressure by a truss, the wall of the sac is comparatively thick and even (in places) of cartilaginous consistency.

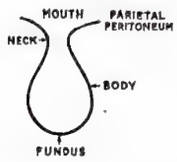

FIG. 1257.—The various parts of a hernial sac.

Contents.—The most common contents of a hernial sac are one or more of the following:

1. Omentum = omentocele (*syn.* epiplocele).
2. Intestine = enterocele. Usually small intestine, but, in some instances, large intestine or the vermiform appendix.
3. A portion of the circumference of the intestine = Richter's hernia.
4. A portion of the bladder, or a diverticulum of the bladder, is sometimes present in addition to other contents in a direct inguinal, a sliding inguinal, and in a femoral hernia.
5. Ovary with or without the corresponding Fallopian tube.
6. A Meckel's diverticulum = Littre's hernia.
7. Fluid. As a part of ascites, or as a residuum thereof. Blood-stained fluid accompanies strangulation.

Coverings are derived from the layers of the abdominal wall through which the sac passes. In long-standing cases they become atrophied from stretching and so amalgamated that they are indistinguishable one from another.

Classification.—A fundamental classification of herniæ, irrespective of their site, is as follows:

1. *Reducible.*
2. *Irreducible.* (*Complication of* 1.)
3. *Obstructed*[1]. } (*Complications of* 2.)
4. *Strangulated.* }
5. *Inflamed.*

Reducible Hernia

The hernia either reduces itself when the patient lies down, or can be reduced by the patient or by the surgeon. The physical signs of reduction vary somewhat with the nature of the contents of the sac. *Intestine* gurgles on reduction, and the first portion is more difficult to reduce than the last. *Omentum* is doughy, and the last portion is more difficult to reduce than the first. A reducible hernia imparts an expansile impulse on coughing.

[1] The term 'incarcerated' should be reserved for impaction of fæces within large intestine.

August Gottlieb Richter, 1742–1812. Lecturer on Surgery, Göttingen, Germany.
Gabriele Falloppio, (Fallopius), 1523–1563. Professor of Anatomy, Surgery and Botany, Padua, Italy.
Johann Freidrich Meckel (The Younger), 1781–1833. Professor of Anatomy and Surgery, Halle, Germany.
Alexis Littre, 1658–1726. Surgeon and Anatomist, Paris. Littre described 'Meckel's' diverticulum in a hernial sac in 1700, 81 years before Meckel was born.

Irreducible Hernia

A hernia is said to be irreducible when its contents cannot be returned to the abdomen, and there is no evidence of other complications. Usually such a condition is brought about by adhesions between the sac and its contents or from overcrowding within the sac. Irreducibility without other symptoms is almost diagnostic of an omentocele. Femoral and umbilical herniæ are most often complicated in this manner. Any degree of irreducibility predisposes to strangulation.

Obstructed Hernia

An obstructed hernia is an irreducible hernia containing intestine the lumen of which is obstructed from without or from within; but there is no interference to the blood-supply to the bowel. The symptoms are less severe and the onset more gradual than is the case in strangulation, but more often than not the obstruction culminates in strangulation. Usually no clear distinction can be made between obstruction and strangulation in herniæ, so the safe course is to assume that strangulation is imminent and treat the case accordingly.

Incarcerated Hernia.—The term ' incarceration ' is often used loosely as an alternative to obstruction or strangulation. As emphasised already, the term ' incarceration ' should be employed only when it is considered that the lumen of that portion of the *colon* occupying a hernial sac is blocked with fæces. In that event the scybalous contents of the bowel should be capable of being indented with the finger, like putty.

Strangulated Hernia

A hernia becomes strangulated when the blood-supply of its contents is seriously impaired, rendering gangrene imminent. Gangrene may occur as early as five or six hours after the onset of the first symptoms of strangulation.

Although inguinal hernia is four times more common than femoral hernia, a femoral hernia is more likely to strangulate.

Pathology.—The intestine is obstructed, and in addition its blood supply is constricted. At first only the venous return is impeded. The wall of the intestine becomes congested and bright red, and serous fluid is poured out into the sac. As the congestion increases, the intestine becomes purple in colour. As a result of increased intestinal pressure the strangulated loop becomes distended, often to twice its normal diameter.. As venous stasis increases, the arterial supply becomes more and more impaired. Ecchymoses appear under the serosa. Blood is effused into the lumen of the loop, and also through the serosa, causing the fluid in the sac to become blood-stained. The shining serosa becomes dull and covered by a fibrinous, sticky exudate. By this time the walls of the intestine have lost their tone; they feel flabby, and are very friable. The lowered vitality of the intestine favours migration of bacteria through the intestinal wall, and the fluid in the sac teems with bacteria. Gangrene appears at the rings of constriction (fig. 1258), which become deeply furrowed and grey in colour. Also from the anti-mesenteric border gangrene spreads upwards, and the colour changes, which vary from black to grey or green, are due to decomposition of blood in

the subserosa. If the strangulation is unrelieved, perforation of the wall of the intestine occurs, either on the convexity of the loop or at the seat of constriction. The mesentery involved in the strangulation becomes congested and hæmorrhagic, and thrombosis of its vessels occurs. Finally it, too, becomes gangrenous. Peritonitis spreading from the sac to the peritoneal cavity is the usual terminal event.

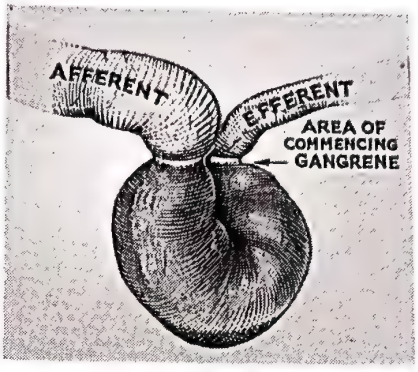

FIG. 1258.—Gangrene commences at the areas of constriction and then at the antimesenteric border.

Clinical Features.—Pain comes on suddenly, and is at first situated over the hernia. Generalised abdominal pain soon supervenes; it is paroxysmal in character and is often located mainly at the umbilicus. Vomiting is forcible and usually oft-repeated. The patient often says that the hernia has recently become larger. On examination, the hernia is *tense*, extremely *tender*, and there is *no expansile impulse on coughing*.

The patient is seriously ill and treatment is vitally urgent. Unless the strangulation is relieved, the paroxysms of pain continue until peristaltic contractions cease with the onset of gangrene when paralytic ileus (often the result of peritonitis) and endotoxin shock (p. 78) develops. Spontaneous cessation of pain is therefore of grave significance.

Strangulated Richter's Hernia (*syn.* Strangulated Partial Enterocele).—A portion of the circumference of the intestine is affected (fig. 1259). The condition, which usually complicates femoral hernia (p. 1118), and, rarely, an obturator hernia, is particularly dangerous as operation is frequently delayed because the clinical features mimic gastro-enteritis. The local signs of strangulation are often not obvious, the patient may not vomit, or vomits only once or twice. Intestinal colic occurs, but the bowels are often opened normally or there may be diarrhœa; absolute constipation (p. 1002) is delayed until paralytic ileus supervenes. For these reasons gangrene of the knuckle of bowel and peritonitis often have occurred before operation is undertaken.

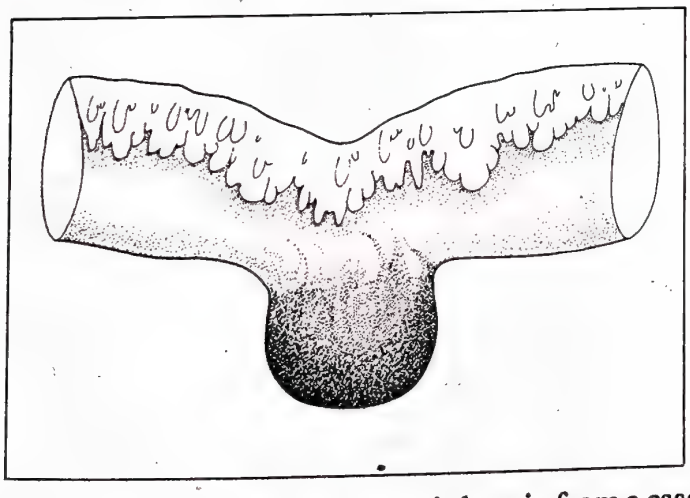

FIG. 1259.—Gangrenous Richter's hernia from a case of strangulated femoral hernia.

Strangulated Omentocele.—The initial symptoms are in general similar to those of strangulated bowel, but the recurring attacks of generalised abdominal pain are not maintained. Vomiting and constipation may be absent. Unlike intestine, omentum can exist on a very meagre blood-supply. The onset of gangrene is therefore correspondingly delayed, and it occurs

first in the centre of the fatty mass. Unrelieved, a bacterial invasion of the dying contents of the sac will almost certainly occur. Infection is limited to the sac for days, and sometimes for weeks. In an inguinal hernia infection usually terminates as a scrotal abscess, but extension of peritonitis from the sac to the general peritoneal cavity is always a possibility.

Inflamed Hernia

Inflammation can occur from external causes, such as pressure from an ill-fitting truss, or from inflammation of contents within the sac, e.g. acute appendicitis or salpingitis. The hernia is tender but *not* tense, and the overlying skin becomes red and œdematous. If it is considered the condition is due to inflammation of an organ within the sac, herniotomy is necessary in order to deal with the cause.

INGUINAL HERNIA

Surgical Anatomy

The superficial inguinal ring is a triangular aperture in the aponeurosis of the external oblique, and lies 1·25 cm above the pubic tubercle. The ring is bounded by a superomedial and an inferolateral crus joined by criss-cross intercrural fibres. Normally the ring will not admit the tip of the little finger (fig. 1260A).

The deep inguinal ring lies 1·25 cm above the inguinal (Poupart's) ligament, midway between the symphysis pubis and the anterior superior iliac spine. It is a U-shaped condensation of the transversalis fascia, incomplete above (fig. 1260C). The competency of the deep inguinal ring depends upon the integrity of this fascia.[1]

The Inguinal Canal.—In infants the superficial and deep inguinal rings are almost superimposed, and the obliquity of this canal is slight. In adults the inguinal canal, which is about 3·75 cm long, is directed downwards and medially from the deep to the superficial inguinal ring. In the male the inguinal canal transmits the spermatic cord, the ilio-inguinal nerve, and the genital branch of the genito-femoral nerve. In the female the round ligament replaces the spermatic cord.

Boundaries of the Inguinal Canal.—The best way to understand these is to study these diagrams (viewing the canal from the superficial to the deep layers as is seen at operation):

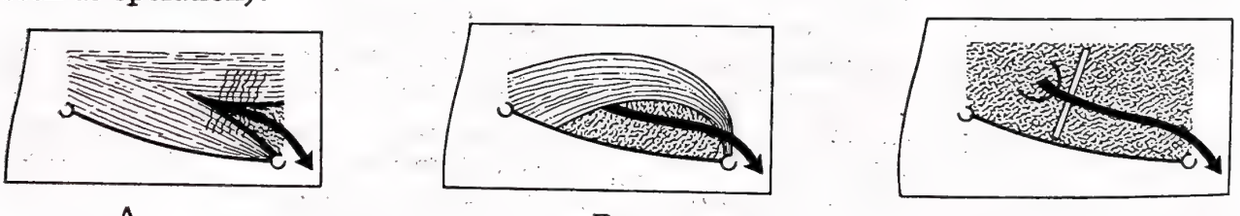

FIG. 1260.—The boundaries of the right inguinal canal. The inguinal ligament passes between the anterior superior iliac spine laterally, and the pubic tubercle medially. A. The superficial layer, the external oblique aponeurosis, showing the crura of the external ring and the intercrural fibres. B. The conjoined muscle (internal oblique and transversus) arches over the cord. Laterally it lies superficial to the cord and the internal ring, then it is above the cord and medially, as the conjoined tendon, behind the cord. C. The deepest layer, the transversalis fascia. The internal inguinal ring, with the inferior epigastric artery lying medially.

Thus, the boundaries of the inguinal canal are as follows:

Anteriorly.—(fig. 1260A and B). External oblique aponeurosis. The conjoined muscle (mainly internal oblique) laterally.

Posteriorly.—Inferior epigastric artery; fascia transversalis; conjoined tendon (internal oblique and transversus) (fig. 1260C and B).

Superiorly.—Conjoined muscles (internal oblique and transversus), (fig. 1260B).

Inferiorly.—Inguinal ligament (fig. 1260A, B and C).

[1] The transversalis fascia is the 'fascial envelope' of the abdomen.

François Poupart, 1661–1708. Surgeon, Hôtel-Dieu, Paris.

An indirect inguinal hernia travels down the canal on the outer (lateral and anterior) side of the spermatic cord. A direct hernia comes out directly forwards through the posterior wall of the inguinal canal. While the neck of the indirect hernia is lateral to the inferior epigastric vessels, the direct hernia usually emerges medial to this except in the saddle-bag or pantaloon type, which has both a lateral and a medial component (p. 1115). An inguinal hernia can be differentiated from a femoral hernia by ascertaining the relation of the neck of the sac to the medial end of the inguinal ligament and the pubic tubercle, i.e. in the case of an inguinal hernia the neck is above and medial, while that of a femoral hernia is below and lateral (fig. 1278).

Indirect (*syn.* Oblique) Inguinal Hernia

An indirect inguinal hernia is the most common of all forms of hernia. Many subscribe to the belief that, at whatever age it appears, it occurs into a preformed sac which is a partially or completely patent processus vaginalis. Normally, shortly before birth, the processus vaginalis becomes obliterated, at first at the deep inguinal ring, and a little later immediately above the upper pole of the epididymis; the tunnel of peritoneum between these two points becomes a fibrous cord.

In the first decade of life inguinal hernia is more common on the right side in the male. This is no doubt associated with the later descent of the right testis (p. 1290). After the second decade left inguinal herniæ are as frequent as right. The hernia is bilateral in nearly 30 per cent. of cases.

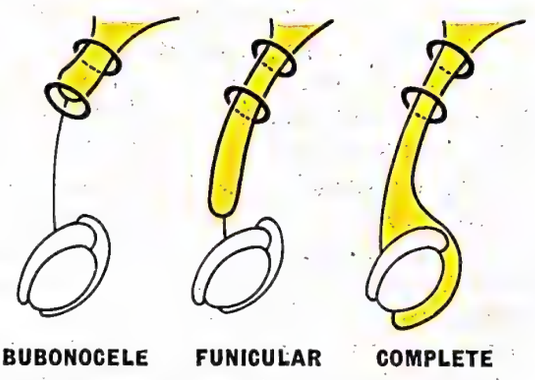

FIG. 1261.—Types of oblique inguinal hernia.

There are three types of oblique inguinal hernia (fig. 1261):

1. **Bubonocele.**[1]—The hernia is limited to the inguinal canal, the processus vaginalis having been obliterated at the superficial inguinal ring. This type of hernia is seen commonly in young adults; the history is usually a short one.

2. **Funicular.**[2]—The processus vaginalis is closed only at its lower end, just above the epididymis. When the sac is occupied, the contents of the sac can be felt separately from the testis, which lies below the hernia. The funicular variety is common in adults who give a history of inguinal hernia of some standing.

3. **Complete** (*syn.* Scrotal).—There is a persistence of the prenatal condition before the processus vaginalis becomes obliterated; nevertheless a complete inguinal hernia is rarely present at birth. Commonly encountered in infancy, it may not appear until adolescent or adult life. The testis appears to lie within the lower part of the hernia.

Clinical Features.—An oblique inguinal hernia can appear at any age. Males are twenty times more commonly affected than females.

In the early stages of the development of the hernia when the sac is still limited to the inguinal canal (bubonocele), the diagnosis presents some difficulty. Often the patient complains of pain in the groin or pain referred to the testicle when he is performing heavy work, or taking strenuous exercise. The patient is asked to cough and a small transient bulging may be seen and

[1] Boubon. Gr. = the groin. Bubo = an enlarged lymph node in the groin or axilla.
[2] Funiculus. L. = a small cord.

FIG. 1262.—Oblique left inguinal hernia which became apparent when the patient coughed, and persisted until it was reduced.

felt together with an expansile impulse. Often the bulge may be better seen by observing the inguinal region from the side or even looking down the abdominal wall while standing slightly behind the respective shoulder of the patient.

When an oblique inguinal hernia has become larger it produces a swelling that appears at first intermittently. In these circumstances the swelling often becomes apparent when the patient coughs, and it persists (fig. 1262) until it is reduced, usually by the act of lying down.[1] Local pain is unusual unless complications have occurred.

FIG. 1263.—Bilateral oblique inguinal herniæ which have descended into the scrotum.

As time goes on the hernia comes down as soon as the patient assumes the upright position. In large herniæ (fig. 1263) there is a sensation of weight, and dragging on the mesentery may produce epigastric pain. If the contents of the sac are reducible, the inguinal canal will be found to be commodious.

In infants the swelling appears when the child cries. An inguinal hernia may be translucent in infancy and early childhood, but never in an adult. In girls an ovary may prolapse into the sac.

Differential Diagnosis in the Male

(*a*) *A vaginal hydrocele.* (*b*) *An encysted hydrocele of the cord.* (*c*) *Spermatocele.* (*d*) *A femoral hernia* (p. 1073). (*e*) *An incompletely descended testis in the inguinal canal.* An inguinal hernia is often associated with this condition. (*f*) *A lipoma of the cord.* This is often a difficult, but unimportant, diagnosis. It is usually not settled until the parts are displayed by operation.

Differential Diagnosis in the Female

(*a*) *A hydrocele of the canal of Nuck* is the commonest differential diagnostic problem. (*b*) *A femoral hernia.*

Treatment of Indirect Inguinal Hernia

Operative Treatment.—*Operation is undoubtedly the treatment of choice.* The use of a truss and contraindications to it is mentioned on pages 1111 and 1121. It must be remembered that patients who have a bad cough from

---

[1] *Notes on the clinical examination.*—The clinician is seated in front of the patient who stands with his legs apart. He is instructed to look at the ceiling and to cough at the ceiling. If the hernia will come down it usually does. The examiner looks for the impulse and feels for the impulse and then satisfies himself on the following points: (1) Is the hernia right, or left, or bilateral? (2) Is it an inguinal or a femoral hernia? (see p. 1118) (3) Is it a direct or an indirect inguinal hernia? (4) Is it reducible or irreducible? (patient has to lie down for this to be ascertained). (5) Is the inguinal hernia incomplete (bubonocele) or complete (scrotal)? (6) What are the contents — bowel (enterocele), or omentum (omentocele or epiplocele)?

Anton Nuck, 1650–1692. Professor of Anatomy and Medicine, Leiden, Netherlands.

chronic bronchitis should not necessarily be denied operation, for these are the very people who are in danger of getting a strangulated hernia. Operation can, if necessary, be undertaken in adults, using spinal, epidural or local anæsthesia.

The types of operation are usually classified as (1) *Herniotomy*, (2) *Herniorrhaphy* and *Hernioplasty*.

Inguinal Herniotomy.—This is the essential basic operation and it entails dissecting out and opening the hernial sac, reducing any contents and then transfixing the neck of the sac and removing the remainder. It is employed either by itself or as the first step in herniorrhaphy or hernioplasty. By itself it is sufficient for the treatment of hernia in infants, adolescents and young or fit adults who have good inguinal musculature. In fact, any attempts at repair (herniorrhaphy or hernioplasty) in such cases are meddlesome, and do more harm than good.

In infants it is not necessary to open the canal, as the internal and external rings are superimposed. Excellent results are obtained. The operation should be done in the morning and the child allowed home in the evening. Usually there is no need for the child to stay in hospital. 'The best nurse is the mother.'

Inguinal Herniorrhaphy (and Hernioplasty).—This operation consists of (1) excision of the hernial sac (herniotomy) plus (2) repair of the stretched internal inguinal ring (transversalis fascia) and (3) strengthening or reconstruction of the posterior wall of the inguinal canal. This is achieved by suturing without tension, or by darning with monofilament materials, such as nylon or polyethylene or wire. Fascial sutures or fascial flaps are occasionally employed, and Dacron or Teflon mesh implants when the deficiency of the wall is extensive.

A Truss: A truss is used when operation is contraindicated because of cardiac, pulmonary, or other systemic disease, or when operation is refused. The hernia must be reducible. A rat-tailed spring truss (fig. 1264) with a perineal band to prevent the truss slipping will, with due care and attention, control a small or moderate-sized inguinal hernia. A truss must be worn continuously during waking hours, kept clean, and in proper repair, and renewed when it shows signs of wear. It must be applied before the patient gets up and while the hernia is reduced. A properly-fitting truss controls the hernia when the patient stands with his legs wide apart, stoops, and coughs violently. However, as Farquharson stressed, often the pad of a truss is seen to lie to the side of the swelling, where the pressure it exerts is both useless and harmful. In these circumstances the truss is a menace, for it increases the risk of strangulation.

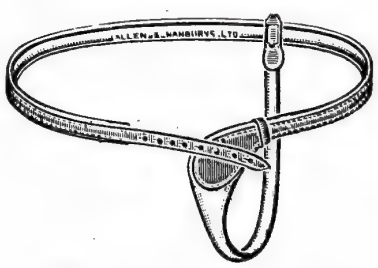

FIG. 1264.—Rat-tailed truss.

For a large irreducible hernia a bag truss is sometimes employed, but as a rule operation should be urged in cases of irreducibility, because of the danger of strangulation.

Infant and Trusses.—Special inflatable rubber trusses, formerly popular for the control of an infant's hernia are rarely used. Provided urgent admission is not required for sudden irreducibility, the parents are advised to wait until operation is performed when the infant is at least three months old.

Eric Leslie Farquharson, 1905–1970. Surgeon, Royal Infirmary, Edinburgh.

OPERATIVE PROCEDURES

(1) Excision of the Hernial Sac (Adult Herniotomy)

An incision[1] is made in the skin and subcutaneous tissues 1·25 cm above and parallel to the medial two-thirds of the inguinal ligament. In large irreducible herniæ the incision is extended into the upper part of the scrotum. After dividing the superficial fascia, the external oblique aponeurosis and the superficial inguinal ring are identified. The external oblique aponeurosis is incised in the line of its fibres, so as to open the inguinal canal. The structures beneath the external oblique aponeurosis are separated from its deep surface before completing the incision into the superficial inguinal ring, which is divided. In this way the ilio-inguinal nerve is safeguarded. By blunt dissection the upper leaf of the external oblique aponeurosis is separated from the internal oblique. The lower leaf is likewise dissected until the inner aspect of the inguinal ligament is seen. The cremasteric muscle fibres are divided longitudinally to open up the subcremasteric space and display the spermatic cord, which is then hooked up on the forefinger.

Excision of the sac. The sac is easily distinguished as a pearly white structure lying on the outer side of the cord and, when the internal spermatic fascia has been incised longitudinally, it can be dissected out and then opened between hæmostats.

Variations in Dissection.—If the sac is small (e.g. bubonocele) it can be freed *in toto*. If it is of the long funicular or scrotal type, or is extremely thickened and adherent (the result of wearing a truss), the fundus need not be sought. The sac is cut across in the inguinal canal. Care must be taken to avoid damage to the vas and the spermatic artery, including the blood supply to the epididymis.

An adherent sac can be separated from the cord by first injecting saline through its posterior wall. A similar tactic is used when dissecting the gossamer sac of infants and children (p. 1111).

Reduction of Contents.—Intestine or omentum is returned to the peritoneal cavity. Omentum is often adherent to neck of fundus of the sac; if to the neck, it is freed, and if to the fundus of a large sac, it may be transfixed, ligated and cut across at a suitable site. The distal part of omentum, like the distal part of a large scrotal sac, can be left *in situ* (the fundus should not, however, be ligated).

Isolation and Ligation of the Neck of the Sac.—Whatever type of sac is encountered, it is necessary to free its neck by blunt and gauze dissection until the parietal peritoneum can be seen on all sides. Only when the extraperitoneal fat is encountered and the inferior epigastric vessels are seen on the medial side has the dissection reached the required limit. If it has not been done already, the sac is opened. The finger is passed through the mouth of the sac in order to make sure that no bowel or omentum is adherent. The neck of the sac is transfixed and ligated as high as possible, and the sac is excised 1·25 cm below the ligature.

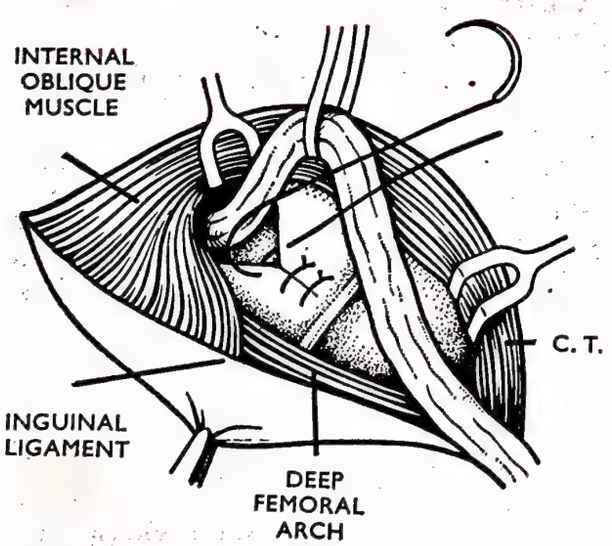

FIG. 1265.—Repair of the internal inguinal ring with lateral displacement of the cord. C. T. = Conjoined Tendon. (*After F. S. A. Doran, F.R.C.S., Bromsgrove.*)

(2) Repair of the Stretched Internal Ring (Lytle) (fig. 1265).

This is an important stage in the operation and must never be omitted. The transversalis fascia is plicated with unabsorbable sutures, the most lateral of these displacing the cord laterally as much

[1] Prior to the skin incision in large inguino-scrotal hernias, the usual antiseptic preparation of the skin should not be extended to the perineal aspect of the scrotum, for, by so doing, severe bacterial contamination of the operation site is likely.

William James Lytle, Contemporary. Consulting Surgeon, Royal Infirmary, Sheffield, England.

as possible and narrowing the diameter of the internal ring to the size of the tip of the little finger.

Lateral displacement of the stump of the sac. Frequently, the surgeon displaces the stump of the sac laterally beneath the arching fibres of the internal oblique. A large curved round-bodied needle, threaded with each of the ends of the ligature used for the transfixion and closure of the neck of the sac, is passed through the lateral fibres of the muscle from within outwards, and tied without tension.

Completion of Operation.—If possible the cremasteric muscle should be reconstituted; the external oblique is directly sutured or overlapped leaving a new external ring which will accommodate the tip of the little finger.

(3) Reconstruction of a weak Posterior Wall of the Inguinal Canal

What to do with a large indirect hernia with a neck of over 10 cm., or a direct inguinal hernia, is often a problem. All are agreed that the first step is the careful repair of the transversalis fascia with lateral displacement of the cord (above), and that the second step, reinforcement of the posterior wall, must be accomplished without tension.

The First Step.—Repair the stretched transversalis fascia as well as circumstances permit, not forgetting to take the repair as far laterally as possible, and narrowing the remnants of the internal ring. Even in a direct hernia the internal ring needs attention.

The Second Step.—Three main types of herniorrhaphy are possible:

(*a*) *Fascial flap.*—A flap of anterior rectus sheath, hinged on the linea semilunaris is lifted and turned down and sewn to the inguinal ligament (Bloodgood) (fig. 1266).

(*b*) *Darning.*—The two layer darn, using nylon or similar material is popular. (Moloney, Patey) (fig. 1267). Strips of fascia (Gallie) were formerly popular (fig. 1268).

(*c*) *Dacron or Teflon mesh* (fig. 1269).

Should further reinforcement be required, the external oblique aponeurosis may be overlapped behind the spermatic cord, thus directing this structure into the subcutaneous fat at the site of the repaired internal ring (Halsted and Keynes modifications). Great care must be exercised to tailor the opening in the aponeurosis through which the cord emerges, neither too small nor too large.

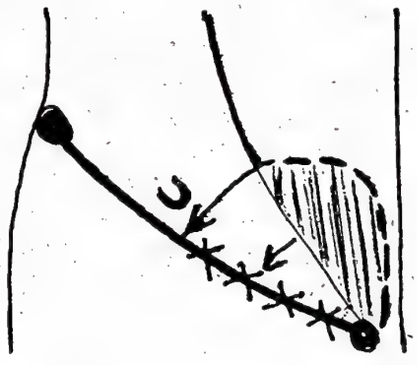

FIG. 1266.—Bloodgood's operation.

Bassini's operation and the rectus sheath relaxing incision (fig. 1270).—Bassini's method of reinforcing the posterior wall of the inguinal canal by suturing the conjoint muscle and tendon to the inguinal ligament, behind the spermatic cord, has been widely practised for many years. To obtain good results the conjoint muscle and tendon must be well developed and the space between it and the inguinal ligament must be narrow enough to permit approximation without tension. A relaxing incision in the rectus sheath (e.g. Tanner's slide) is necessary to achieve this essential requirement. Unabsorbable sutures, e.g. braided nylon, are employed. The external oblique aponeurosis is reunited in front of the cord.

Direct Inguinal Hernia

Between 10 and 15 per cent. of inguinal herniæ are direct. Over half of the herniæ are bilateral.

A direct inguinal hernia is always acquired. The sac passes through a weakness or defect of the transversalis fascia in the posterior wall of the inguinal canal. In some cases the defect is small and closely related to the insertion of the conjoint tendon, while in others there is a generalised bulge. Often the patient has poor lower abdominal musculature, as shown by the

Joseph Colt Bloodgood, 1867–1935. Surgeon, Johns Hopkins Hospital, Baltimore, Maryland, U.S.A.

Edoardo Bassini, 1844–1924. Professor of Surgery of Padua, Italy.
Norman Cecil Tanner, Contemporary. Consulting Surgeon, Charing Cross Hospital, London.

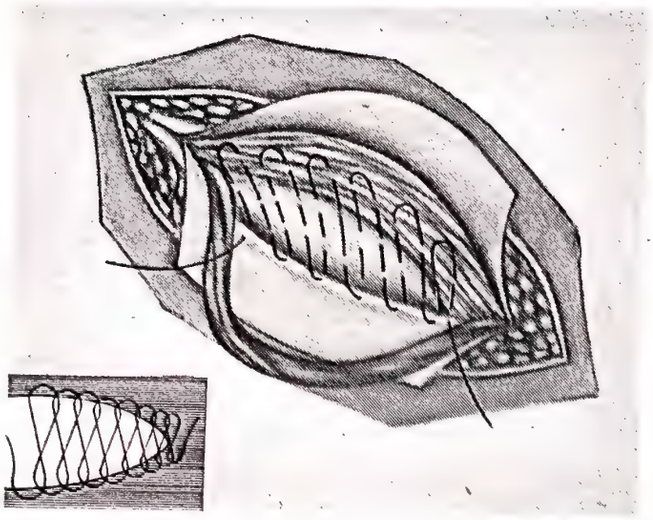

FIG. 1267.—The first layer of the two-layer darn of the posterior wall of the inguinal canal. The darning is conducted from the neighbourhood of the pubic tubercle up to and above the deep inguinal ring and back to the starting point. The darning is kept fairly loose, and it forms a lattice upon which fibrous tissue is laid down. The external oblique aponeurosis is reunited either in front or behind the cord. Meticulous asepsis is essential. Inset: An alternative lattice darn.

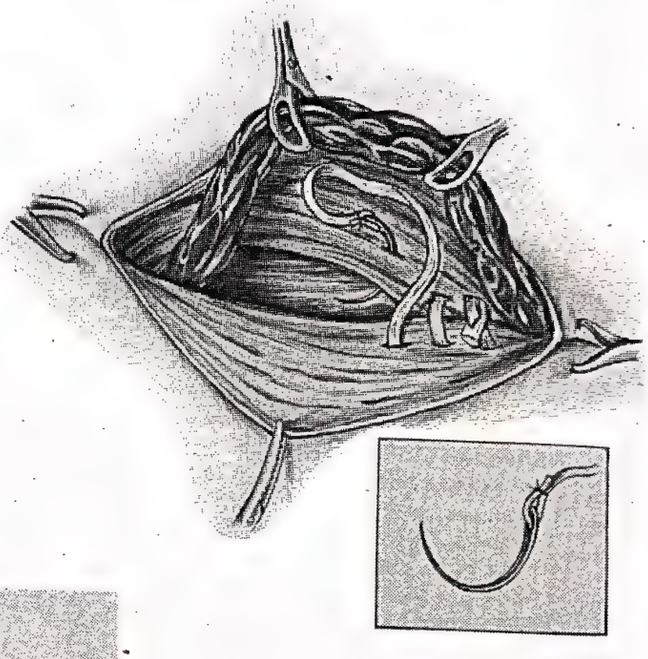

FIG. 1268.—Darn using fascia. In Gallie's graft, a strip of fascia lata 1·25 cm wide is obtained from the outer side of the thigh. This can be obtained by a long incision, or by means of a fasciotome which cuts a strip from the fascia lata through a small skin incision. Inset: Method of attaching strip of fascia to the needle, which has especially large eye (Gallie's needle).

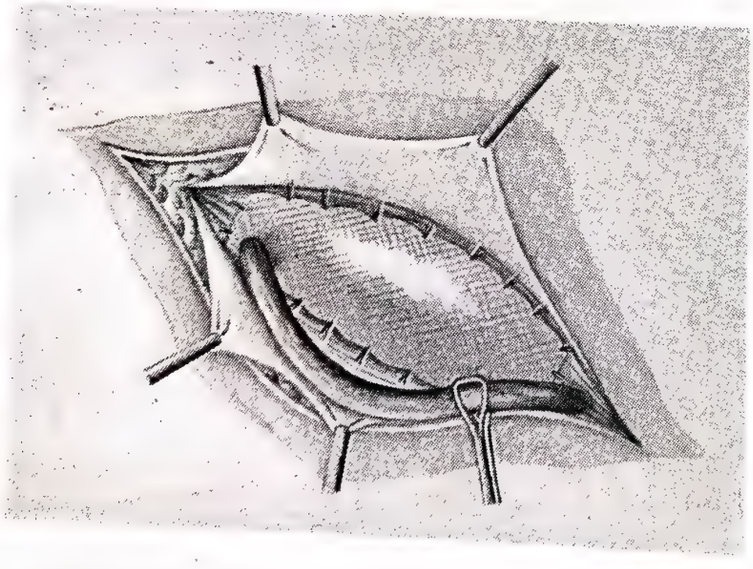

FIG. 1269.—Dacron mesh reinforcement. The mesh is attached to the inguinal ligament, the coverings of the pubis, the rectus sheath and the conjoined muscle. It is also fashioned by a slot laterally above and below the cord at the internal ring.

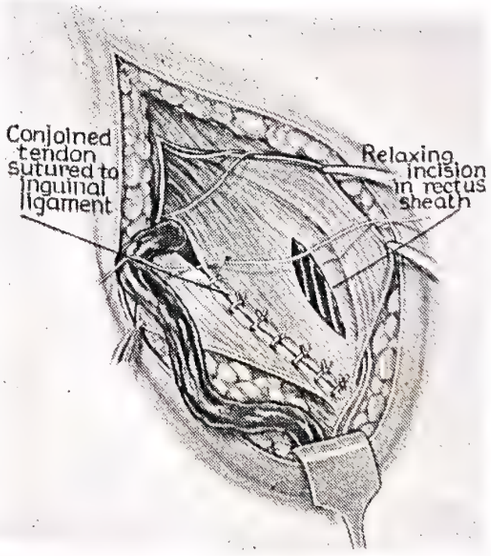

FIG. 1270.—Bassini's operation with relaxing incision (Tanner's slide). The conjoined muscle and tendon is approximated to the inguinal ligament without tension. (*After L. W. Ester, Jnr.*)

presence of elongated bulgings (Malgaigne's bulges). Women practically never develop a direct inguinal hernia (Brown). Predisposing factors are a chronic cough, straining, and heavy work.

Direct herniæ rarely attain a large size or descend into the scrotum. In contradistinction to an oblique inguinal hernia, a direct inguinal hernia lies behind the spermatic cord. The sac is often smaller than the hernial mass would indicate, the protruding mass mainly consisting of extraperitoneal fat. As the neck of the sac is wide, direct inguinal herniæ rarely strangulate.

Injury to the ilio-hypogastric or ilio-inguinal nerves during the gridiron operation for appendicitis appears to be associated with the development of a right inguinal hernia, usually, but not necessarily, of the direct variety.

• **Funicular direct inguinal hernia** (*syn.* prevesical hernia) is a narrow-necked hernia with prevesical fat and a portion of the bladder that occurs through a small oval defect in the medial part of the conjoined tendon just above the pubic tubercle. It occurs principally in elderly males, and occasionally it becomes strangulated. Unless there are definite contraindications, operation should always be advised.

Dual (*syn.* **Saddle-bag; Pantaloon**) **Hernia.**—Here there are two sacs which straddle the inferior epigastric artery, one sac being medial and the other lateral to this vessel. The condition is not a rarity, and is a cause of recurrence, one of the sacs having been overlooked at the time of operation.

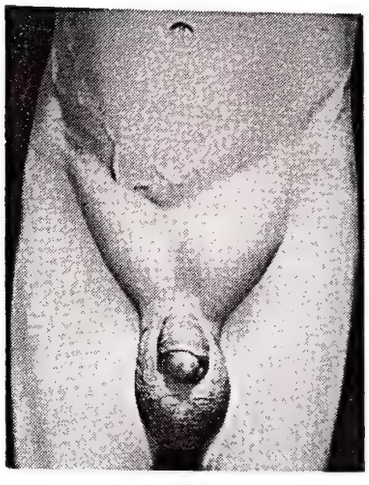

FIG. 1271.—Bilateral direct inguinal herniæ.

Treatment.—For herniæ that are enlarging, and those in comparatively young adults, especially when the patient is engaged in a strenuous occupation, operation must be advised.

Operation for Direct Hernia.—The principles of repair of direct hernia are the same as those of an indirect hernia with the exception that the hernial sac need not be removed. The sac, after it has been dissected free from surrounding structures, is inverted into the abdomen and the transversalis fascia repaired in front of it. Some form of reconstruction of the posterior wall of the inguinal canal completes the operation. Fascial flaps, fascial or nylon darns, and tantalum gauze and Dacron net implantations are all popular (pp. 1113–1114).

Strangulated Inguinal Hernia

Strangulation of an inguinal hernia occurs at any time during life, and in both sexes. Oblique inguinal hernias strangulate commonly; the direct variety but rarely owing to the wide neck of the sac. Sometimes a hernia strangulates on the first occasion that it descends; more often strangulation occurs in patients who have worn a truss for a long time, and in those with a partially reducible or irreducible hernia.

In order of frequency, the constricting agent is: (*a*) the neck of the sac; (*b*) the external abdominal ring in children; (*c*) rarely adhesions within the sac.

Contents.—Usually small intestine is involved in the strangulation; the next most frequent is omentum; sometimes both are implicated. For large

Joseph François Malgaigne, 1806–1865. Professor of Surgery, Paris.
Francis Robert Brown, 1889–1967. Surgeon, Royal Infirmary, Dundee, Scotland.

intestine to become strangulated in an inguinal hernia is of the utmost rarity, even when the hernia is of the sliding variety (p. 1117).

Pathological and Clinical Features are described on pp. 1106–1108.

Strangulation during Infancy.—The incidence of strangulation is 4% (Gross), and the ratio of females to males is 5:1. But this is much higher than current experience suggests. More frequently the hernia is irreducible but not strangulated. In most cases of strangulated inguinal hernia occur- ring in female infants the content of the sac is an ovary, or an ovary plus its Fallopian tube.

FIG. 1272.

Maydl's hernia (*syn.* Hernia-in-W) (fig. 1272) is rare. The strangulated loop of the W lies within the abdomen, thus local tenderness over the hernia is not marked. At operation two comparatively normal-looking loops of intestine are present in the sac. After the obstruction has been relieved, the strangulated loop will become apparent if traction is exerted on the middle of the loops occupying the sac.

Treatment of Strangulated Inguinal Hernia.—The treatment of strangulated hernia is usually by *emergency operation.*[1] If dehydration and collapse are present, intravenous fluid replacement (p. 89) and gastric aspiration for one to three hours are invaluable. It is *absolutely essential* to make sure that the stomach is emptied just before commencing the anæsthetic. The passing of a large-bore stomach tube is the best way of preventing vomiting, drowning, and cardiac arrest during the induction. The bladder must also be emptied, if necessary by a catheter.

Inguinal Herniotomy for Strangulation.—An incision is made over the most prominent part of the swelling. The external oblique aponeurosis is exposed, and the sac, with its coverings, is seen issuing from the superficial inguinal ring. In all but very large herniæ it is possible to deliver the body and fundus of the sac together with its coverings and (in the male) the testis on to the surface. Each layer covering the anterior surface of the body of the sac near the fundus is incised, and if possible it is stripped off the sac. The sac is then incised, the fluid therein is mopped up or aspirated very thoroughly, for it may be highly infected. The external oblique aponeurosis and the superficial inguinal ring are divided. Returning to the sac, a finger is passed into the opening, and employing the finger as a guide, the sac is slit up along its length. If the constriction lies at the superficial inguinal ring or in the inguinal canal, it is readily divided by this procedure. When the constricting agent is at the deep inguinal ring, by applying hæmostats to the cut edge of the neck of the sac and drawing them downwards, and at the same time retracting the internal oblique upwards, it may be possible to continue slitting up the sac over the finger beyond the point of constriction. When the constriction is too tight to admit a finger, a grooved director is inserted and the neck of the sac is divided with a hernia knife in an upward and inward direction, i.e. parallel to the inferior epigastric artery, under vision. Once the constricting agent has been divided, the strangulated contents can be drawn down. Devitalised omentum is excised after being securely ligated, by interlocking stitches if bulky. Viable intestine is returned to the peritoneal cavity. Doubtfully viable and gangrenous intestine is dealt with as described on p. 1006. If the hernial sac is of moderate size and can be separated easily from its coverings, it is excised and closed by a purse-string suture. When the sac is large and adherent, much time is saved by cutting across the sac as described (p. 1112). Having tied off the neck of the sac, if the condition of the patient permits, a simple form of herniorrhaphy can be carried out.

---

[1] 'The danger is in the delay, not in the operation'—Astley Cooper.

Robert Edward Gross, Contemporary. Ladd Professor of Children's Surgery, Harvard University Medical School, Boston, Mass., U.S.A.
Karel Maydl, 1853–1903. Professor of Surgery, Prague, Czechoslovakia.
Sir Astley Paston Cooper, 1768–1841. Surgeon, Guy's Hospital, London.

Conservative Measures.—These are usually indicated in infants. The child is given a sedative and then slung to a Balkan beam[1] or to the bedrail by his feet (the judgment of Solomon[2] position) for no longer than three hours. In 75 per cent. of cases reduction is effected, and there appears to be no danger of gangrenous intestine being reduced (Irvine Smith).

N.B.—Vigorous manipulation (taxis) has no place in modern surgery, and is mentioned only to be condemned. Its dangers include:

1. Contusion or rupture of the intestinal wall.

2. Reduction-en-masse (fig. 1273). 'The sac together with its contents, is pushed forcibly back into the abdomen; and as the bowel will still be strangulated by the neck of the sac, the symptoms are in no way relieved' (Treves). 3. Reduction into a loculus of the sac. 4. The sac may rupture at its neck and its contents are reduced, not into the peritoneal cavity, but extraperitoneally.

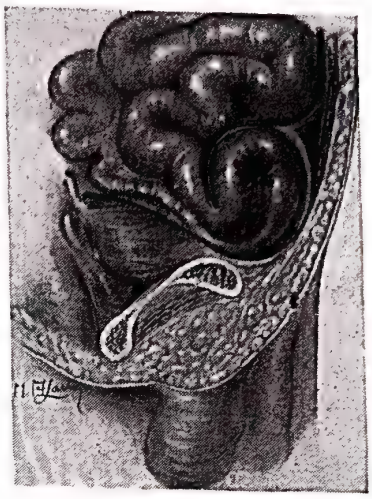

FIG. 1273.—Reduction-en-masse.

Recurrent Inguinal Hernia

Although some individual series show a recurrence-rate of under 1 per cent., the general rate of recurrence is nearer 10 per cent. The recurrence takes place within a year in most cases.

The following summarises the principal causes of recurrence:

1. **Pre-operative.**—Faulty selection of cases (e.g. those with Malgaigne's bulging (p. 1115)) or chronic bronchitis.

2. **Operative.**—Faulty technique.

(*a*) Failure to ligate the sac at the neck. (*b*) Tension and tying stitches too tightly so that intervening tissues are devitalised. (*c*) Imperfect hæmostasis, predisposing to infection. (*d*) The use of absorbable sutures in the repair of the inguinal canal.

3. **Post-operative.**—The common causes of a recurrence are (*a*) infection of the wound; (*b*) persistent cough; (*c*) heavy lifting before three months after herniorrhaphy; (*d*) urethral obstruction; (*e*) straining at defæcation.

Treatment.—Unless there is some reason why further operation is unlikely to be successful, e.g. persistent cough, re-operation performed carefully with special precautions against recurrence, e.g. nylon darn, fascial graft, tantalum gauze or Dacron mesh, is often indicated.

The Spermatic Cord as a Barrier to Effective Closure of the Inguinal Canal.—In the elderly patient, removal of the testis and cord aids in an effective repair in the case of recurrent inguinal hernia, sliding hernia, and some large direct herniæ. The signed permission of the patient must always be obtained beforehand.

Sliding Hernia (*syn.* **Hernie-en-Glissade**) (Fig. 1274)

As a result of slipping of the posterior parietal peritoneum on the underlying cellular tissue, the posterior wall of the sac is not formed of peritoneum alone, but by the sigmoid colon and its mesentery on the left, the cæcum on the right and, sometimes, on either side by a portion of the bladder. It should be clearly understood that the cæcum, appendix, or a portion of the colon *wholly within* a hernial sac does not constitute a sliding hernia. A small bowel sliding hernia occurs once in 2,000 cases; a sacless sliding hernia once in 8,000 cases.

(*a*) (*b*) (*c*)

FIG. 1274.—Sliding hernia.—(*a*) Cystogram showing bladder involving a left inguinal hernia. (*b*) Diagram of the same. (*c*) Caecum and appendix in right sliding hernia.

Clinical Features.—A sliding hernia occurs almost exclusively in males. Five out of six sliding herniæ are situated on the left side; bilateral sliding herniæ are exceedingly rare. The patient is nearly always over forty, the incidence rising with the weight of years. There are no clinical findings that are pathognomonic of a sliding hernia, but it should be suspected in every large globular inguinal hernia descending well into the scrotum.

Occasionally large intestine is strangulated in a sliding hernia; more often non-strangulated large intestine is present behind the sac containing strangulated small intestine.

Treatment.—A sliding hernia is impossible to control with a truss, and as a rule the hernia is a cause of considerable discomfort. Consequently operation is indicated, and the results generally are good.

Operation.—It is unnecessary to remove any of the sliding hernial sac provided it is freed completely from the cord and the abdominal wall, and that it is replaced deep to the repaired fascia transversalis. In most instances it is desirable to perform orchiectomy (p. 1117) in order to effect a secure repair. No attempt should be made to dissect the cæcum or colon free from the peritoneum under the impression that these are adhesions in which case peritonitis or a fæcal fistula resulting from necrosis of a devascularised portion of the bowel may occur. This is specially liable to occur on the left side, as vessels in the meso-colon may be injured.

FEMORAL HERNIA

Femoral hernia is the third most common type of hernia (incisional hernia comes second). It accounts for about 20 per cent. of herniæ in women, and 5 per cent. in men. The overriding importance of femoral hernia lies in the facts that it cannot be controlled by a truss, and that of all herniæ it is the most liable to become strangulated.

Surgical Anatomy.—The femoral canal occupies the most medial compartment of the femoral sheath, and is shaped like a truncated cone. It extends from the femoral ring above to the saphenous opening below. It is 1·25 cm long, and 1·25 cm wide at its base, which is directed upwards. The femoral canal contains fat, lymphatic vessels, and the lymph node of Cloquet. It is closed above by the septum crurale, a condensation of extraperitoneal tissue pierced by lymphatic vessels, and below by the cribriform fascia.

The femoral ring (fig. 1275) is bounded:

Anteriorly by the inguinal ligament.

Posteriorly by Astley Cooper's (ilio-pectineal) ligament, the pubic bone, and the fascia over the pectineus muscle.

Jules Germain Cloquet, 1790–1883. Professor of Anatomy and Surgery, Paris.

Medially by the concave knife-like edge of Gimbernat's (lacunar) ligament (fig. 1275), which is also prolonged along the ilio-pectineal line as Astley Cooper's ligament. *Laterally* by a thin septum separating it from the femoral vein.

Throughout an operation for the repair of a femoral hernia, *on the lateral side*, the femoral vein, with the internal saphenous vein emptying into it, must be protected. *On the medial side* of the neck of the sac great care must be taken not to injure the bladder, particularly since a portion of the bladder may form part of the wall of the sac (a sliding femoral hernia).

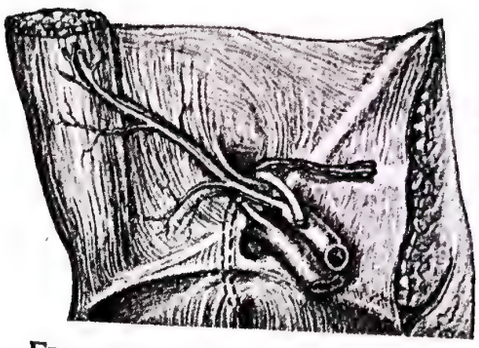

FIG. 1275.—The right femoral ring from within. The dotted structure is an abnormal obturator artery.

Sex Incidence.—The female to male ratio is about 2:1, but it is interesting that whereas the female patients are frequently elderly, the male patients are usually between thirty to forty-five years. The condition is more prevalent in women who have borne children than in nulliparæ.

Pathology.—A hernia passing down the femoral canal descends vertically as far as the saphenous opening. While it is confined to the inelastic walls of the femoral canal the hernia is necessarily narrow, but once it escapes through the saphenous opening into the loose areolar tissue of the groin, it expands, sometimes considerably. A fully distended femoral hernia assumes the shape of a retort (fig. 1276), and its bulbous extremity may be above the inguinal ligament. By the time the contents have pursued so tortuous a path they are usually irreducible and apt to strangulate.

FIG. 1276.

Clinical Features.—Femoral hernia is very rare before the fifteenth year. Between twenty and forty years of age the prevalence rises, and continues to old age. The right side (fig. 1277) is affected twice as often as the left, and in 20 per cent. of cases the condition is bilateral. The symptoms to which a femoral hernia gives rise are less pronounced than those of an inguinal hernia; indeed, a small femoral hernia may be

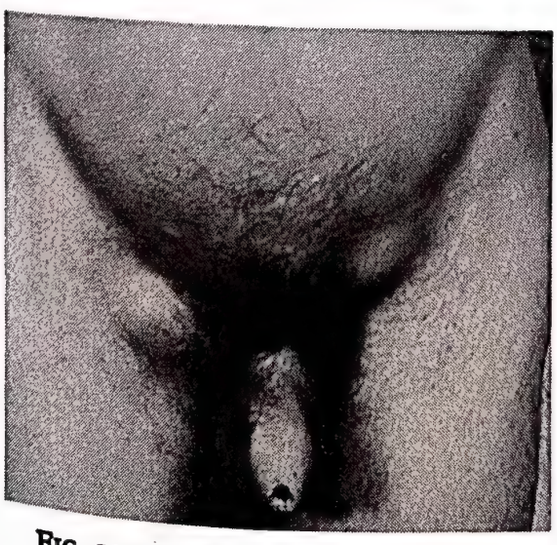

FIG. 1277.—The patient has a left inguinal and a right femoral hernia.

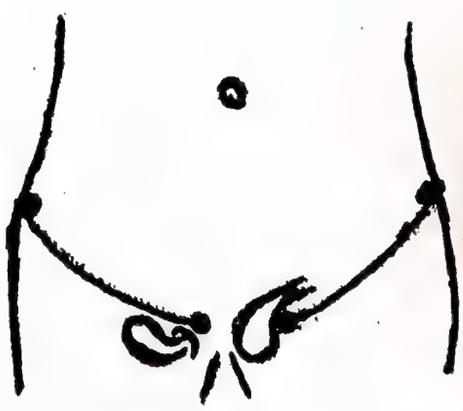

FIG. 1278.—The essentials of differential diagnosis between a femoral and an inguinal hernia (see p. 1109).

unnoticed by the patient or disregarded for years, until perhaps one day it strangulates. Adherence of greater omentum sometimes causes a dragging pain. Occasionally a large sac is present.

Differential Diagnosis

A Femoral Hernia has to be distinguished from:

(1) *An Inguinal Hernia.*—An inguinal hernia lies above and medial to the medial end of the inguinal ligament at its attachment to the pubic tubercle. The femoral hernia lies below this (fig. 1278). Occasionally the fundus of a femoral hernia sac overlies the inguinal ligament.

(2) *A Saphena Varix* (fig. 1279).—A saphena varix is a saccular enlargement of the termination of the long saphenous vein and it is usually accompanied by other signs of varicose veins. The swelling disappears completely when the patient lies down, while a femoral hernia sac usually is still palpable. In both there is an impulse on coughing. A saphena varix will, however, impart a fluid thrill to the examining fingers when the patient coughs, or when the saphenous vein below the varix is tapped with the fingers of the other hand. Sometimes a venous hum can be heard when a stethoscope is applied over a saphena varix.

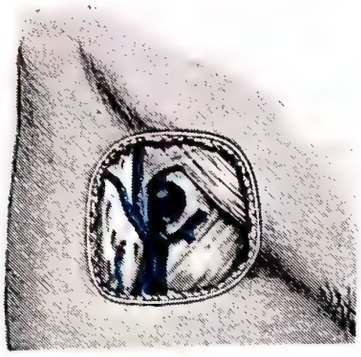

FIG. 1279.—Saphena varix.

(3) *An Enlarged Femoral Lymph Node.*—If there are other enlarged lymph nodes in the region the diagnosis is tolerably simple, but when Cloquet's lymph node alone is affected the diagnosis may be impossible unless there is a clue, such as an infected wound or abrasion on the corresponding limb or on the perineum.

(4) *Lipoma.*

(5) *A Femoral Aneurysm.*—The intrinsic signs of an aneurysm are described on p. 136.

(6) *A Psoas Abscess.*—There is often a fluctuating swelling—an iliac abscess—which communicates with the swelling in question (fig. 1280). Examination of the spine and an X-ray will settle the diagnosis.

(7) *A distended Psoas Bursa.*—The swelling diminishes when the hip is flexed, and osteoarthritis of the hip is present.

(8) *Rupture of the adductor longus* with hæmatoma.—If there is no superficial discoloration, the diagnosis can be very difficult.

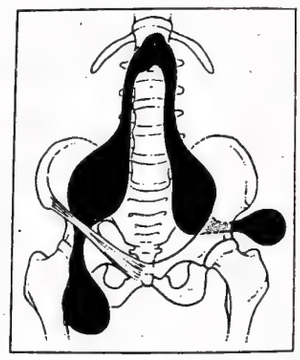

FIG. 1280.—A psoas abscess appearing beneath the inguinal ligament may simulate a reducible femoral hernia. Likewise, when it points in the buttock, a gluteal hernia has been suspected. *(After J. F. Calot.)*

Hydrocele of a Femoral Hernial Sac.—The neck of the sac becomes plugged with omentum or by adhesions, and a hydrocele of the hernial sac results.

Laugier's femoral hernia is a hernia through a gap in the lacunar (Gimbernat's) ligament. The diagnosis is based on the unusual medial position of a small femoral hernial sac. Nearly always the hernia has strangulated.

Narath's femoral hernia occurs only in patients with congenital dislocation of the hip and is due to lateral displacement of the psoas muscle. The hernia lies hidden behind the femoral vessels.

Cloquet's hernia is one in which the sac lies under the fascia covering the pectineus muscle. Strangulation is likely. The sac may coexist with the usual type of femoral sac (see interparietal inguinal hernia, p. 1129).

Strangulated Femoral Hernia.—It cannot be emphasised too strongly that not only does a femoral hernia become strangulated frequently, but often gangrene develops rapidly. This is accounted for by the narrow, unyielding

Stanislas Laugier, 1799–1872. Surgeon, Hôtel Dieu, Paris.
Albert Narath, 1864–1924. Professor of Surgery, Heidelberg, Germany.

femoral ring. In 40 per cent. of cases the obstructing agent (fig. 1281) is not Gimbernat's (lacunar) ligament but the narrow neck of the femoral sac itself (Henry Souttar). The frequent occurrence of a *Richter's hernia* (p. 1107) also must be stressed.

Gaur has reported that, in the elderly with thin elastic skin, the superficial inferior epigastric or the circumflex iliac vein may be seen to be distended if strangulation is present.

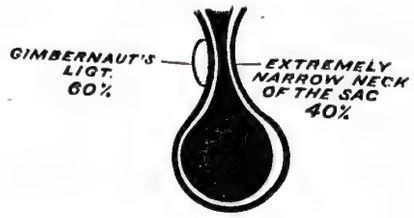

FIG. 1281.

Treatment of Femoral Hernia

The constant risk of strangulation is sufficient reason for urging the patient to have herniorrhaphy performed. A *femoral truss is highly unsatisfactory* in that it becomes displaced when the thigh is flexed (unless the hip-joint has been arthrodesed), and strangulation is thereby encouraged.

Operative Treatment.—The low operation (Lockwood), the high operation (McEvedy), and the inguinal operation (Lotheissen) all have their advocates. In all cases the bladder *must* be emptied immediately before commencing the operation.

The Low Operation (Lockwood).—The sac is dissected out below the inguinal ligament via a groin-crease incision. It is essential to peel off all the anatomical layers which cover the sac. These are often thick and fatty. After dealing with the contents (e.g. freeing adherent omentum) the neck of the sac is pulled down, ligated as high as possible and allowed to retract through the femoral canal. The canal is closed by suturing the inguinal ligament to the ilio-pectineal line using three unabsorbable sutures (e.g. monofilament nylon.)

The High (McEvedy) Operation.—A vertical incision is made over the femoral canal and continued upwards above the inguinal ligament. Through the lower part of the incision the sac is dissected out. The upper part of the incision exposes the inguinal ligament and the rectus sheath. The superficial inguinal ring is identified, and an incision 2·5 cm above the ring and parallel to the outer border of the rectus muscle is deepened until the extraperitoneal space is found. By gauze dissection in this space the hernial sac entering the femoral canal can be easily identified. Should the sac be empty and small, it can be drawn upwards; if it is large, the fundus is opened below, and its contents, if any, dealt with appropriately before delivering the sac upwards from its canal. The sac is then freed from the extraperitoneal tissue and its neck is ligated. An excellent view of the iliopectineal ligament is obtained and the conjoined tendon is sutured to it with non-absorbable sutures (fig. 1282).

An advantage of the operation is that if resection of intestine is required, ample room can be obtained by opening the peritoneum. The disadvantage of the operation is that if infection occurs incisional hernia is not very unusual.

Lotheissen's Operation.—The inguinal canal is opened as for *inguinal* herniorrhaphy. The transversalis fascia is incised to the medial side of the epigastric vessels and the opening is enlarged. The peritoneum is now in view; one must be certain that it *is* the peritoneum and not the bladder or a diverticulum thereof. The peritoneum is picked up with dissecting forceps, and incised. It is now possible to ascertain if any intraperitoneal structure is entering the femoral sac. Should the sac be empty, hæmostats are placed upon the edges of the opening into the peritoneum, and by gauze dissection the sac is withdrawn from the femoral canal. An empty sac

Sir Henry Sessions Souttar, 1875–1964. Surgeon, The London Hospital.

Georg Lotheissen, 1868–1941. Surgeon, Kaiser Franz Josef Hospital, Vienna.

can be delivered easily; in the event of the sac being occupied, the technique described below for strangulation should be followed.

The Lotheissen Repair.—The conjoined tendon is sutured to the iliopectineal line to form a shutter. While protecting the external iliac vein with the forefinger, unabsorbable sutures are passed through the periosteum and Cooper's ligament overlying the iliopectineal line (fig. 1283). The retractor having been removed, the

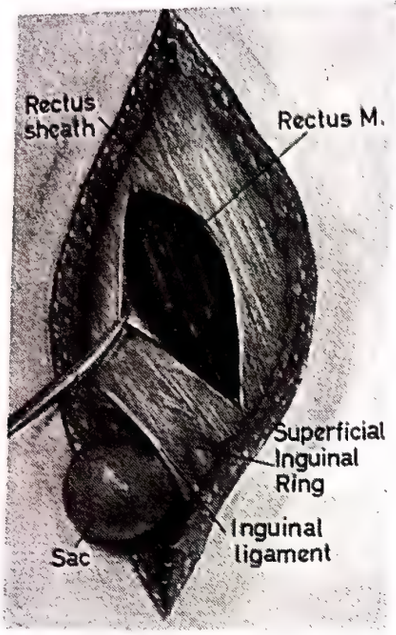

FIG. 1282.—McEvedy's operation.

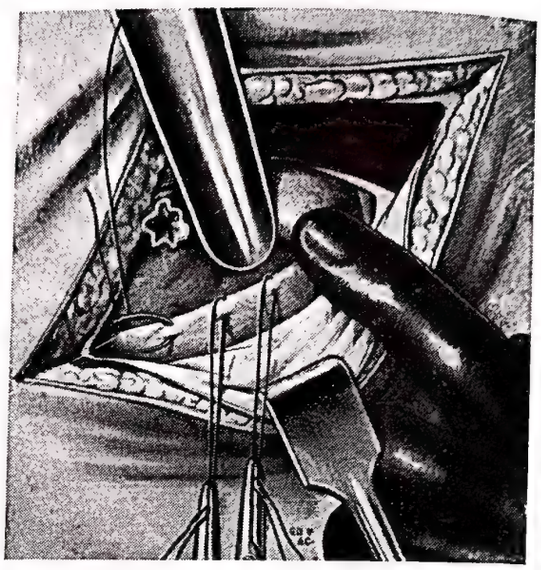

FIG. 1283.—Method of placing the deep sutures (see text). The finger is protecting the femoral vein.

long ends of the sutures are passed from within, outwards, through the conjoined tendon, and tied, thus approximating the conjoined tendon to the iliopectineal line. If there is any tension, a Tanner's slide (p. 1113) will facilitate this step. The incised external oblique is sutured.

Strangulated Femoral Hernia.—It is necessary to modify some of the steps of the Lotheissen operation. As soon as the external oblique has been exposed, the inferior margin of the wound is retracted strongly, thereby displaying the swelling. The coverings of the sac are incised and peeled off, until the sac, dark from contained bloodstained fluid, is apparent. The sac is incised, and the fluid that escapes is mopped up with great care. The retractor is removed and the operation is continued above the inguinal ligament in the same way as described already. Once the peritoneum has been opened above the inguinal ligament, one can see exactly what is entering the sac. Should the obstruction lie in a narrow neck of the sac, the beak of a hæmostat is insinuated, and with great care the neck is stretched[1]. The contents of the sac are delivered, and dealt with, p. 1112. Sometimes, in order to facilitate reduction of the hernial contents, it becomes necessary to divide or digitally to avulse part of Gimbernat's ligament.

UMBILICAL HERNIA

Exomphalos (*syn.* omphalocele) occurs once in every 6,000 births; it is due to failure of all or part of the mid-gut to return to the cœlom during early fœtal life. Sometimes a large sac ruptures during birth (fig. 1284). When the sac remains unruptured, it is semi-translucent, and although very thin it consists of three layers—an outer layer of amniotic membrane, a middle layer of Wharton's jelly, and an inner layer of peritoneum. There are two varieties of exomphalos:

[1] An abnormal obturator artery is present either on the medial or the lateral side of the neck of the sac in 28 per cent. of cases.

Thomas Wharton, 1614–1673. Physician, St. Thomas's Hospital, London.

Exomphalos Minor.—The sac is relatively small and to its summit is attached the umbilical cord (fig. 1285). Inadvertently a loop of small intestine or a Meckel's diverticulum has been included in the ligature applied to the base of an umbilical cord containing this protrusion.

Exomphalos Major.—The umbilical cord is attached to the inferior aspect of the swelling

FIG. 1284.—Exomphalos. The delicate sac burst during delivery.

FIG. 1285.—Exomphalos minor.

FIG. 1286.—Exomphalos major.

(fig. 1286), which contains small and large intestine, and nearly always a portion of the liver. Half the cases belong to this group.

Treatment: (*a*) *Exomphalos Minor.*—It is necessary only to twist the cord, so as to reduce the contents of the sac through the narrow umbilical opening into the peritoneal cavity, and to retain them there by strapping applied firmly. In spite of a sero-purulent discharge from beneath it, on no account must the strapping be removed for fourteen days (Denis Browne).

(*b*) *Exomphalos Major.*—Operation within the first few hours of life is the only hope, otherwise the sac will burst. In order to prevent further distension of the contents of the sac, the infant should not be fed. A few newborn infants with a ruptured sac have survived following immediate operation and antibiotic therapy. A drip blood-transfusion is desirable.

Operation.—It must be realised that most of the contents of the sac have never been housed within the abdominal cavity; consequently that cavity is unduly small, and to attempt to replace the contents of the sac is like endeavouring to put 2 kg. of sugar into a 1 kg. bag—a feat that so often results in respiratory embarrassment, compromise of venous return, and possibly intestinal obstruction. It is necessary to create flaps of skin by undermining the subcutaneous tissue on either side, so that the flaps can be brought together over the sac. If necessary relaxing incisions must be made in the loins to permit closure. For several days following the operation it is advisable to carry out aspiration through an indwelling gastric tube, in order to relieve or prevent distension. If the patient survives the construction of this protective cutaneous coverage, repair of the hernia can be delayed for months, or even years. At the second operation, it is surprising to find that the peritoneum and the muscles can be drawn together and closed in layers.

Congenital Umbilical Hernia.—On rare occasions a well-developed umbilical hernia is present at birth; the condition is believed to be due to intra-uterine epithelialisation of a small exomphalos.

Umbilical Hernia of Infants and Children.—This is a hernia through a weak umbilical scar usually the result of neonatal sepsis (p. 1097). The

Sir Denis John Wolko Browne, 1892–1967. Surgeon, Hospital for Sick Children, Great Ormond Street, London.

FIG. 1287. — Infantile umbilical hernia.

ratio of males to females is 2:1. The hernia is often symptomless, but increase in the size of the hernia by crying causes pain, which makes the infant cry the more. Small herniæ are spherical; those that increase in size tend to assume a conical shape (fig. 1287) and are present apart from crying. Obstruction or strangulation below the age of three years is extremely uncommon.

Treatment.—Conservative treatment by *masterly inactivity* is successful in about 93 per cent. of cases. When the hernia is symptomless, reassurance of the parents is all that is necessary, for in a very high percentage of cases the hernia will be found to disappear spontaneously during the first few months of life. Cure may also be hastened by pulling the skin and abdominal musculature together by adhesive strapping placed across the abdomen.

Herniorrhaphy.—In cases where masterly inactivity fails, operation is required, and it should be carried out, preferably, about the age of two years.

Operation.—In infants a small curved incision is made immediately below the umbilicus. The skin cicatrix is dissected upwards, and the neck of the sac is isolated. After ensuring that the sac is empty of contents, it is either inverted into the abdomen or it is ligated by transfixion and excised. The defect in the linea alba is closed with two unabsorbable sutures.

Para-umbilical Hernia of Adults (syn. supra-, infra-umbilical hernia). —It should be noted that in adults the hernia does not occur through the umbilical scar. It is a protrusion through the linea alba just above the umbilicus or, occasionally, just below that structure (fig. 1288). As it enlarges, it becomes rounded or oval in shape (fig. 1289) with a tendency to sag downwards, viz.

Para-umbilical herniæ increase steadily in size and frequently attain very large dimensions (fig. 1290). The neck of the sac is often remarkably narrow as compared with the size of the sac and the volume of its contents, which consist of greater omentum often accompanied by small intestine and, alternatively or in addition, a portion of the transverse colon. In old-standing cases the sac sometimes becomes loculated due to adherence of omentum to its fundus.

Clinical Features.—Women are affected five times more frequently than men. The patient is usually corpulent and between the ages of thirty-five and fifty. Increasing obesity, with flabbiness of the abdominal muscles, and repeated pregnancy are important factors. These herniæ soon become irreducible because of omental adhesions within the sac. A large umbilical hernia causes a local dragging pain by its weight. Gastro-intestinal symptoms are common and are probably due to traction on the stomach or transverse

FIG. 1288.—Small.

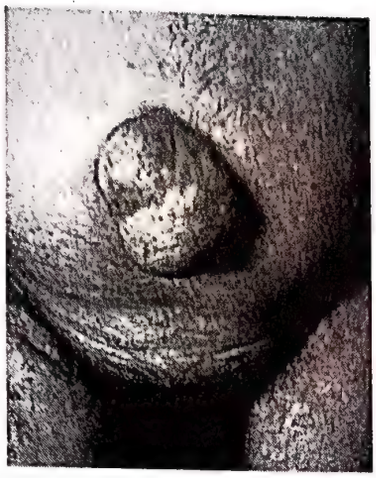

FIG. 1289.—Large. Para-umbilical hernia.

FIG. 1290.—Very large.

colon. Often there are transient attacks of intestinal colic due to subacute intestinal obstruction. In old-standing cases intertrigo of the adjacent surfaces of the skin is a troublesome complication.

Treatment.—Untreated, the hernia increases in size, and more and more of its contents become irreducible. Eventually, strangulation may occur. Therefore without undue delay operation should be advised in nearly all cases. If the patient is obese and the hernia is symptomless, operation can be postponed with advantage until weight has been reduced.

Mayo's Operation.—A transverse elliptical incision is made around the umbilicus. The subcutaneous tissues are dissected off the rectus sheath to expose the neck of the sac. The neck is incised to expose the contents. Intestine is returned to the abdomen. Any adherent omentum is freed, and ligated by transfixion if it is bleeding. Excess adherent omentum can be removed with the sac if necessary. The sac is then removed and the peritoneum of the neck closed with catgut. The aponeurosis on both sides of the umbilical ring are incised transversely for 2·5 cm or more—sufficiently to allow an overlap of 5 or 7·5 cm. Three to five mattress sutures are then inserted into the aponeurosis as shown in fig. 1291. When this row of mattress sutures has been tied, the over-lapping upper margin is stitched to the sheath of the rectus abdominis and the midline aponeurosis. It is important to denude this area of fat before stitching the flap in position. In fat patients, who ooze blood and liquid fat, a drain is provided at each end of the wound. The subcutaneous fat and skin are then approximated with deep sutures. If the patient has a tendency to bronchitis, it is wise to prescribe antibiotic therapy and breathing exercises.

FIG. 1291.—Mayo's operation for umbilical hernia.

A few operators, dissatisfied with the results of Mayo's operation (which is acclaimed generally to be satisfactory), prefer to employ the fascial flap operation depicted in fig. 1292.

Additional Lipectomy.—In patients with a para-umbilical hernia associated with a large pendulous, fat-laden abdominal wall the operation can, with great advantage, be combined with lipectomy by fashioning the incisions to embrace a larger area of the fat-laden superficial layers of the abdominal wall.

William James Mayo, 1861–1939. Surgeon, The Mayo Clinic, Rochester, Minnesota, U.S.A., described this operation in 1901.

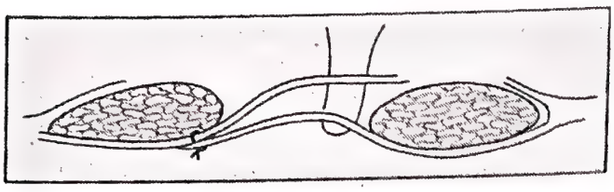

FIG. 1292.—Method of repairing a gap in the linea alba. (*After Charles Wells, F.R.C.S.*)

Strangulation is a frequent complication of a large para-umbilical hernia in adults. Owing to the narrow neck and the fibrous edge of the linea alba, gangrene is liable to supervene unless early operation is carried out. Also it should be remembered that in large hernias, the presence of loculi may result in a strangulated knuckle of bowel in one part of an otherwise soft and non-tender hernia.

Operation.—In early cases the operation does not differ from that for non-strangulated cases. Gangrenous contents are dealt with as in other situations. If a portion of the transverse colon is gangrenous, it should be exteriorised by the Paul-Mikulicz method (fig. 1153) and the gangrenous portion excised. If the ring is large enough to transmit the colon unhampered, it is left alone; otherwise it is enlarged. It is important that the small intestine be thoroughly scrutinised as a small loop may have been trapped and slipped back when the constriction was relieved. If non-viable gut is overlooked, peritonitis quietly supervenes, and the symptoms are ascribed to 'post-operative discomfort'. The condition of the patient steadily deteriorates until she succumbs after a few days (Franklin).

INCISIONAL HERNIA

(*syn.* VENTRAL HERNIA: POST-OPERATIVE HERNIA)

Ætiology.—An incisional hernia usually starts as a symptomless, partial disruption of the deeper layers of a laparotomy wound during the immediate or very early post-operative period. It is more than probable that such an event will pass unnoticed, for the skin stitches remain intact. A sero-sanguinous discharge from a laparotomy incision is often a signal of dehiscence (p. 1101), and calls for systematic palpation of the immediate proximity of the incision, with the examiner duly masked and gloved. Resuture of the deeper disrupted layers of the incision obviates the more difficult repair of an established hernia later on. Incisional hernia occurs most often in obese individuals, and a persistent post-operative cough and post-operative abdominal distension are its precursors. There is a high incidence of incisional hernia following operations for peritonitis because, as a rule, the wound becomes infected. The accommodation of a necessary drainage tube in a stab incision, as opposed to placing such a tube through the laparotomy wound, reduces the frequency of its occurrence.

The concept that the hernia occurs during late convalescence is erroneous. Provided the main nerves to the abdominal musculature have not been damaged, a *soundly healed* laparotomy scar will withstand the buffeting of any walk of life, including repeated pregnancy.

Clinical Features.—Incisional hernia presents no difficulty in diagnosis. There are great variations in the degree of herniation. The hernia may occur through a small portion of the scar, often the lower end. More frequently there is a diffuse bulging of the whole length of the incision. A post-operative hernia, especially one through a lower abdominal scar, usually increases steadily in size, and more and more of its contents become irreducible. Sometimes the skin overlying it is so thin and atrophic that normal

Richard Harrington Franklin, Contemporary. Surgeon, Royal Postgraduate Medical School, London.

peristalsis can be seen in the underlying coils of intestine. Attacks of subacute intestinal obstruction are common, and strangulation is liable to occur at the neck of a small sac or in a loculus of a large one.

Treatment.—*Palliative.*—An abdominal belt is sometimes satisfactory, especially in cases of a hernia through an upper abdominal incision.

Operation.—Many procedures are advocated.

Pre-operative Measures.—In order to obtain a lasting repair, very special preparation is required. If the patient is obese, reduction by dieting should precede the operation. To attempt to return the contents of a very large hernia to the main abdominal cavity if they have not been there for several years is to court danger, unless weight reduction has been effected. In these circumstances, not only is there a risk of failure of the hernioplasty, but there is a greatly increased risk of paralytic ileus from visceral compression, and of pulmonary complications from elevation of the diaphragm.

The 'Keel' Operation (Rodney Maingot).—In this operation, the hernial sac is not opened. It is dissected out and pushed back into the abdomen, and by a series of inverting and pleating layers of unabsorbable sutures the abdominal deficiency is closed. This repair, viewed as a cross-section, looks something like the keel of a ship (fig. 1293). The incidence of post-operative ileus and distension is less than that occurring after operations in which the hernial sac is opened. The technique includes: (*a*) A wide excision of skin and scar tissue overlying the sac. Special care must be taken not to damage any bowel which is often adherent to the underside of the sac, (*b*) an extensive mobilisation of skin-flaps and fat, and exposure of healthy and strong aponeurosis around the neck of the sac, (*c*) inversion of the sac into the abdomen, pleating it with strong interrupted unabsorbable sutures, care being taken not to damage any underlying bowel. A second, third, or fourth layer of sutures are inserted until, finally, the healthy margins of the aponeurosis are brought firmly together. Any degree of tension in this final layer can be averted by a few relaxation incisions in the aponeurosis, parallel to the suture line.

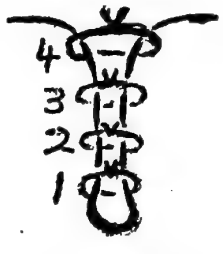

FIG. 1293.—Cross-section of the 'keel' operation.

When the scar is paper-thin and devoid of normal skin, Ibrahim advises that no attempt should be made to separate dermal scar from sac—both should be inverted as one.

Cattell's Operation.—In this operation the hernial sac is dissected out with equal care, but then it is formally opened, the viscera are reduced, and the repair starts from the inside margins of the sac (fig. 1294). During the freeing of the contents of the sac any adherent omentum can be ligated and divided, leaving a portion of it attached to the fundus of the sac and skin. The layers of repair are as follows: The peritoneum and the abdominal wall are approximated at the neck with an interlocking suture of thick chromic catgut, including all layers of the abdominal wall that are attached to the hernial ring (fig. 1294(*a*)). An incision is made

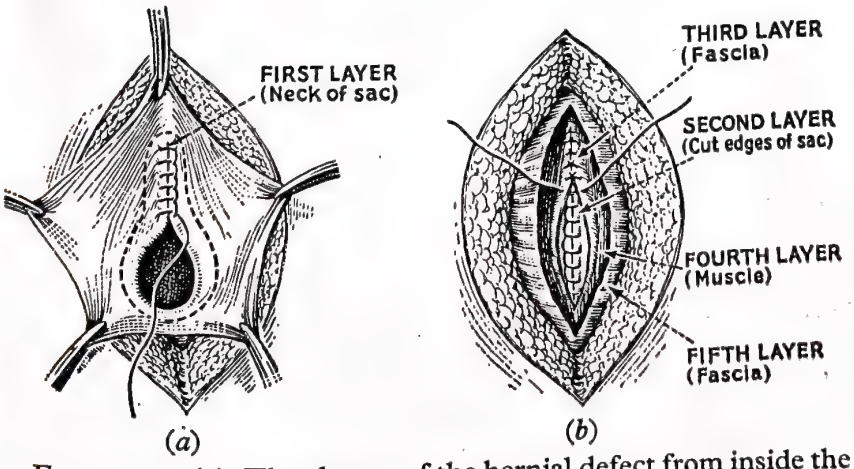

FIG. 1294.—(*a*). The closure of the hernial defect from inside the sac. Dotted line indicates the excess sac. (*b*). Approximation of the third layer. (*After R. B. Cattell.*)

through the sac as shown by the dotted line in fig. 1294(*a*). (2) The cut edges of the base of the sac are approximated with unabsorbable sutures. An elliptical incision is made 2 cm. lateral to the previous suture line. (3) The medial borders of the incision are approximated. The lateral edges of the fascia are freed from the overlying muscles for some distance, and this fascial layer is approximated with interrupted sutures at the upper and lower ends of the wound. This is done to relieve tension on the muscles. (4 and 5) The muscles and the remaining fascial layer are approximated by alternating stitches (fig. 1294(*b*)). Tension-relaxing incisions may be required and should be placed well laterally.

Plastic Fibre Mesh or Net closures.—These are becoming increasingly popular. The sac is dealt with in either of the methods just described. Any deficiency in the abdominal wall can very easily be bridged without tension by laying and sewing on a sheet of tantalum gauze, or a mesh or net made of Nylon or Dacron, cut to well oversize and tacked down to the aponeurosis.

Careful haemostasis and meticulous asepsis are essential during these operations. Post-operative collections of serum can be removed by drainage, using plastic tubing led, via skin punctures lateral to the wound, into closed suction drainage bottles (e.g. Redi-vac).

Post-operative Treatment.—Gastric decompression and intravenous fluids are employed, and nothing by mouth allowed until the bowels have functioned. Early ambulation is to be discouraged, but exercises, especially of the legs, are to be encouraged. The patient should not resume strenuous exercise for three months.

EPIGASTRIC HERNIA

(*syn.* FATTY HERNIA OF THE LINEA ALBA)

An epigastric hernia occurs through the linea alba anywhere between the xiphoid process and the umbilicus, usually midway between these structures. Such a hernia commences as a protrusion of extra-peritoneal fat through the linea alba, where the latter is pierced by a small blood-vessel. Sometimes more than one hernia is present.

A swelling the size of a pea consists of a protrusion of extraperitoneal fat only (fatty hernia of the linea alba (figs. 1295 and 1296)). If the protrusion

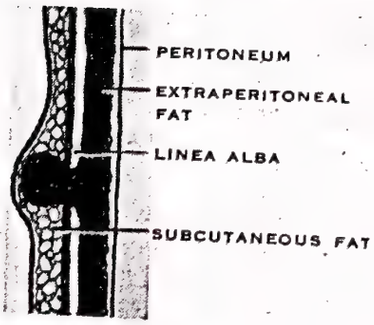

FIG. 1295.—Fatty hernia of the linea alba.

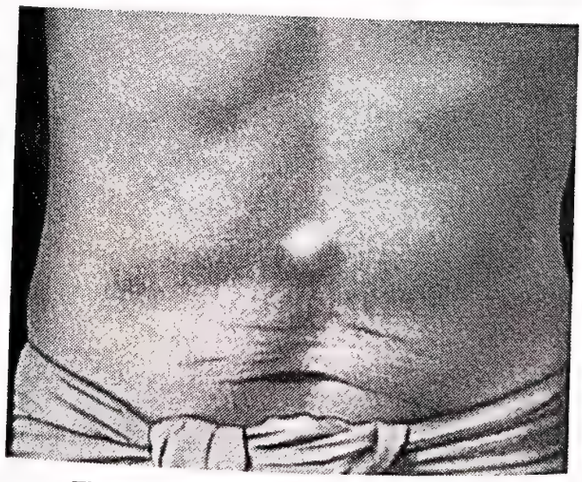

FIG. 1296.—Epigastric hernia.

enlarges, it drags a pouch of peritoneum after it, and so becomes a true epigastric hernia. The mouth of the hernia is rarely large enough to permit a portion of a hollow viscus to enter it; consequently, either the sac is empty or it contains a small portion of greater omentum.

It is probable that an epigastric hernia is the direct result of a sudden strain tearing the interlacing fibres of the linea alba. The patients are often manual workers between thirty and forty-five years of age.

Clinical Features:

(*a*) *Symptomless.*—A small fatty hernia of the linea alba can be felt better than it can be seen, and may be symptomless, being discovered only in the course of routine abdominal palpation.

(*b*) *Painful.*—Sometimes such a hernia gives rise to attacks of local pain, worse on physical exertion, and tenderness to touch and tight clothing, possibly because the fatty contents become nipped sufficiently to produce partial strangulation.

(*c*) *Referred Pain* (Peptic ulcer cases).—It is not uncommon to find that the patient, who may not have noticed the hernia, complains of pain suggestive of a peptic ulcer. On the other hand, a patient suffering from a gastric or duodenal ulcer may attribute all his symptoms to an epigastric hernia. In many cases of epigastric hernia there is coexistent upper abdominal disease.

Treatment.—If the hernia is giving rise to symptoms, operation should be undertaken.

Operation.—An adequate vertical or transverse incision is made over the swelling, exposing the linea alba. The protruding extraperitoneal fat is cleared from the hernial orifice by gauze dissection. If the pedicle passing through the linea alba is slender, it is separated on all sides of the opening by blunt dissection. After ligating the pedicle, the small opening in the linea alba is closed by unabsorbable sutures. When a hernial sac is present it is opened and any contents reduced, after which the sac is excised before repairing the linea alba. Sometimes smaller protrusions of fat are found above and below the hernia. These should also be dealt with.

DIVARICATION OF THE RECTI ABDOMINIS

Divarication of the recti abdominis is seen principally in elderly multiparæ. When the patient strains, a gap can be seen between the recti abdominis through which gap the abdominal contents bulge. When the abdomen is relaxed the fingers can be introduced between the recti.

Treatment.—An abdominal belt is all that is required.

A similar condition is met with in babies, only the divarication exists above the umbilicus. No treatment is necessary; as the child develops a spontaneous cure results.

RARE EXTERNAL HERNIAS

Interparietal Hernia (*syn.* Interstitial Hernia).—An interparietal hernia has a hernial sac that passes between the layers of the anterior abdominal wall. The sac may be associated with, or communicate with, the sac of a concomitant inguinal or femoral hernia. Lack of knowledge of this condition is the cause of misdiagnosis and mismanagement.

Other Varieties (figs. 1297 and 1298): 1. *Properitoneal* (20 per cent.).—Usually the sac takes the form of a diverticulum from a femoral or inguinal hernia.

FIG. 1297.—Bilateral interstitial and bilateral inguinal hernias. The interstitial hernias were between the external and internal oblique muscles, the left containing several feet of small bowel. (*V. J. Hartfield, formerly S.E. Nigeria.*)

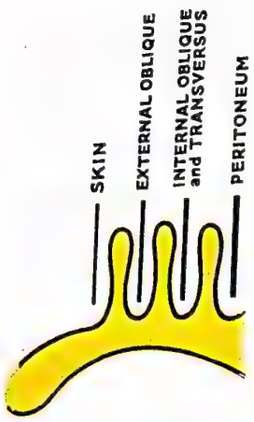

FIG. 1298.—The planes that an interparietal hernia may occupy.

2. *Intermuscular* (60 per cent.).—The sac passes between the muscular layers of the anterior abdominal wall, usually between the external oblique and internal oblique muscles. The sac is nearly always bilocular, and is associated with an inguinal hernia.

3. *Inguino-superficial* (20%).—The sac expands beneath the superficial fascia of the abdominal wall or the thigh. This type is commonly associated with an incompletely descended testis.

Clinical Features.—The incidence in the male is higher than in the female. Most patients present with intestinal obstruction, due to obstruction or strangulation of the hernia. In these circumstances the cause of the obstruction should be apparent in the intermuscular and inguino-superficial varieties, but in the properitoneal variety, as no swelling is likely to be apparent, delays in diagnosis occur and consequently the mortality in this variety is high.

Treatment.—Operation is imperative because of intestinal obstruction. In all cases of inguinal and femoral hernia a finger should be introduced into the sac with the object of detecting an unsuspected intraparietal loculus.

A Spigelian hernia is a variety of interparietal hernia. This type of hernia is one occurring through the Spigelian fascia, commonly at the level of the arcuate line (fig. 1299). The fundus of the sac, clothed by extraperitoneal fat, may lie beneath the internal oblique muscle, where it is virtually impalpable. More often it advances through that muscle and spreads out like a mushroom between the external and internal obliques and gives rise to a more evident swelling. The patient is often corpulent, and usually over fifty years of age, men and women being affected equally. Typically, a soft, reducible mass will be encountered lateral to the rectus muscle and below the umbilicus. After reduction a small oval defect can often be felt and because of the rigid fascia surrounding its neck, strangulation may occur.

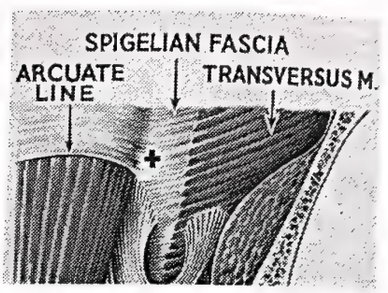

FIG. 1299.—The usual site for a Spigelian hernia.

Treatment.—Operation should be advised and repair is simple. The external oblique aponeuosis is split. After isolating the sac, dealing with any contents, and ligating and excising it, the transversus, internal oblique, and external oblique muscles are approximated in layers.

FIG. 1300.—Inferior lumbar hernia. It contained cæcum, appendix and small bowel. Note filiarial skin rash on buttocks. (*V. J. Hartfield, Sussex.*)

Lumbar Hernia. — Most primary lumbar herniæ gain exit through the inferior lumbar triangle of Petit (fig. 1300), bounded below by the crest of the ilium, laterally by the external oblique, and medially by the latissimus dorsi. Some come through the superior lumbar triangle, which is bounded by the twelfth rib above, medially by the sacrospinalis, and laterally by the posterior border of the internal oblique. An extensive incisional lumbar hernia sometimes follows an operation upon an infected kidney, in which the wound suppurated post-operatively.

Differential Diagnosis.—A lumbar hernia must be distinguished from: (*a*) A cold abscess pointing to this position. (*b*) Phantom hernia due to local muscular paralysis. Lumbar phantom herniæ can result from any interference with the nerve-supply of the affected muscles (e.g. poliomyelitis). (*c*) Lipoma.

Treatment.—A primary lumbar hernia, being small, does not entail an extensive operation for its repair. On the other hand, a post-operative lumbar hernia may be large, and the defect is

Andrien Van der Spieghel (Spigelius), 1578–1625. Professor of Anatomy, Padua, Italy.
Jean Louis Petit, 1664–1750. Director of the Academy of Surgery, Paris.

impossible to repair unless fascial flaps are used. When necessary, the area can be reinforced still further by stitching in place a piece of tantalum gauze or Dacron mesh.

Perineal hernia (*syn.* hernia through the pelvic floor) is not uncommon in the ageing dog—a reducible swelling appears immediately lateral to the anus. In human beings, except following excision of the rectum, perineal hernia is rare. Several varieties are encountered:

(*a*) *Antero-lateral perineal hernia* occurs in women and presents as a swelling of the labium majus.

(*b*) *Postero-lateral perineal hernia*, which passes through the levator ani to enter the ischio-rectal fossa.

Treatment.—A combined operation is generally the most satisfactory. The hernia is exposed by an incision directly over it. The sac is opened and its contents are reduced. The sac is cleared from surrounding structures and the wound is closed. With the patient in semi-Trendelenburg position, the abdomen is opened and the mouth of the sac is exposed. The sac is inverted, ligated, and excised, and the pelvic floor is repaired as adequately as possible.

(*c*) *Median sliding perineal hernia* is a complete prolapse of the rectum (p. 1070).

(*d*) *Post-operative hernia through a perineal scar* may occur after excision of the rectum.

Obturator Hernia.—The hernia, which passes through the obturator canal, occurs six times more frequently in women than in men. Most of the patients are over sixty years of age. The swelling is liable to be overlooked because it is covered by the pectineus. It seldom causes a definite swelling in Scarpa's triangle, but if the limb is flexed, abducted, and rotated outwards, sometimes the hernia becomes more apparent. The leg is usually kept in a semi-flexed position and movement increases the pain. In more than 50 per cent. of cases of strangulated obturator hernia pain is referred along the obturator nerve by its geniculate branch to the knee. On vaginal or rectal examination the hernia sometimes can be felt as a tender swelling in the region of the obturator foramen.

Cases of obturator hernia which present themselves have usually undergone strangulation, which is often of the Richter type (p. 1107).

Treatment.—(*a*) Perform lower laparotomy (on the side of the lesion, if known). Confirm the diagnosis and then adopt full Trendelenburg's position; (*b*) the constricting agent is the obturator fascia. Taking every precaution to avoid spilling infected fluid from the hernial sac into the peritoneal cavity, this fascia can be stretched to allow reduction by inserting suitable forceps through the gap in the fascia and opening the blades with care. If incision of the fascia is required, it is made parallel to the obturator vessels and nerve; (*c*) the contents of the sac are dealt with; (*d*) the broad ligament is stitched over the opening to prevent recurrence.

Gluteal and Sciatic Herniæ.—A *gluteal hernia* passes through the greater sciatic foramen, either above or below the piriformis. A *sciatic hernia* passes through the lesser sciatic foramen. *Differential diagnosis* must be made between these conditions and (*a*) A lipoma or fibro-sarcoma beneath the gluteus maximus. (*b*) A tuberculous abscess. (*c*) A gluteal aneurysm. All doubtful swellings in this situation should be explored by operation.

CHAPTER 53

URINARY SYMPTOMS. INVESTIGATION OF THE URINARY TRACT. ANURIA

URINARY SYMPTOMS

THREE symptoms, a veritable triple alliance, accompany most urinary affections. They are pain, frequency, and hæmaturia.

Pain, associated with affections of the urinary tract embraces :

Renal pain is usually a fixed dull ache situated mainly in the costo-vertebral angle, but also in the upper and outer quadrant of the abdomen. It may be due to stretching of the renal tissue or irritation of the wall of the kidney pelvis.

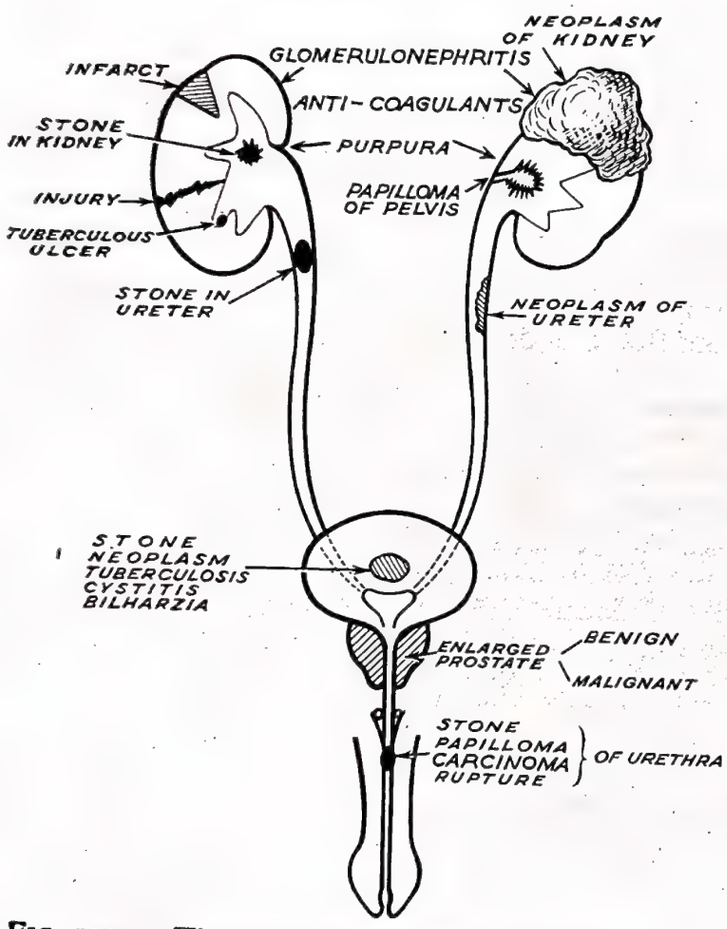

FIG. 1301.—The more common causes of hæmaturia.

Renal[1] *and ureteric colic,* a violent spasmodic pain, is due to obstruction producing distension and increased muscular activity.

Vesical pain varies from slight suprapubic discomfort to strangury, which is agonising pain referred to the external urinary meatus, accompanied by an intense desire to micturate, but resulting in the expulsion (by straining) of only a few drops of blood-stained urine.

Prostatic and seminal vesicular pain is deep-seated in the rectum ; it is often referred to the perineum, but sometimes to the suprapubic region or one or both iliac fossæ.

Urethral pain is scalding, and occurs during micturition.

Frequency may be due to incomplete emptying, as in prostatism, to irritability of the bladder as by inflammation or stone, to a contracted bladder, to a diuresis, or sphincter weakness.

[1] Renal colic is a term that is deeply rooted. Pain passing from loin to groin is more accurately termed ureteric colic.

Hæmaturia.—Blood in the urine, however transient, is a symptom that must never be ignored. Painless hæmaturia is so often a herald of new-growth in some part of the urinary tract that a complete urinary investigation should be implemented immediately. When hæmaturia is painful, the patient demands relief, and the task of persuading him to undergo a thorough examination is less difficult. The causes of hæmaturia are manifold, and the more common ones are depicted diagrammatically in fig. 1301.

Pink or red urine may occur after eating beetroot, while many drugs, e.g. Dindevan, Pyridium, and Furadantin may make the urine a deep orange red. Actual bleeding occurring while a patient is on anticoagulants should make the practitioner consider the possibility of unsuspected renal or vesical pathology.

INVESTIGATION OF THE URINARY TRACT

A general physical examination must be included in the investigation of any urinary tract condition. Of particular importance are the state of the heart, the blood-pressure, the chest (chest X-ray). A *hæmoglobin estimation* is essential, as anæmia is a close and aggravating partner to uræmia.

1. **The urine** is examined chemically and bacteriologically. For the latter a midstream specimen of urine is essential for (*a*) it avoids contamination as far as possible and (*b*) it is without the risks of catheterisation.

2. **Tests of Renal Function.**—Because of the large reserve of renal tissue, considerable structural damage can occur before functional damage becomes apparent. Kidney function can be impaired in three principal ways: the renal plasma-flow may be reduced, the glomeruli damaged, or the function of the tubules impaired. In essential hypertension the chief fault lies in the renal plasma-flow. In glomerulonephritis the main effect is reduction in the glomerular filtration rate, while in pyelonephritis the brunt falls on tubular function. In back pressure due to obstruction all become impaired.

Range of Specific Gravity (concentration dilution test).—The power of the kidneys to concentrate and dilute urine is a good test of their functional integrity. Fluid is withheld for twelve hours overnight. The specific gravity of the first two morning specimens should reach 1·020; a specific gravity of 1·025 in a urine free of protein indicates good renal function. A litre of water is given by mouth. Within four hours the specific gravity should be as low as 1·002. A fixed specific gravity of 1·010 under these varying circumstances is good presumptive evidence of impaired function of the distal renal tubules.

The blood urea (or non-protein nitrogen) is normally between 20 and 40 mg. per 100 ml (3·3–6·6 mmol/l) of blood. A reading above 40 mg (6·6 mmol/l) is suspicious, and one more than 50 mg (8·3 mmol/l) is indicative that the kidney function is impaired by at least 50 per cent.

Creatinine Clearance.—This is a convenient method of measuring the glomerular filtration rate. One sample of blood and an accurately timed collection of urine for a period of about twenty-four hours are all that is required. The estimation of creatinine in each, enables a clearance to be arrived at. The normal clearance is between 80 and 120 ml. per minute. It decreases in old age.

3. **Intravenous Pyelography (I.V.P.).**—Strictly speaking this is *urography*, because more than the kidney pelvis is examined. It is a contrast X-ray, and the radio-opaque medium employed is sodium diatrizoate (*syn.* Hypaque) which is mainly secreted by the proximal tubules.

Contraindications.—(*a*) When renal function is poor, secretion is insufficient to produce a reasonable film. (*b*) Idiosyncrasy to iodine must be excluded by a small preliminary test dose (1 ml. i.v.). A history of asthma or other allergic conditions should put one on guard in this respect. (*c*) A suspicion of myelomatosis. Precipitation of the myeloma protein can produce anuria.

If untoward signs develop during the injection, stop the injection at once. Give oxygen for anoxia, a pressor drug for low blood pressure, dextrose-saline solution for shock which is to be followed by dextran if needed. Important antidotal drugs in the treatment of acute sensitivity reactions are (*a*) anthisan, 100 mg. intravenously or (*b*) hydrocortisone, 100 mg. intravenously.

Preparation.—A mild vegetable aperient is given on two evenings preceding the examination. No fluid should be taken for 8 hours before the investigation, and the patient is instructed to empty the bladder just before the injection.

Technique.—40–60 ml. of sodium diatrizoate (Hypaque 45 per cent.) are injected into a suitable vein, usually an arm, with the patient recumbent. None of the solution must be permitted to escape into the tissues around the vein, for it is irritating. Rapid injection and exposure of a film immediately the injection is completed will give valuable nephrograms. If the kidneys are functioning normally, the medium appears simultaneously in the calyces and pelves of both kidneys two minutes later. As a routine, X-ray films are exposed at 5, 10, 15, and 25 minutes.

FIG. 1302.—Normal excretory pyelograph (I.V.P.).

Compression applied to the abdomen by a strap enhances the clarity of the pyelographs, because it delays emptying of the renal pelvis. The concentration reaches its maximum in 15 to 30 minutes (fig. 1302). After the 25-minute film has been taken, a film in the erect position is valuable: (i) to demonstrate the mobility of the kidneys, (ii) to visualise the ureters, (iii) to show emptying of the kidneys. Normally, visible excretion is completed in one to one and a half hours. The later radiographs show the bladder filled with the medium. In order to display the termination of the ureters, the patient should micturate immediately before the final radiograph. The amount of residual urine in the bladder, if any, can also be demonstrated in this way. When the renal pelves and calyces fail to empty within the normal limits, further radiographs are taken at half-hourly intervals.

Infusion Pyelogram.—In patients with a blood urea of 100 to 200 mg/100 ml (16·6–33·2 mmol/l), an infusion 50 per cent. Hypaque 2 ml/kg in an equal volume of normal saline, over a period of 10 minutes, may produce useful urograms.

4. **Instrumental Examination of the Urinary Organs** can be accomplished under local anæsthesia.

In the Male.—If the prepuce is present, it is retracted and all smegma is removed by washing with soap and water followed by swabbing with a mild antiseptic solution. Cocaine is dangerous, absorption via the urethral mucosa into the circulation sometimes causing collapse and even death. 1 per cent. lignocaine with 0·25 per cent. chlorhexidine gluconate as a local antiseptic in a jelly base (Lidothesin) is safe and effective. About 15 ml. is squeezed into the urethra and retained for five minutes with the aid of a penile clamp placed proximal to the glans.

In the Female.—The vulva is washed with soap and water followed by swabbing with a mild antiseptic solution. The labia minora are held apart and the local anæsthetic jelly is injected into the urethra.

Bouginage is described on p. 1270, and **Catheterisation** on p. 1239.

Cystoscopy.—By cystoscopy, the interior of the bladder is inspected and the ureteric orifices observed. If 7 ml. of a 0·4% solution (adult dose) of *indigo-carmine* are injected intravenously, the excretion of the dye down the ureters can be watched; normally it should appear within four or five minutes.

FIG. 1303.—A ureteric catheter about to enter the left ureteric orifice. Cystoscopic view.

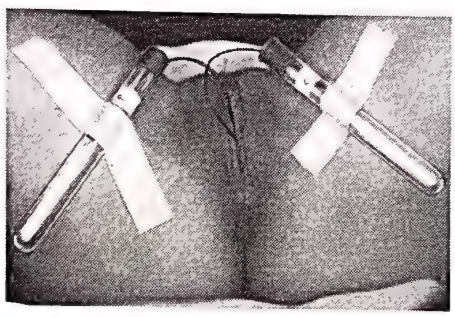

FIG. 1304.—Specimens of urine being collected after ureteric catheterisation. The test-tubes are capped with rubber finger-stalls.

Delay of excretion of the dye on one side is indicative of unilateral urinary obstruction or disease, while delay on both sides suggests bilateral renal impairment. By employing a catheterising cystoscope, ureteric catheters can be passed up each ureter (fig. 1303), and specimens of urine collected from each kidney (fig. 1304).

Retrograde (*syn.* **instrumental**) **pyelography** is employed when a clearer definition than that afforded by the intravenous pyelogram is required, e.g. suspected renal neoplasm or early tuberculosis, or to collect urine from each kidney separately for differential functional tests. The ureters are catheterised, and the patient is conveyed to the radiological table. A plain radiograph is taken and developed before injecting the medium in order to ensure that the ureteric catheters are not too advanced. 25% sodium diatrizoate (hypaque) is used for the injection. An initial film after 3 to 4ml. have been injected will outline a normal pelvis (fig. 1305). Should a large hydronephrosis be present, more medium will be required to obtain clear

In 1877, Max Nitze, Professor of Urology, Berlin, in conjunction with Beneche, an Optician of Vienna, produced the first cystoscope.

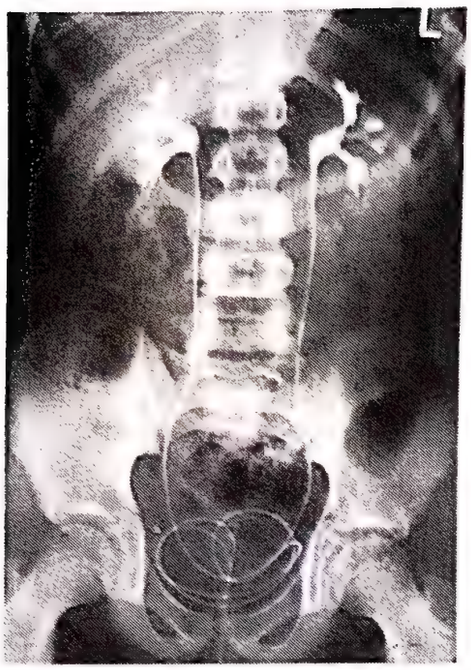

FIG. 1305.—Normal retrograde pyelogram. The definition is much clearer, consequently this procedure is invaluable in confirming doubtful abnormalities visualised by the excretory method, or where excretion is poor.

definition. By this method it is possible to inject the pelvis of both kidneys at the same sitting, but in cases of poor renal function it is essential to make each examination independently. In either event, after the X-ray exposure has been made, as much of the medium as possible is aspirated from the renal pelvis. Examination with the aid of an image intensifier gives immediate information of the size of the renal pelvis and calyces; the activity can be observed, and functional obstructions easily displayed.

Cystography: (*a*) *Excretory*.—The cystographs which accompany the later films of excretory pyelography may not be sufficiently dense to give a clear delineation of pathological conditions in the bladder. Sketch

(*b*) *Retrograde* is employed principally to confirm the presence and dimensions of a vesical diverticulum. A small catheter is passed and the urine in the bladder is evacuated. If a diverticulum is suspected, the patient lies on his face so as to favour drainage of urine from the diverticulum. A plain radiograph is taken to exclude a calculus in the diverticulum. The bladder is then filled with medium until the patient feels a desire to micturate. An excellent contrast medium for cystography is a 25 per cent. solution of iodoxyl (B.P.). A radiograph is taken with the bladder full, and again after the bladder has been emptied. If there is a diverticulum present, it will remain full of medium after the medium has left the main cavity (p. 1212). The extent of a very large neoplasm of the bladder can sometimes be demonstrated better by cystography than by cystoscopy.

(*c*) *Micturating cystograms* are best performed with an X-ray image-intensifier. The function of the bladder neck, and the presence of ureteric reflux of urine, can be observed on a monitoring screen as the patient empties his bladder. Simultaneous recording of bladder pressure with flow rates, alongside the X-ray display, on videotape are most useful in detecting unstable detrusor activity (fig. 1388).

Urethroscopy: (*a*) *Anterior urethroscopy* is employed when the presence of a urethral stricture (fig. 1301) or strictures is suspected, or in cases of chronic urethritis, in order to exclude or confirm the presence of an infected urethral crypt or a granuloma (a ' soft ' stricture). Anterior urethroscopy is conducted under air inflation of the urethra.

(*b*) *Posterior urethroscopy* permits inspection of the prostatic and membranous urethræ. It is carried out with an irrigating urethroscope. The most notable normal spectacle of posterior urethroscopy is the verumontanum, which presents as an eminence on the floor of the prostatic urethra. On the summit of this projection is the sinus pocularis (fig. 1306), with the ejaculatory ducts opening on either side. The verumontanum is reddened and enlarged in cases of chronic vesiculitis. In cases of chronic prostatitis, one or more of the numerous prostatic ducts, which normally

are difficult to visualise, may be seen exuding pus. When the prostate is enlarged, the lateral lobes project into the internal meatus producing an inverted V; a middle lobe or bar can be easily seen.

Urethrography.—Urethrography (fig. 1307) is especially valuable for gaining information concerning the length of a urethral stricture, of dilatation or diverticulum formation above a stricture, or of failure of the medium to pass a stricture. It also reveals dilated prostatic ducts in chronic

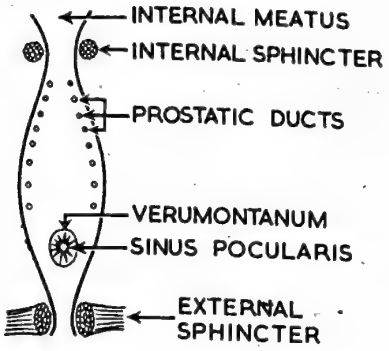

FIG. 1306.—Structures on the floor of the posterior urethra. (*After J. C. Ainsworth-Davis, F.R.C.S., London.*)

FIG. 1307.—Normal urethrograph.

prostatitis and especially in tuberculous prostatitis. It is valuable for determining the presence of contraction of the bladder neck. The one contraindication to its use is the presence of urethral hæmorrhage. The medium employed must be chosen with great care, for should there be a breach in the continuity of the lining membrane of the urethra, the medium will enter the circulation (fig. 1470).

Lipiodol brings with it the danger of oil embolus and this medium should never be employed. Even worse is to inject barium emulsion, and deaths have occurred from its use in cases of ruptured urethra.

The medium must therefore be harmless should some of it enter the circulation, and the injection must not be rapid or forceful. Perabrodil (80 per cent.) complies with these stipulations as it can be injected intravenously. For general purposes the most satisfactory medium is Umbradil viscous V. This is a jelly which is squeezed from a tube into the butt end of a urethral syringe. It is injected easily and contains the local anæsthetic lignocaine. The injection is made most satisfactorily by employing Knutsson's apparatus which has a penile clamp attached (fig. 1308).

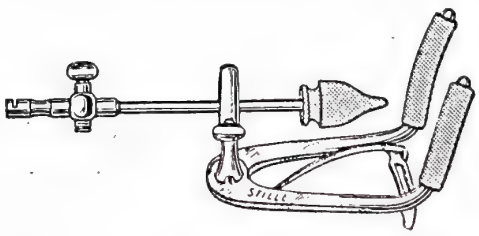

FIG. 1308.—Knutsson's apparatus for urethrography.

Renal Arteriography (fig. 128)

Renal arteriography can provide information unobtainable by retrograde pyelography. To be enabled to visualise the renal arterial architecture is of diagnostic value in the following conditions.

1. Hypertension, if unilateral ischæmia (e.g. due to renal artery stenosis) is suspected. 2. Renal neoplasm. 3. Renal cyst. 4. Chronic pyelonephritis. 5. Aneurism of the renal artery.

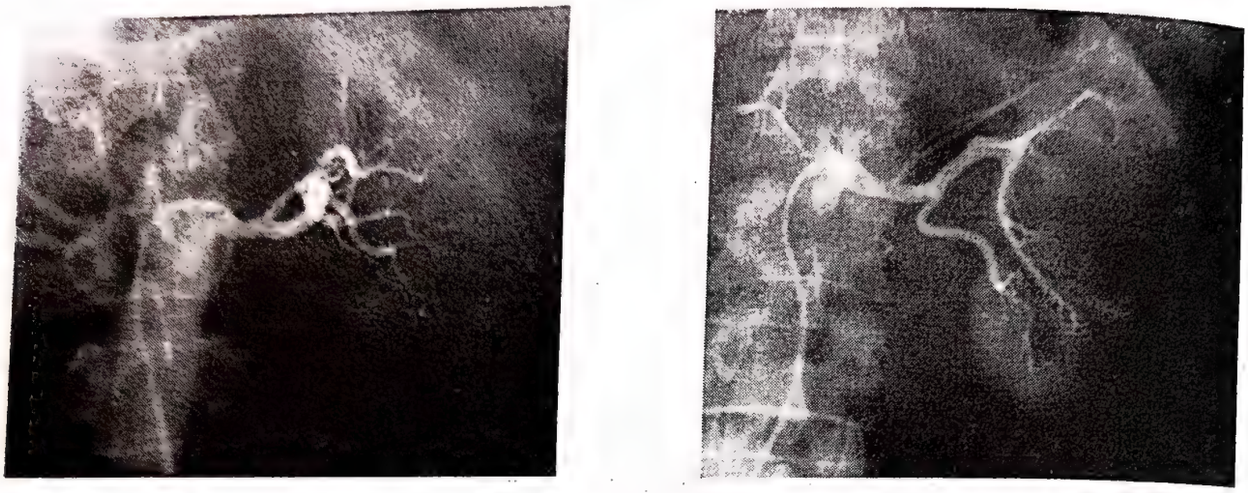
There are two methods of performing renal arteriography.

(*a*) **Translumbar aortography** is carried out under general anæsthesia. A

Folke Knutsson, Contemporary. Director Roentgen Department University Hospital, Uppsala, Sweden.

needle is passed into the abdominal aorta just above the renal arteries (level of L.I.), the contrast medium is injected and four films are taken in rapid succession. To minimise accidents a small quantity of medium is injected and a film taken to ensure that the needle is in its correct position (p. 129).

(*b*) **Retrograde Arteriography.**—A Seldinger's needle is used (fig. 129). The needle is passed into the femoral artery. The stilette is removed. A spiral guide wire (a ' leader ') with a supple tip is passed into the artery and the needle is removed. The artery is compressed to avoid bleeding and polythene tubing is threaded on to the



(*a*) (*b*)

FIG. 1309.—Selective renal arteriography. (*a*) normal kidney. (*b*) renal cyst (p. 1149).

leader and so guided through the skin and arterial puncture into the artery. The polythene tube is advanced to the desired level, a small quantity of Hypaque being injected to render it opaque to X-rays. The medium is then injected. *Selective Renal Arteriography* can be achieved by using a hooked polythene catheter, and guiding it into the renal artery (fig. 1309).

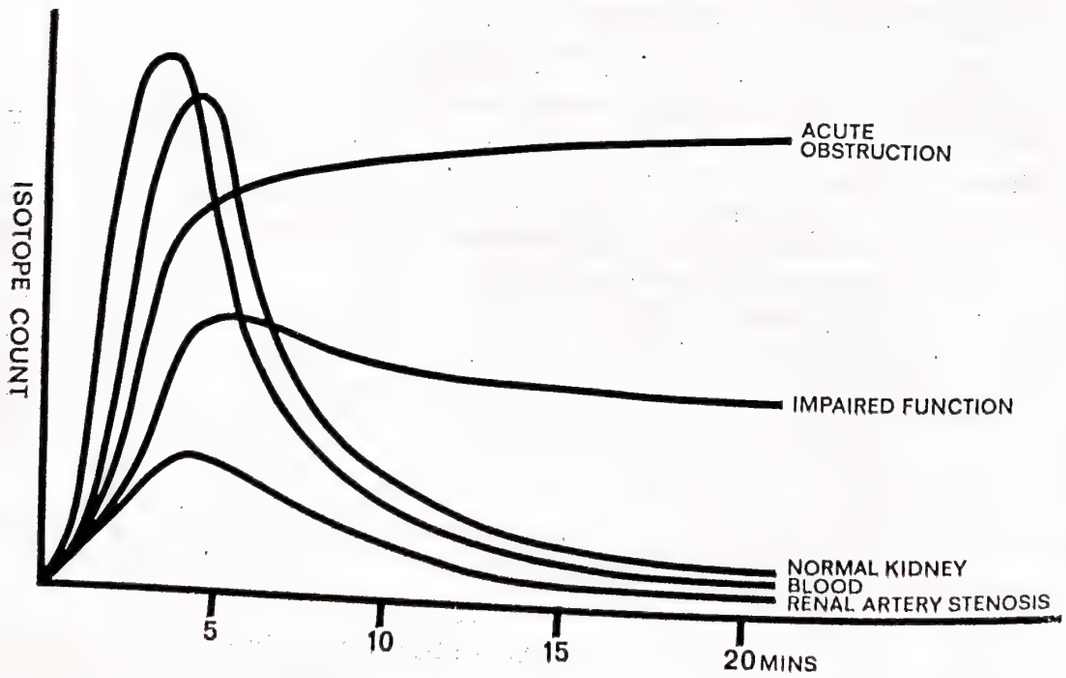


FIG. 1310.—Radio isotope renogram (see text).

In either method not more than 30 ml. of Hypaque (65 per cent.), one of the least toxic media, should be injected. If these stipulations are adhered to, accidents are minimised. The dangers of the procedure are (*a*) tubular necrosis of the kidneys, (*b*) paraplegia, often temporary, probably due to contrast medium producing spasm

of the vessels of the spinal cord, (*c*) elevation of a plaque of atheroma and possibly the production of a dissection in the aortic wall, and a dissecting aneurysm.

Operation should not be performed for at least one week after renal angiography.

Perirenal insufflation of oxygen to delineate a renal or adrenal swelling is described on p. 622.

Renal tomography is sometimes used in combination with other radiographic procedures as it can help in doubtful cases to differentiate between tumours and cysts and outline the renal margin.

Radio Isotope Renogram (fig. 1310).—A balanced pair of gamma-ray counters located over the kidneys measures the renal uptake and excretion of radioactive Hippuran[1]. If urine, blood and an inactive body area are monitored at the same time additional information can be obtained. The rate of blood flow through the kidney, the rate of concentration, and the rate of clearance can be shown graphically. 1. Initial steep rise (½ minute) vascular phase. 2. Renal excretion and secretion in next 4–6 minutes. 3. Decline flattening to about or below blood levels. A comparison of function and even differential function can be assessed in this way.

Renal Scintiscan will, as in thyroid studies (p. 589), reveal cold areas which may be cysts or tumours with poor blood supply.

ANURIA (*syn.* SUPPRESSION OF URINE)

Oliguria should be defined as an excretion of less than 300 *ml. of urine in twenty-four hours. Anuria is an absence of excretion for twelve hours.*

The most helpful classification of anuria is into pre-renal, renal, and post-renal. Although suppression of urine is commonly and conveniently referred to as anuria, except in post-renal (ureteric obstruction) cases the suppression is seldom absolutely complete.

Pre-renal Anuria

The blood pressure in the glomeruli is normally about 90 mmHg (12 kPa); when the systolic blood pressure falls below 70 mm (9·3 kPa), filtration from glomeruli ceases. If the glomeruli are diseased, a higher pressure (up to 100 mmHg (13·3 kPa)) may be inadequate to maintain filtration. The causes of pre-renal anuria are traumatic shock, severe hæmorrhage, spinal anæsthesia, extensive burns, dehydration from vomiting, diarrhœa, or excessive sweating, and cardiac failure.

Treatment.—Blood transfusion in the case of hæmorrhage, the treatment of shock (p. 79) if that be the cause of the fall in the blood-pressure, or in cases of dehydration the administration of dextrose-saline solution intravenously often restores urinary excretion. If hypotension is long maintained, damage to the renal epithelium results, and the condition passes on to one of renal anuria, due to tubular necrosis.

Acute Renal Anuria (Acute tubular necrosis)

Acute renal anuria results from damage to, or ischæmia of, the renal tubular epithelium (fig. 1311). The principal causes met with in surgical practice are:

[1] Hippuran = Sodium iodohippurate. (Mallinckrodt, U.S.A.)

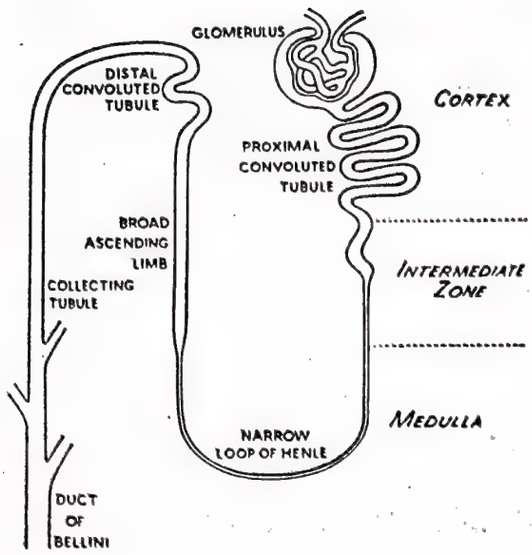

FIG. 1311.—Necrosis of the proximal convoluted tubule produces immediate anuria. (*After H. L. Sheehan.*)

1. Severe shock (hypotension) lasting two hours or more.
2. Incompatible blood transfusion.
3. Bilateral pyelonephritis.
4. The crush syndrome (p. 81).
5. Concealed accidental hæmorrhage and abortion.
6. Certain poisons. The most important are (*a*) media used for aortography, (*b*) the toxin of eclampsia, (*c*) chemicals—mercury salts, carbon tetrachloride.
7. Acute pancreatitis.
8. Operations on jaundiced patients.
9. Bacteræmic shock.

When renal anuria is reversible, and it is treated correctly, the condition is divided into three phases: 1. *The oliguric phase.* 2. *The phase of diuresis.* 3. *The phase of recovery.*

Clinical Features.—The average duration of the oliguric phase is ten to twelve days. Dark urine in small amounts and with a specific gravity of 1·010 is passed, or will be found on catheterisation. Anorexia is an early symptom which is followed by hiccough. Within four or five days there is copious effortless vomiting. Abdominal distension is common. Untreated, or treated incorrectly, the blood urea mounts by 20 to 30 mg (3·3–5·0 mmol) daily (fig. 1264). The systolic blood-pressure may be elevated—200 mm Hg (26·6 kPa) after two or three days.

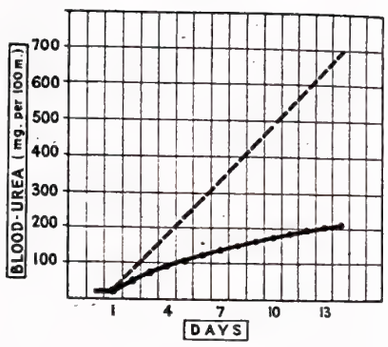

FIG. 1312.—Dotted line: rise of blood urea in untreated anuria. Solid line: same when treated by fluid limitation and protein-free diet. (*After G. M. Bull.*)

Still untreated, or treated incorrectly, about the sixth day increasing drowsiness, thirst, a dry skin, and a dry brown tongue are characteristic findings. The respiratory and pulse-rates become slower and irregular, and Cheyne-Stokes' respirations are often in evidence. The final stages are usually characterised by muttering delirium followed by coma.

Treatment: Special Early Measures.—(*a*) If there is any doubt as to the cause, post-renal (obstructive) anuria must be eliminated by plain radiography and ureteric catheterisation (p. 1239). (*b*) In cases of incompatible blood transfusion, renal damage can sometimes be prevented by provoking a diuresis within an hour of the reaction—500 ml. of Rheomacrodex or mannitol (p. 77) is given intravenously. If no urine is secreted (the bladder is emptied naturally—or via a catheter), all fluids are restricted forthwith.

In all other circumstances of acute renal anuria it is imperative not to force

Lorenzo Bellini, 1643–1704. Professor of Philosophy and Anatomy, Pisa, Italy.
John Cheyne, 1777–1836, and William Stokes, 1804–1878. (See footnote, p. 95.)

fluids.[1] The important substances in the genesis of uræmia are not urea and other end products of nitrogen metabolism, but water and electrolytes, such as potassium. If patients receive 3,500 ml. or more per day, 75 per cent. die with signs of water overload, and evidence of pulmonary or cerebral œdema at necropsy. Another reprehensible practice is to prescribe potassium citrate for a patient on the threshold of suppression of urine; it has caused many deaths from hyperkalæmia.

Treatment of an Established Case.—The essentials are:

1. *Water Balance.*—In the absence of vomiting, the elimination of water by an anuric patient is limited to extra-renal routes, i.e. lungs, skin, and fæces. In a temperate climate this loss is 600 to 1,000 ml. per day. As it is estimated that there is a daily production of 400 ml. of water from the oxidation of body fat and proteins, the daily fluid intake of an anuric patient must be limited to 500 ml. plus an amount equal to that of the water vomited or recovered by gastric aspiration.

Additions must be made for diarrhœa and excessive sweating: regarding the latter, an extra 200 ml. is allowed for each 0·5 degree of the patient's temperature above 37·8° C. When the weather is exceedingly hot, the allowance is increased, but even in these circumstances it should rarely exceed 1,000 ml. per twenty-four hours.

Bedside evaluation—thirst, moisture of the tongue, and the skin—are excellent guides of adequate hydration.

2. *Electrolytic Balance.*—In the absence of diarrhœa and vomiting, the only effective channel for excretion of electrolytes is by the kidneys. Consequently, in anuria the administration of electrolytes often leads to gross disturbances of electrolytic balance; in particular, hyperpotassæmia is liable to cause sudden death from cardiac arrest. The blood urea, of course, rises and the serum bicarbonate falls.

3. *Nitrogen Metabolism.*—The end-products of protein katabolism, other than urea, are possibly toxic. Furthermore, by the breakdown of both exogenous and endogenous protein, potassium is liberated. For these reasons it is essential to prohibit protein intake altogether, and to reduce endogenous nitrogen metabolism as much as possible. A high carbohydrate intake depresses endogenous nitrogen metabolism.

The Protein-free, Mineral-free, Strictly-limited-fluid Regimen.—The object is to provide 2,000 Calories (8 400 kJ) per day, and at the same time to limit fluid intake as detailed above. This is a diet upon which the patient can subsist without discomfort for periods up to three weeks (Bull). According to circumstances, the regimen can be varied:

(*a*) When the patient can take fluid by mouth without vomiting or undue nausea, a daily intake of 500 ml. of 40 per cent. lactose, given in small frequent amounts, is likely to be acceptable because the solution tastes less sweet than dextrose.

(*b*) When the patient is anorexic, nauseated, and prone to vomit, a plastic

[1] According to Harrington, the pioneer of water closets, it does no good to keep trying to flush a lavatory when it is blocked!!!

Graham MacGregor Bull, Contemporary. Director, Medical Research Council, Clinical Research Centre, London.

gastric tube is passed transnasally and the 500 ml. of 40 per cent. dextrose or lactose is gravitated by the drip method. A plastic tube is chosen because its relative stiffness makes it less likely to be expelled if the patient vomits. As far as possible the vomitus must be collected and measured, for obviously it is highly important to supplement the loss with precision. To stop the drip for two to four hours at a time helps some patients to retain the solution. Alternatively, 50 to 100 ml. of doubly centifruged cream is added to the dextrose solution. This enables the solution to be tolerated by some patients who otherwise would reject it.

(*c*) When the patient is unable to retain the fluid gravitated into the stomach, or toxæmia or a head injury makes him stuporous and therefore liable to inhale vomitus, there is but one alternative—to give the 40 per cent. dextrose solution intravenously. The modern method is to give this clot-provoking solution into the inferior or superior vena cava by a polythene tube passed from the long saphenous or cubital vein.

In order to discourage thrombosis, heparin (1,000 units per 500 ml.) is added to the infusion. Even so post-mortem examination has shown intravenous clotting in a high percentage of cases. For this reason the intravenous route should be employed only in cases of absolute necessity. Some advise passing the polythene tube but a few inches into a peripheral vein and to change the vein if clotting occurs. By gravitating the fluid in this way it is hoped that the menace of pulmonary embolism is lessened.

Vitamins.—Irrespective as to whether the alimentary or the intravenous route is employed, the daily vitamin intake should be identical with that of a patient subsisting wholly on parenteral feeding (pp. 89 to 94).

Prevention of Infection.—Anuric patients become infected easily, therefore all who come in contact with the patient should be gowned and masked. A nasal swab should be taken from the patient at the onset of anuria. If *Staphylococcus aureus* is cultured, a suitable antibiotic should be given at once. Penicillin, 1 mega unit per twenty-four hours, can safely be given. Many antibiotics are cumulative even when given in greatly reduced doses. Tetracycline must be avoided because of its nephrotoxicity in poor renal function.

Watching for Hyperkalæmia.—Serial electrocardiographs are a better check to the development of this complication than reliance on plasma potassium determinations (p. 88).

Diuretic Phase.—In reversible lesions, usually about the eighth day, the epithelium of the lower nephrons regenerates sufficiently to prevent resorption of the glomerular filtrate, and a little urine is passed. This is a most hopeful sign, and given correct management and previously healthy kidneys (Causes 1 to 7, p. 1140) an increasing twenty-four-hourly output during the subsequent week is usual. When diuresis commences, an amount of water equal to the output of urine for the previous twenty-four hours is added to the daily allowance. It is more difficult to estimate an appropriate allowance of electrolytes, for the restitution of renal electrolyte-regulating function returns slowly. A heavy loss of sodium and potassium may occur and must be replaced. Estimation and quantitative replacement of the loss in the previous twenty-four hours is the most accurate way of management. Only when renal

excretion reaches 1 litre per day does the blood-urea level commence to fall. Once diuresis exceeds 1 litre in twenty-four hours, the intragastric tube is removed and the patient is fed on a high caloric, low-protein diet containing an adequate daily amount of mineral salts.

Other methods of treatment in special circumstances :

1. **The Artificial Kidney.**—The principle of the artificial kidney is that of dialysis across a membrane which is permeable to crystalloids and not to colloids, with the patient's blood on one side of the membrane and a saline bath on the other; excessive crystalloids will leave the blood and enter the bath, which is constantly flowing. The indications for dialysis are: (*a*) Serum potassium above 7·0 mEq/litre (mmol/l), (*b*) Serum bicarbonate level below 12 m Eq/litre (mmol/l), (*c*) Gross overhydration, or (*d*) a blood urea above 300 mg/100 ml (65 mmol/l). Fits or coma may also be indications.

The artificial kidney requires a trained team to operate the machine, hence it is available only in a few centres. It is therefore necessary to describe other methods of ridding the patient of excessive electrolytes, particularly potassium.

2. **Peritoneal Dialysis.**—This method has been used with success. The simplest method and the one least likely to give rise to peritonitis is to insert a polythene tube into the peritoneal cavity by means of a trocar and cannula. Into the peritoneal cavity is gravitated moderately slowly a hypertonic solution (20% dextrose solution with 6 g sodium chloride per litre added). The fluid is retained by clipping the tube for two hours and then allowing it to flow out. The process is continued for up to forty-eight hours. Thus the peritoneum acts as a dialysing membrane.

3. **Ion Exchange Resins.**—If the patient does not vomit, then ion exchange resins in the sodium phase have been used successfully to withdraw potassium ions into the intestine in exchange for sodium ions. Five grammes of Resonium 'A', dissolved in the patient's allowance of dextrose solution, is given eight times a day. Calcium Resonium is often appropriate in uraemia as the serum calcium may be low. Rectal infusion of both resins is effective and most useful when the patient is vomiting.

Post-renal (*syn.* Obstructive) Anuria

1. **Calculus anuria** arises in one of the following ways:

a. A calculus becomes impacted in the ureter of the only functioning kidney, the other kidney being congenitally absent, previously removed, or destroyed by disease.

b. Both ureters become obstructed by stones or crystals.

Clinical Features.—Usually the patient is a man between forty and sixty years of age with a long history of urinary lithiasis, but in about 20 per cent. of cases calculous anuria arises without previous symptoms.

Onset.—Typically an attack of renal colic precedes the anuria, the onset of which is sudden. This pain may disappear and be replaced by a constant severe pain in the loin. In a few cases there is little, if any, pain, and the anuria is preceded by several days of increasing oliguria.

Stage of tolerance usually lasts from three to six days. The patient feels comparatively well and may continue his work. During this time the blood urea mounts steadily, and as it does so headache, sleeplessness, constipation, and lassitude supervene. By the end of this stage the blood urea is often over 200 mg/100 ml (33·2 mmol/l).

Stage of uræmia follows, and is characterised by the same clinical features described in late renal anuria.

Examination.—The obstructed kidney is tender and there is guarding by the overlying muscles. A large palpable kidney is probably functionless and the seat of a hydronephrosis or pyonephrosis; a recently obstructed kidney is never enlarged.

Action to be taken:

(1) *Pass a catheter* to exclude retention. A few ounces of blood-stained urine may be obtained.

(2) *Plain X-ray* may show the obstructing calculus, but more often visualisation is difficult. This is because the small size of the stone (it is seldom larger than an orange-pip), makes it difficult to see against superimposed bone and intestinal gas shadows. Sometimes a large branched renal calculus is displayed on the functioning side. Disparity in the size of the kidneys may be apparent.

FIG. 1313.—Stone impacted in the ureteric orifice as seen by cystoscopy.

(3) *Cystoscopy*. Pass a catheter up both ureters. This may pass or dislodge the stone and the emergency is over. Leave the catheter in position to drain, and when the general condition of the patient is satisfactory, remove the calculus by open uretero-lithotomy. (Just prior to this, further radiographs must be taken to confirm the site of the stone. An I.V.P. is permissible and helpful if the blood urea has fallen to within normal limits.) Occasionally at cystoscopy a stone is seen wedged in the ureteric orifice (fig. 1313) whereupon attempts should be made to dislodge the stone with a ureteric catheter, or by meatotomy of the orifice.

(4) *Operation*—if a catheter will not pass. In this case the stone should be removed by open operation. If no stone is visualised by the X-ray, then the kidney on the side which was more painful should be explored. Pyelostomy, or nephrostomy (figs. 1314 and 1315) may be necessary. If the

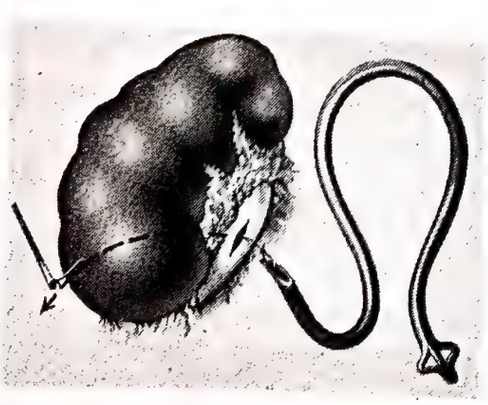

FIG. 1314.—Cabot's method of performing nephrostomy.

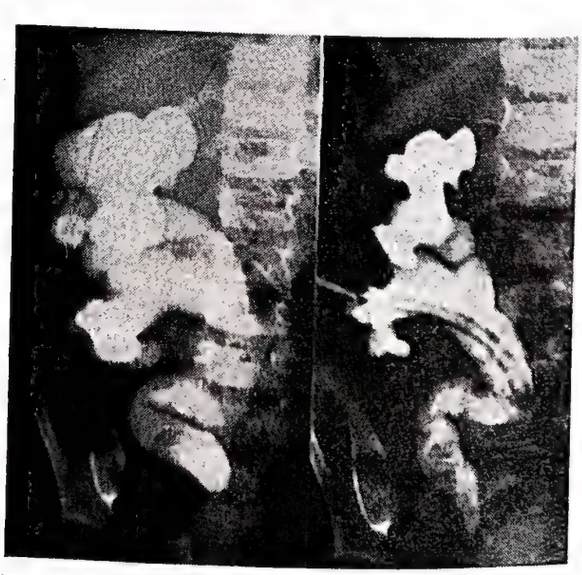

FIG. 1315.—Pyelograms before and after nephrostomy.

Hugh Cabot, 1872–1945. Professor of Surgery, Minnesota Graduate School of Medicine, Rochester, Minnesota, U.S.A.

kidney explored is found to be hopelessly diseased, nephrostomy must be performed on the other side.

(5) *When the obstruction has been relieved* either by ureteric catheterisation or operation, and until diuresis is established, the general treatment is similar to that described on p. 1139. In cases where nephrostomy has been necessary, preparations should be made for blood transfusion, for sometimes the hæmorrhage from the incised œdematous kidney is excessive.

2. **Anuria due to Sulphonamide Crystalluria.**—Sulphapyridine, sulphadiazine, and occasionally sulphathiazole in the presence of an acid medium are changed into acetyl salts which are insoluble. Crystals (fig. 1316) are deposited in the kidney tubules and ureters. The condition is now infrequent, and occurs mainly in patients with partial obstruction to the kidneys, and in those who are dehydrated.

FIG. 1316.—Acetylated sulphapyridine crystals resemble small wheat sheaves.

Treatment.—When a patient undergoing sulphonamide therapy develops renal colic and oliguria, the drug should be withheld and the high fluid intake further increased, and fruseamide 80 mg given i.v. Should anuria supervene there should be no delay in performing cystoscopy and attempting to catheterise the ureters. Provided the catheters can be inserted, the kidney pelves are washed out with 2·5% sodium bicarbonate solution. The crystalline mass can, on occasions, be dislodged with a stone dislodger (p. 1170). As an alternative to cystoscopic manœuvres, splanchnic block anæsthesia may succeed. If these measures are unsuccessful, unilateral or bilateral pyelostomy may be performed.

3. **Anuria due to Uric Acid Crystalluria** can occur in rapidly breaking-down neoplasms—more particularly lymphomas. The pelvis and ureters can become completely blocked by uric acid and urate crystals. Serum uric acid estimations should be performed on such cases having radiotherapy, and the urine should be kept alkaline. (The solubility of uric acid is vastly increased in a pH of 7–8.)

4. **Anuria due to Accidental Ligation of the Ureters.**—This is a hazard mainly of hysterectomy. Immediate exploration to divide the ligatures encircling the ureters should follow once the site of the obstruction has been determined by passing ureteric catheters. Pyelostomy should be reserved for cases unfit for this.

5. **Anuria due to Involvement of both Ureters in a Neoplastic Process, e.g. Carcinoma of the Cervix.**—Excluding terminal cases, the only treatment is transplantation of ureters into the bowel or bilateral nephrostomy.

6. **Anuria due to Involvement of Ureters in Retroperitoneal Fibrosis** (p. 1171).

CHAPTER 54

THE KIDNEYS AND URETERS

Embryology.—A bud from the lower end of the mesonephric (Wolffian) duct grows backwards behind the peritoneum to the sacral region (fig. 1317). The stalk of the bud forms the ureter and its dilated extremity the pelvis. Sometimes the bud is duplicated or the stalk becomes bifurcated, giving rise to congenital anomalies (see below). From six weeks to eight months, the primitive pelvis divides repeatedly to form generations of collecting tubules, the early (4th to 5th) generations ultimately forming the pelvis and calyces.

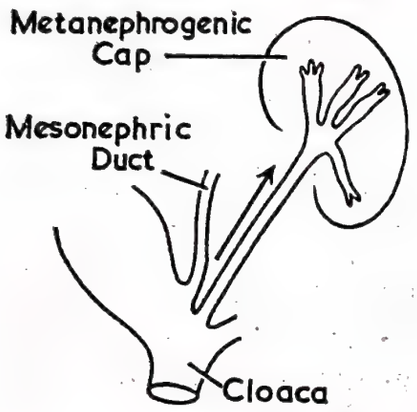

FIG. 1317.—The development of the kidney.

Later generations form the collecting tubules, and adjacent mesoblast produces a glomerular apparatus and nephric tubules which establish a continuity with the collecting system. It is failure of this junction which has been postulated as one cause for the development of polycystic kidneys. Between the fifth and eighth week of this development the kidney ascends on the posterior abdominal wall to reach its subcostal position. It also rotates so that the previously forward facing hilum faces medially.

The fœtal kidney is at first lobulated, but in the human the lobules become welded together by the growth of a new cortex and the capsule. In some mammals, e.g. oxen and bears, fœtal lobulation is retained throughout life.

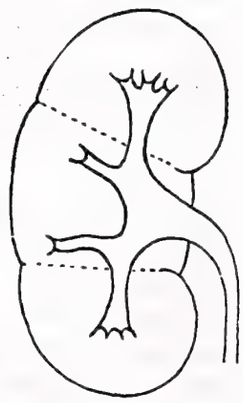

FIG. 1318.—The three divisions of the kidney render resection (partial nephrectomy) of the upper or lower division a practical proposition. *(After the late Carl Semb.)*

Surgical Anatomy.—The parenchyma of each kidney usually is drained by seven pairs of calyces, three in the upper and two each in the middle and lower segments (fig. 1318). Each of the three segments represents an anatomical and physiological unit with its own blood supply, an important point in view of the increased indications for partial nephrectomy (Carl Semb).

Surgical Physiology.—Ciné-pyelography indicates that there are sphincters at the junction of the minor and major calyces, and at the pelvi-ureteric junction. Each segment of the calyceal system fills before its contents are passed into the next chamber.

CONGENITAL ABNORMALITIES OF THE KIDNEY

Absence of One Kidney.—Sometimes pyelography reveals only one functioning kidney, and at cystoscopy only one ureteric orifice is present, alternatively a ureter and pelvis are present on the non-functioning side, but the parenchyma is almost or entirely absent. In either case the functioning kidney is hypertrophied. An absent or congenitally atrophic kidney is present in about 1:1,400 individuals.

Renal ectopia occurs once in 1,000 cases. The kidney is arrested in some part of its normal ascent, usually at the brim of the pelvis. As a rule the kidney of the opposite side is present and in its normal position. The left kidney is ectopic far more often than the right; the reason is unknown. Ectopia may present a diagnostic problem when acute disease develops in the ectopic kidney.

Kaspar Friedrich Wolff, 1733–1794. Professor of Anatomy and Physiology, St. Petersburg (now Leningrad, U.S.S.R.).
Carl Boye Semb, 1895–1971 (see footnote, p. 722).

Horse-shoe Kidney.—The most medial subdivisions of the primary mesonephric bud of each side fuse and the kidneys fail to ascend completely. The adrenal glands, being developed separately, are in their normal positions. The abnormality (found once in every 1,000 necropsies) is more common in the male. Usually the bridge joining the lower poles lies in front of the fourth lumbar vertebra. Fusion occurs very early, when the embryo is but thirty to forty days old, at which time the two masses of mesoblast destined to form the kidneys lie very close together. Exceptionally, it is the upper poles that are fused.

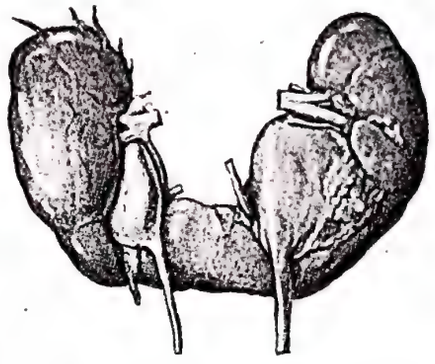

FIG. 1319.—Horse-shoe kidney. Note the ureters passing in front of the fused lower poles.

Clinical Features.—Horse-shoe kidneys are prone to become diseased, largely because the ureters are angulated as they pass over the fused isthmus (fig. 1319). This produces urinary stasis; consequently simple infection, tuberculosis, and calculus formation are common complications. Although a fixed mass below the umbilicus may suggest a horse-shoe kidney, the final diagnosis is established by pyelography. The most characteristic finding is that the lowest calyx on each side is reversed in position (i.e. directed towards the vertebral column). Rarely most, or all, of the calyces are reversed (fig. 1320). In a large percentage of cases the ureters curve like a flower vase. While horse-shoe kidney is not a contraindication to pregnancy, urinary complications are more frequent.

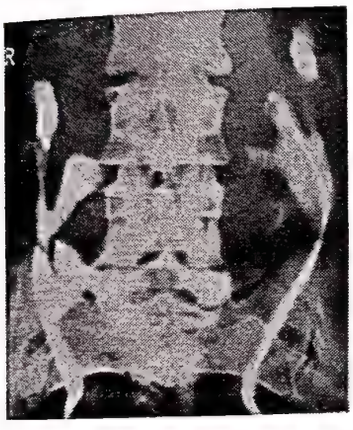

FIG. 1320.—Pyelogram of a horse-shoe kidney. Only rarely are all the calyces directed towards the spinal column. (*A. Jacobs, F.R.C.S., Glasgow.*)

Treatment.—In cases giving rise to pain, or when non-specific infection is present, division of the isthmus is usually curative. The operation can be conducted extraperitoneally, but a trans-peritoneal approach gives a much better view of the renal arteries and veins, and it is easier to decide whether a nephropexy is desirable. The area should be drained extraperitoneally. When one half of a horse-shoe kidney is irreparably diseased, e.g. calculi or neoplasm, heminephrectomy should be performed provided the remaining half has adequate function.

Unilateral fusion (*syn.* crossed dystopia) is rare. Both kidneys are situated in one loin. One kidney, carrying its own blood-vessels and with the ureter opening into the bladder in a normal position, crosses the middle line, and its upper pole fuses with the lower pole of the normally placed kidney. In this instance both kidney pelves are situated one above the other medial to the renal parenchyma (unilateral long kidney). In some cases the pelvis of the crossed kidney faces laterally (unilateral S-shaped kidney (fig. 1321)).

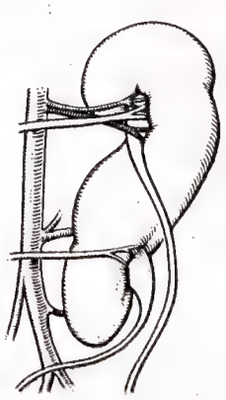

FIG. 1321.—Unilateral S-fusion of the kidneys.

Congenital Cystic Kidneys (*syn.* Polycystic Kidneys); —In 18 per cent. of cases there is a congenital cystic liver.

occasionally the pancreas and lung are affected similarly. The disease is hereditary and can be transmitted by either parent. This is important in relation to genetic counselling as the risk of transmitting the autosomal dominant trait is very high. The disease is not easily demonstrable on pyelography before the late 'teens' and rarely gives clinical manifestation until the fourth decade.

Pathology.—The organs may become enormously enlarged. The surface gives an appearance of many bubbles. On section the renal parenchyma is riddled with cysts of varying sizes, some containing clear fluid, others thick brown material, and still others coagulated blood.

Clinical Features in the Adult.—The condition is slightly more common in women than in men. There are six clinical features:

(*a*) *Renal Enlargement.*—The large knobby kidneys when discovered in the course of a routine examination can hardly be mistaken. Sometimes congenital cystic kidneys are revealed only at laparotomy for some other condition. *Unilateral Renal Swelling.*—One kidney contains larger cysts than the other, and the physical signs are similar to those of a renal neoplasm.

Patients with congenital cystic kidneys pass abundant urine of low specific gravity (1·010 or less) containing a slight trace of albumin but neither casts nor cells. On cystoscopy there is often considerably delay in the excretion of indigo-carmine, even in cases with a normal or only slightly elevated blood urea.

(*b*) *Pain* is due either to the weight of the organ dragging upon its pedicle or to tension within the cysts. Often the pain is a dull ache in the loin; sometimes it takes the form of renal colic, when a calculus, which is not rare in this condition, should be suspected.

(*c*) *Hæmaturia.*—In about 25 per cent. of cases, as a result of over-distension, one of the cysts ruptures into the renal pelvis and causes hæmaturia. Usually moderate hæmaturia lasts for a few days, and recurs at varying intervals; sometimes it is profuse.

(*d*) *Infection.*—The most common complication of congenital cystic kidneys in adult life is pyelonephritis.

(*e*) *Hypertension.*—About 75 per cent. of patients with congenital cystic kidneys above the age of twenty have hypertension. Why some escape this complication is not clear. Possibly the high blood pressure is due to a separate genetic factor frequently linked with congenital cystic kidneys.

(*f*) *Uræmia.*—The patient complains of anorexia, headache, and indefinite gastric symptoms, and is frequently given a placebo, until persistent symptoms demand a complete clinical examination. Later drowsiness and vomiting occur. Signs of uræmia often commence suddenly during middle life; only one quarter of patients with this condition survive the age of fifty-five years. Severe anæmia is common.

Pyelography.—Excretory pyelography is the best way of confirming the diagnosis, but when the concentration of Hypaque is insufficient to cast a clear shadow, retrograde pyelography is necessary. Only one side should be injected, the other being deferred for a week lest œdema further impairs

renal function. The shadows of the kidneys are enlarged in all directions. The renal pelvis is elongated and may be compressed. The calyces are stretched over the cysts and are often narrow (like the legs of a spider) or bell-like (fig. 1322).

Treatment :

(*a*) *Expectant.*—Routinely the patient should drink a large quantity of water, have a low-protein diet, and take iron to prevent anæmia. Infection, when it occurs, should be treated by an appropriate drug.

(*b*) *Operative.*—By relieving pressure on the remaining renal parenchyma, Rovsing's operation, if performed early, improves renal function. In many instances, life is prolonged five years or more.

FIG. 1322—Polycystic kidney. Pyelographic appearance. Note length of kidney and elongated bell-like calyces stretched over cysts.

Rovsing's Operation.—One kidney and then the other is exposed. The cysts are incised with a narrow-bladed scalpel, first on the convex border, then on the posterior surface and, finally, as the kidney becomes more manageable in size, the peritoneum is peeled away and the anterior surface is dealt with similarly.

So improved by bilateral Rovsing's operation was one of our patients who was admitted in a state of uræmia, that two and a half years later he was serving in the Life Guards! Rovsing's operation should be performed, not as a last resort, but as soon as possible after the condition is recognised.

Infantile Polycystic Disease is an unrelated condition—autosomal recessive—and much rarer. The kidneys are large, may obstruct birth and many cases are stillborn. Most others die in early life from renal failure.

Unilateral Multicystic Disease is much commoner. It presents as a mass in the flank. No function is detectable on pyelography, and exploration and removal is the treatment of choice. In the differential diagnosis, Wilms's tumour (p. 1186), neuroblastoma and hydronephrosis are all rarer conditions.

Solitary Renal Cyst.—While the term 'solitary' serves to distinguish the condition from congenital cystic disease of the kidneys, it is found that not infrequently one or two similar but smaller cysts are also present.

Ætiology.—The origin of the cyst may be identical (but on a smaller scale) with that of congenital cystic kidney (p. 1147); or it could arise from bygone trauma or infection causing blockage of a tubule. The mature age at which the cyst is usually found is in favour of the latter supposition.

Clinical Features.—There are no pathognomonic symptoms or signs. Sometimes there are no symptoms until a swelling is noticed, at others there is a dull ache in the loin. The cyst can become infected and if a swelling is palpable, and particularly if the swelling is tender, the creditable diagnosis of pyonephrosis will be made. A spontaneous hæmorrhage into the cyst occurs from time to time, in which case sudden renal pain is likely to be experienced. Occasionally the cyst presses on the pelvi-ureteric junction and causes urinary symptoms.

Radiology.—(*a*) Pyelography reveals a filling defect with one of more calyces stretched over it, simulating the deformity produced by a neoplasm, but typically more rounded. (*b*) It is possible to distinguish a renal cyst from a renal neoplasm by selective renal arteriography (fig. 1309) or by puncture percutaneously, or by an ultrasound scan.

Nils Thorkild Rovsing, 1862–1927. Professor of Surgery, Copenhagen.

Treatment.—Exploration should be advised. Renal cysts can be caused by a tumour blocking tubules and interfering with the vascular supply to the same area of the kidney. Having displayed the kidney the operation is varied according to circumstances.

(*a*) *Kirwin's Method.*—When the cyst is blue-domed and aspiration reveals clear fluid, that portion of the cyst wall lying above the surface is excised. The cavity is filled with perinephric fat and after securing hæmostasis of the cut edges, a corrugated drain is left down to the area, the fascia of Gerota closed over it, and the wound closed in layers.

(*b*) *Partial nephrectomy* is performed if the contents of the cyst are blood-stained (one-third of such cysts contain a papilliferous neoplasm).

(*c*) *Nephrectomy* is performed if there are indications that the cyst is a malignant degeneration of a neoplasm, e.g. irregular induration at the periphery of the cyst.

Differential Diagnosis.—In sheep-raising districts, *hydatid cyst of the kidney* is common. On the right side (if hydatid disease is suspected) the swelling is liable to be mistaken for a hydatid cyst of the liver. Occasionally the patient complains of passing 'grape skins' (ruptured daughter cysts) in the urine. The treatment is excision of the cyst, but in many cases the cyst is so large that nephrectomy is advisable.

Aberrant renal vessels are found on the left side more frequently than on the right; in females more often than males; unilateral examples are three times more common than bilateral.

Aberrant renal vessels can cause hydronephrosis (p. 1156 and fig. 1340); more frequently, however, aberrant vessels accentuate a hydronephrosis present on account of another reason (fig. 1337).

Usually the aberrant artery is small; occasionally it is comparatively large, supplying one-quarter of the renal parenchyma. Division will cause infarction of the corresponding portion of renal tissue. On the other hand, an obstructing aberrant renal *vein* can be divided with impunity, because the venous collateral circulation is very generous.

CONGENITAL ABNORMALITIES OF THE RENAL PELVIS AND URETER

Duplication of a renal pelvis is the most common congenital anomaly of the upper renal tract and is found in about 4 per cent. of patients. It is usually unilateral, and is somewhat more common on the left side than on the right. The upper renal pelvis is comparatively small (fig. 1323) and drains the upper group of calyces; the larger lower renal pelvis drains the middle and lower groups of calyces.

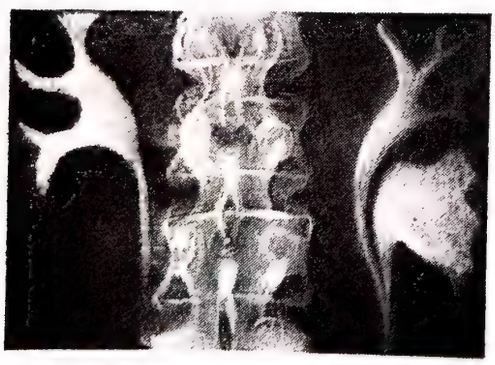

FIG. 1323.—Pyelogram showing a kidney with a double pelvis.

FIG. 1324.—Double ureter. Retrograde pyelogram.

Thomas Joseph Kirwin, 1889–1959. Director of Department of Urology, Fourth and Fifth Avenue Hospitals, New York, U.S.A.

Dumitra Gerota, 1867–1939. Professor of Surgery, Bucharest, Rumania.

Duplication of a Ureter.—Double ureters are present in addition to double renal pelves in about 3 per cent. of cases submitted to pyelography. The ureters often join, usually in the lower third of their course (fig. 1324), and have a common orifice into the bladder. Less frequently the ureters open independently into the bladder (fig. 1325), in which case the ureter draining the upper pelvis crosses its fellow, and opens below and medial to it.

FIG. 1325. — Complete duplication of the left ureter as seen through the cystoscope.

Clinical Features.—In many instances a double renal pelvis or a double ureter is found by chance in the course of an investigation of the urinary organs. A double pelvis is more liable to become the seat of infection, calculus formation, or hydronephrosis than a normal pelvis. Initially such disease is confined to one part of the duplication. In cases of complete duplication of the ureter the lower ureteric orifice is sometimes the site of congenital atresia.

Treatment.—Ureteric meatotomy can be performed in some early cases of stricture of a ureteric meatus. Difficulty is encountered in cases of Y-shaped bifid ureter, because a ureteric catheter cannot be made to enter the smaller orifice. Heminephrectomy with removal of its ureter is eminently satisfactory when disease normally requiring total nephrectomy is confined strictly to one half of a kidney that has a double pelvis. The exception to the rule is, of course, a neoplasm.

Ectopic Ureteric Orifice.—Should a second ureteric bud arise from the mesonephric duct later than usual, the orifice of the accessory ureter is prone to occupy a grossly abnormal position. This is a rare anomaly. In both sexes the existence of double ureter is determined by excretory pyelography.

In the female an ectopic ureter opens either into the urethra below the sphincter urethræ (fig. 1326) or into the vagina, and causes an intractable incontinence of urine. The diagnosis can nearly always be made from the history alone. A girl or woman who has dribbled for as long as she can remember, despite the fact that she has a desire to void, and does urinate, has an ectopic ureteric orifice. The demonstration of this orifice is often extremely difficult. because it is guarded by a valve. The diagnosis may be established by giving an intravenous injection of indigo-carmine, and placing one swab into the vestibule and another in the vagina; the one coloured blue signifies the position of the ectopic orifice. Sometimes laparotomy is the only way of finding or excluding the additional ureter.

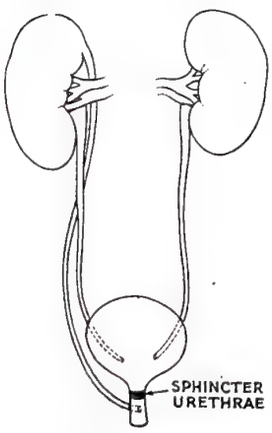

FIG. 1326.—Ectopic ureter in a female.

In the male the aberrant opening may be situated at the apex of the trigone, in the posterior urethra, in a seminal vesicle, or in an ejaculatory duct. As in all these diverse situations, the ectopic ureteric orifice is situated above the sphincter urethræ, the male patient is continent, but recurrent acute or chronic pyelonephritis is apt to supervene in the renal tissue served by the ectopic ureter. Posterior urethroscopy, after the intravenous injection of indigo-carmine, may be of help in demonstrating that a male patient has an ectopic ureter.

Treatment.—*In the female* excision of that segment of the kidney served by the ectopic ureter is usually advisable, because it is so often hydronephrotic and chronically infected. In the rare event of the urine draining from it being sterile, the ectopic ureter can be implanted into the bladder, or joined to its fellow.

In the male—Often no treatment is required. Should urinary infection supervene hemi-nephrectomy is indicated.

Congenital mega-ureter may be unilateral (fig. 1327) or bilateral, and in late stages is accompanied by hydronephrosis. Commoner in males the condition is often symptomless until infection has occurred. If, however, the patient experiences pain, a diagnosis can be made before the onset of infection. The lower end of the ureter and orifice appear normal but constitute an obstruction. Reflux is not present; a ureteric catheter passes easily. Vigorous peristaltic activity can be seen in the dilated ureter under the image intensifier, but efflux is small, while marked delay in emptying of the pelvis and ureter is seen in late films many hours after.

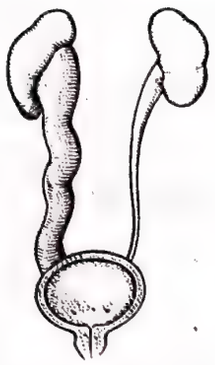

FIG. 1327.—Unilateral congenital mega-ureter.

Treatment.—In infected cases, percystoscopic meatotomy and drainage of the dilated ureter with a ureteric catheter for about six weeks has been found to be effective in clearing up the infection. Reflux afterwards is likely however, and the condition is better treated by initial nephrostomy and then when the infection is completely controlled by open excision of the lower ureter, followed by excision of excessive length of tortuous ureter, refastening the end by wedge excision to narrow the lumen, and tunnel re-implantation to prevent reflux. When the renal parenchyma is severely damaged, nephro-ureterectomy is curative. In bilateral cases where function is diminishing, cutaneous ureterostomy should be considered.

FIG. 1328.—Substitution of a segment of ileum for the mega-ureter, which is shown attached to the bladder.

Post-caval Ureter.—The right ureter passes behind the inferior vena cava (fig. 1329) instead of lying to the right of it. This may cause obstructive symptoms. Should these symptoms warrant it, the ureter can be divided in the dilated portion and reanastomosed in front of the cava. Occasionally the retrocaval portion of the ureter is fibrotic and must be excised. A long oblique anastomosis should be made of the normal lower ureter to the dilated upper portion.

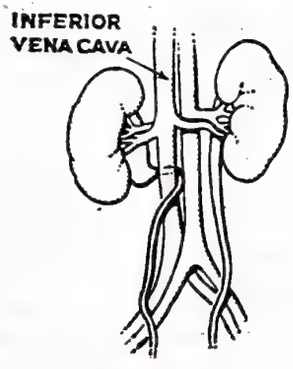

FIG. 1329.—Post-caval ureter.

Ureterocele is due to congenital atresia of a ureteric orifice which causes a cystic enlargement of the intramural portion of the ureter. Usually the wall of the cyst is composed of mucous membrane only; infrequently the muscle coat is included. This condition may be discovered in childhood; often it is not recognised until adult life. Women are more often affected than men, and in 10 per cent. of cases the condition is bilateral. The condition, producing some obstruction, does render the patient more liable to stone formation and recurrent infection. The cystoscopic findings are characteristic: when the wall consists of mucous membrane there is a translucent cyst over which blood-vessels radiate (fig. 1330); in the rare variety containing muscle in the wall, the cyst is opaque. In either case the sac is seen to enlarge rapidly with each efflux of urine, and then slowly to collapse. The pyelographic findings are characteristic (fig. 1331).

Treatment.—Many cases are symptomless and no treatment is required. Hydronephrosis, stone, or recurrent infection may necessitate treatment. Cauterising a hole through the wall of the cyst with a diathermy electrode is a simple and satisfactory procedure. A micturating cystogram should be performed three months later to exclude urinary reflux. In advanced unilateral cases associated with a hydro- or pyonephrosis and dilatation of the whole of the ureter, nephrectomy is needed.

FIG. 1330.—Right-sided ureterocele. *(After J. C. Ainsworth-Davies, F.R.C.S., London.)*

INJURIES TO THE KIDNEY

In civil life blows or falls upon the loin are the most fruitful sources of such injuries, while blows from in front and crushing accidents add their quota (road traffic accidents). Hæmaturia following minor injuries should suggest the possibility of pre-existing renal abnormality, e.g. stone, hydronephrosis, or tuberculosis.

The degree of injury varies considerably from a small subcapsular hæmatoma to a complete tear involving the whole thickness of the kidney (fig. 1332); in addition, the kidney may be partially or wholly avulsed from its pedicle. Tears of the renal parenchyma follow the lines of the uriniferous tubules. The whole of one pole may be detached.

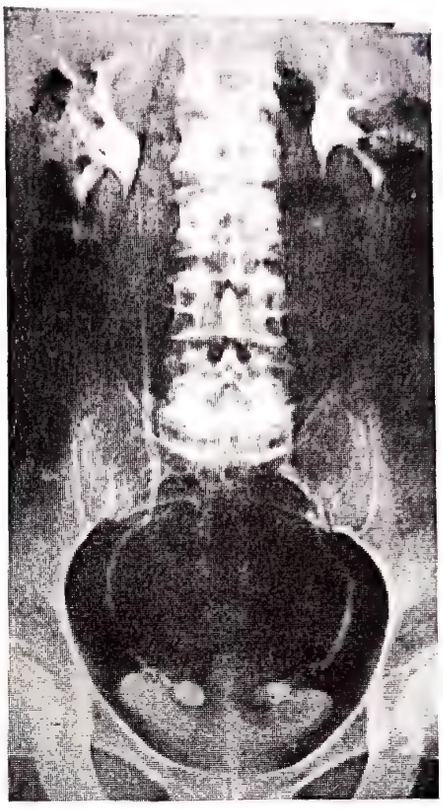

FIG. 1331.—Intravenous pyelographic appearance of ureterocele. Typical adder-head appearance of lower ureters which remain filled with Hypaque (diatrizoate).

The injury is extraperitoneal, except very occasionally in children in whom there is little perinephric fat; in these cases the peritoneum, being intimately related to the kidney, is liable to be torn in addition to the renal capsule, allowing blood and, perhaps, urine to escape into the peritoneal cavity.

Clinical Features.—Rarely is there superficial bruising, but there is likely to be local pain and tenderness.

Hæmaturia is a cardinal sign of a damaged kidney, but it may not make its appearance until some hours after the accident. If the hæmorrhage is profuse, it may be followed by clot colic.

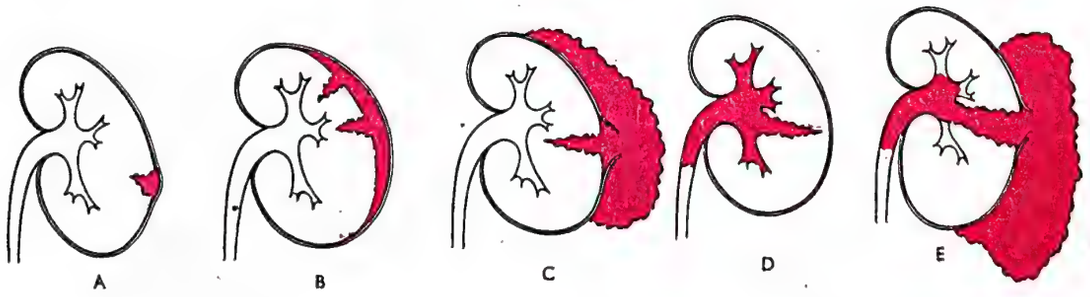

FIG. 1332.—Various types of renal injuries: A, small subcapsular hæmorrhage; B, large subcapsular hæmorrhage; C, cortical laceration with perinephric hæmatoma; D, medullary laceration with bleeding into the renal pelvis; E, complete rupture. (*After P. Adams.*)

Severe Delayed Hæmaturia.—Sudden profuse hæmaturia can occur between the third day and the third week after the accident in a patient who appears to be progressing favourably. It is due to a clot becoming dislodged.

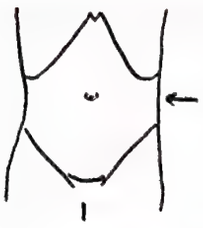

FIG. 1333.

Meteorism.—In many cases of renal injury, abdominal distension comes on about twenty-four to forty-eight hours after the accident. In all probability it is caused by a retroperitoneal hæmatoma implicating splanchnic nerves.

A perinephric hæmatoma should be suspected if there is even a slight flattening of the normal contour of the loin (fig. 1333), always provided there is no scoliosis.

Management and treatment

Conservative treatment is usually successful and must be instituted at once. However, it must be remembered that injury to other organs may be associated with injury to the kidney.

1. The patient must rest flat in bed until macroscopic hæmaturia has been absent for one week.
2. Morphine should be given for pain, and as a sedative.
3. Hourly pulse and blood-pressure chart must be kept.
4. Give a sulphonamide or antibiotic to prevent infection of the hæmatoma.
5. Save a sample of each specimen of urine passed.
6. Group and cross-match blood. A transfusion may be required for shock or continuing hæmorrhage.
7. An intravenous urogram (I.V.P.) should be obtained urgently to show that the other kidney is normal. A leak of urine on the damaged side is often demonstrated.

Under this regimen the hæmaturia should diminish, pain and guarding decrease, and pulse and colour of the patient improve.

Exploration is necessary in 20 to 25 per cent. and is undertaken if : 1. There are signs of progressive blood loss. 2. A swelling develops in the loin. 3. Signs of peri-renal infection develop. The aim is to conserve the kidney or part of it if possible.

In all cases the peritoneum should be opened to exclude damage to other organs.

Should the necessity for an urgent operation arise and facilities for pyelography not be available, the presence of a functioning kidney on the contralateral side can often be confirmed by chromo-cystoscopy (p. 1135). When the kidney is found to be ruptured in several places, or the kidney pedicle is damaged, nephrectomy must be undertaken. Small tears can be sutured over Oxycel or a piece of detached muscle, either of which promotes hæmostasis. Larger single rents in the middle of the kidney are best dealt with by performing nephrostomy through the rent and suturing the kidney on either side of the tube. If laceration is confined to one pole of the kidney, partial nephrectomy may be practicable.

When a sole existing kidney is sufficiently damaged to necessitate exploration, it must be repaired. Failing this, the wound is packed firmly with gauze in the hope that not only will the bleeding be controlled but that the ruptured kidney may heal.

Multiple Injuries.—Simultaneous splenectomy and left nephrectomy have been carried out successfully when both organs have been ruptured. The mortality of cases of rupture of the kidney with damage to the liver or hollow organs, often complicated by fractured ribs, pelvis, or vertebræ, is high.

Complications.—1. Clot retention in the bladder can be cleared with a plastic catheter and a glass syringe.

2. Pararenal pseudo-hydronephrosis (fig. 1334) may occur in the course of a few weeks, due to a combination of a complete tear of the renal cortex and ureteric obstruction.

3. Hypertension may follow fibrosis of the kidney, usually after three months or more. Nephrectomy will be necessary.

4. **Aneurysm of a renal artery** (fig. 1335) is a rare complication of injury to a kidney. The most frequent symptom is pain in the renal region, and, when the aneurysm is large, a non-tender swelling will be felt. Only occasionally is it pulsatile, and a bruit may be heard. An X-ray may show a shadow in relation to the pelvis of the kidney. An I.V.P. demonstrates that the swelling is extrarenal with the renal pelvis displaced laterally. Aortography will confirm the diagnosis. Attacks of hæmaturia occur, and are probably due to congestion of the renal parenchyma. The aneurysm may rupture into the peritoneal cavity or into the perirenal tissues, with fatal results.

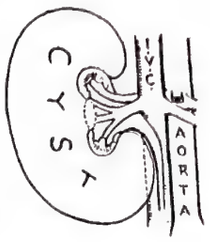

FIG. 1334.—A pararenal pseudo-hydronephrosis.

Treatment by nephrectomy and excision of the aneurysm is usually required. In a few cases a saccular aneurysm has been resected with preservation of the renal vessels and the kidney.

FIG. 1335.—Aneurysm of the renal artery containing laminated thrombus.

INJURIES TO THE URETER

Rupture of a ureter can occur as the result of an accident causing hyperextension of the spine. The clinical diagnosis is impossible until a diminished quantity of urine is passed, followed by a swelling in the loin or iliac fossa. An I.V.P. shows a diffuse shadow below the kidney on the injured side.

Injury of one or both ureters during a pelvic operation is considerably more common than the foregoing and occurs most often during the course of a difficult hysterectomy. Preliminary catheterisation of the ureters prevents such accidents, for with catheters within them, the ureters can be felt and seen unmistakably. The accidents include division of the ureter, ligating it, crushing it in forceps or removing a portion of its wall.

Injury recognised at the Time of the Operation.—The uretero-vesical continuity should be restored by one of the methods described below, unless the patient's condition is poor, when ligation of the proximal end of the ureter is the best course. If the patient rallies within two days, temporary nephrostomy is carried out, and a reparative operation undertaken later.

Injury not recognised at the Time of the Operation:

(*a*) **Unilateral Injury.**—There are three possibilities:

1. *No Symptoms.*—If one ureter is ligated securely with unabsorbable material and the contralateral kidney and ureter are normal, in 68 per cent. of cases the kidney on the obstructed side undergoes silent atrophy. Thus the accident remains unsuspected unless the patient, some time later, undergoes a urological examination.

2. *Development of loin pain and a fever*, possibly proceeding to a pyonephrosis, occurs in less than a half of the remainder. Excretory pyelography reveals no excretion on the side of the lesion. If this is discovered early, and the patient is fit, re-exploration to free the ureter is best: alternatively, nephrostomy, and later repair of the ureter.

3. *A urinary fistula develops* through the abdominal incision or, following hysterectomy, through the vagina. Again, a temporary nephrostomy may be performed, and a reparative operation postponed until œdema and infection have abated after an interval of about six weeks.

(*b*) **Bilateral Injury.**—In cases of anuria following ligation of both ureters during hysterectomy an attempt is made to pass ureteric catheters, when both ureters will be found to be occluded. The wound should be explored and ligatures removed.

Repair of the Injured Ureter

1. If the ends are clean cut and no length is lost, each end should be split for 1·5 cm and the edges united as a flat ribbon (fig. 1336). A soft latex T-tube is left with one limb across the gap for two weeks. This is to be preferred to end-to-end suture which frequently results in stricture formation.

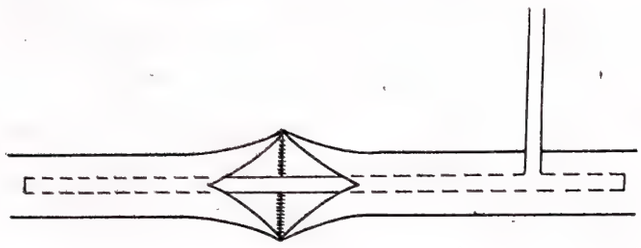

FIG. 1336.—Repair of the ureter using a T-tube.

2. In division low down, it may be possible to reimplant the ureter into the bladder.

3. *Boari's Operation.*—A flap of bladder is turned up to replace the lower ureter.

4. Occasionally, where conservation of all renal tissue is vital, replacement by a segment of ileum is necessary.

Nephrectomy may be the best course, for example, in the elderly patient with a malignant condition, the other kidney being normal.

HYDRONEPHROSIS

A hydronephrosis is an aseptic dilatation of the whole or part of the kidney due to a partial or intermittent obstruction to the outflow of urine.

A hydronephrosis may be unilateral or bilateral.

Unilateral hydronephrosis is due to some form of *ureteral* obstruction, often at the pelvi-ureteric junction; any length of ureter above the obstruction is dilated also. The causes are:

Extramural.—1. 'Aberrant Vessels'. In a number of cases of pelvic hydronephrosis a lower polar artery or vein arising from the main vessels in an aberrant position obstructs the upper ureter where it crosses in front of it. The pyelographic appearance is shown in fig. 1340 (*b*). In many more instances this is not an aberrant vessel, but a normal inferior renal artery or vein that has been displaced downwards by the enlarged

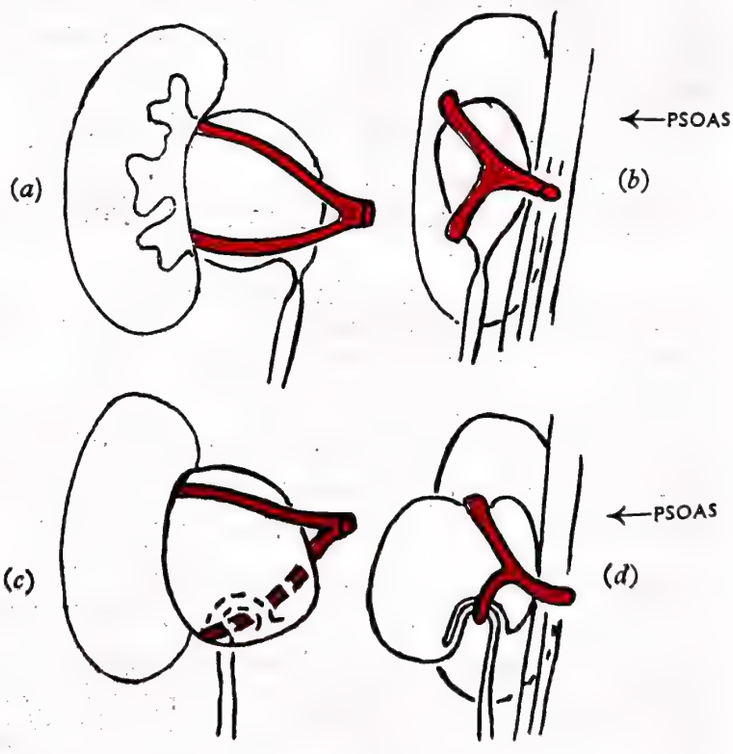

FIG. 1337.—'Congenital' hydronephrosis with obstruction at pelvi-ureteric junction. (*a*) Initial arrangement. (*b*) Lateral view of the hilum. (*c*) and (*d*) show pelvis of kidney prolapsing forward between branches of the renal artery.

Achille Boari. Nineteenth-century Italian surgeon.

renal pelvis. This displaced vessel, while adding considerably to the rapid increase in the size of the hydronephrosis, is not the cause thereof (fig. 1337).

2. Involvement of ureter by growth outside it, e.g. carcinoma of the cervix, prostate, rectum, colon, or cæcum.

3. Idiopathic retroperitoneal fibrosis (p. 1171).

Intermural.—1. Congenital stenosis, physiological narrowing, or achalasia at the pelvi-ureteric junction.

2. Ureterocœle and congenital small ureteric orifice.

3. Inflammatory stricture of the ureter following removal of a stone that was lodged in one portion of the ureter for a considerable time, or tuberculosis of the ureter. Stricture of the ureter may follow uretero-ureteric anastomosis or trauma to the ureter during a pelvic operation.

4. Neoplasm of a ureter, or the bladder involving a ureteric orifice.

Intramural.—A calculus in the ureter or small calculus in the renal pelvis. The latter often gives rise to intermittent hydronephrosis.

Bilateral hydronephrosis is generally the result of some form of *urethral* obstruction, but it can also be caused by one of the lesions described above occurring on both sides.

When due to lower urinary obstruction, the cause may be:

(*a*) *Congenital:*

1. Congenital stricture of the urethral meatus or, very rarely, phimosis.

2. Congenital valves of the posterior urethra, or congenital contracture of the bladder neck.

(*b*) *Acquired:*

1. A neoplasm of the bladder which involves both ureteric orifices.

2. Prostatic enlargement or carcinoma; acquired contracture of the bladder neck.

3. Carcinoma of the cervix (occasionally carcinoma of the rectum), involving both ureters.

4. Inflammatory or traumatic urethral stricture. Phimosis.

When the obstruction lies in the urethra, muscular hypertrophy of the bladder occurs, and the ureters, by reason of this hypertrophy, become partially obstructed in the intramural portion of their course.

Pathology.—The pathological changes differ in some respects according to whether the kidney has an extrarenal or an intrarenal pelvis (fig. 1338), the former being much more common. In a kidney with an extrarenal pelvis, at first the pelvis alone becomes dilated (pelvic hydronephrosis) (fig. 1337). As time goes on, if the obstruction is not relieved the calyces become increasingly dilated and the renal parenchyma is progressively destroyed by pressure atrophy. In a kidney with an intrarenal pelvis the destruction of the

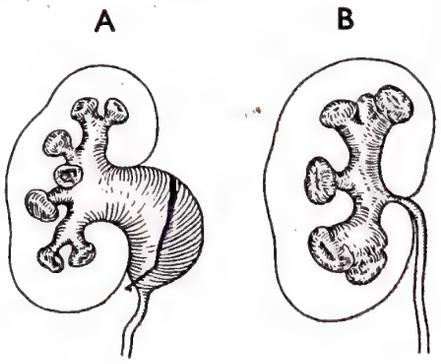

FIG. 1338. — Hydronephrosis occurring in an (A) Extrarenal, (B) Intrarenal pelvis of the kidney, the former being more liable to be obstructed by a blood-vessel.

parenchyma occurs more rapidly. In either case, it may be a matter of years before the diagnosis is made, by which time the kidney may be merely a lobulated sac containing pale uriniferous fluid of low specific gravity. On bisecting the specimen longitudinally a series of compartments representing the dilated calyces will be found. Rarely is the renal parenchyma destroyed in its entirety, although in advanced cases the amount remaining is very small.

CLINICAL FEATURES

Unilateral Hydronephrosis

The female/male ratio is 2:1; the right side is more commonly affected. Presenting features include:

1. *Insidious.*—Pain is slight; often there is only a dull ache or a sense of weight in the loin which may be brought on by alcohol or excessive fluid intake. On examination an enlarged, sometimes a greatly enlarged, kidney is found. In these cases the obstruction is usually at the pelvi-ureteric junction.

2. *Attacks of renal colic* occur. Often there is no palpable swelling.

3. *Intermittent Hydronephrosis.*—After an attack of renal colic with its accompanying abdominal rigidity passes off, a swelling in the loin is found. Some hours later, or on the next day, following the passage of a large quantity of urine due also to some reflex polyuria, the pain is relieved and the swelling disappears (Dietl's crisis).

Bilateral Hydronephrosis

1. *Due to Lower Urinary Obstruction.*—There is little to call attention to the hydronephrosis except, perhaps, a dull ache in the loins. The symptoms are overshadowed by those of the causative lesion (p. 1157). Symptoms of uræmia—thirst, loss of appetite are commoner than loin pain. There is often polyuria of low specific gravity containing a small quantity of albumin. The kidneys are unlikely to be palpable because before the hydronephroses become large enough to be felt, renal failure will have occurred.

2. *Due to Bilateral Upper Urinary Obstruction.*—This is rare compared with a unilateral lesion. Symptoms may be bilateral, but more frequently are on one side only, an I.V.P. revealing hydronephrosis on the other side.

3. *Due to Pregnancy.*—Dilatation of the ureters and renal pelves occurs in every pregnancy. Both renal pelves and ureters are affected, but the right side to a much greater extent than the left. The dilatation commences during the first few weeks of gestation, and reaches its zenith between the fifth and sixth months. It then remains stationary until after delivery, when involution occurs within two to twelve weeks. The condition is due to atony of the ureteric musculature brought about by the hormone progesterone. Possibly pressure of the fœtal head on the ureters plays some part during the last months of pregnancy. The main importance of the condition is an increased liability to infection (p. 1173). Exceptionally the hydronephrosis persists.

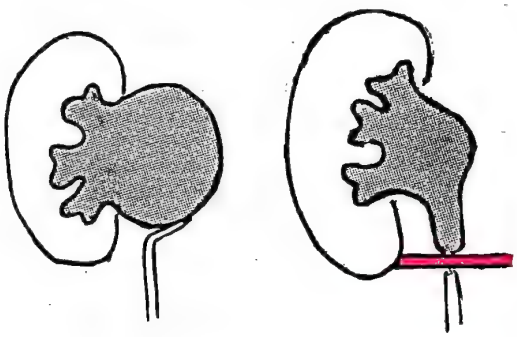
Pyelography (I.V.P.).—Except during pregnancy, when X-rays are contraindicated for fear of causing a congenital malformation, the diagnosis is

Joseph Dietl, 1804–1878. Professor of Pathology and Therapeutics, Cracow. In his later years he achieved fame as a politician.

made by *excretory pyelography*. When the hydronephrosis is advanced, films taken six to twenty-four hours after the injection of the medium may show a hydronephrotic kidney which was imperceptible on films taken at the routine times. As a rule the earliest pyelographic manifestation of a hydronephrosis is dilatation of the renal pelvis, for in the majority of cases the pelvis is extrarenal. The next change is decreasing concavity and then flattening of the minor calyces and dilatation of the major calyces, which are the first changes when the pelvis is intrarenal. In moderate-sized hydronephroses the minor calyces become convex and finally club-shaped (fig. 1339) and the major calyces considerably broadened. In advanced cases

FIG. 1339.—The progress from normal to clubbing of the minor calyces in hydronephrosis, as seen radiologically. (*After J. B. Macalpine.*)

there is extreme dilatation of the renal pelvis and the calyces (fig. 1340), or no excretion of opaque media. Doubtful cases may be clarified on occasion by inducing a diuresis during excretion pyelography which may 'blow up' a hydronephrosis. *Retrograde pyelography* (fig. 1341) is required only when the results of excretory pyelography are inconclusive. Delay in emptying may be shown by a film taken ten minutes after the pelvis has been filled retrogradely; by this time a normal pelvis should have emptied.



(*a*) (*b*)

FIG. 1340.—(*a*) Pyelographic appearance in 'congenital' hydronephrosis with obstruction at the pelvi-ureteric junction. (*b*) Pyelographic appearance in obstruction due to a polar vessel.

The indications for operation are bouts of renal pain, increasing dilatation of the renal pelvis and calyces, or evidence of infection.

Treatment.—*Conservation* of renal tissue is the aim. Nephrectomy should only be performed when the renal parenchyma has been largely destroyed. Mild bilateral cases with few symptoms should be followed up, but only operated upon if dilatation is increasing.

Careful freeing of the ureters (ureterolysis) is an essential preliminary to specific procedures:

Ligation and division of an obstructing blood-vessel, together with clearance of adhesions in the neighbourhood of the pelvi-ureteric junction, gives a lasting cure in the few cases due to this cause. The objection to dividing the obstructing artery is that ischæmic infarction ensues in the portion of kidney supplied.

Reconstruction of a hydronephrosis is employed in cases of advanced pelvic hydronephrosis providing a reasonable thickness of renal parenchyma remains. The Anderson-Hynes operation (fig. 1342) is probably the best. The affected kidney is displayed and the upper third of the ureter and the renal pelvis are mobilised. A renal

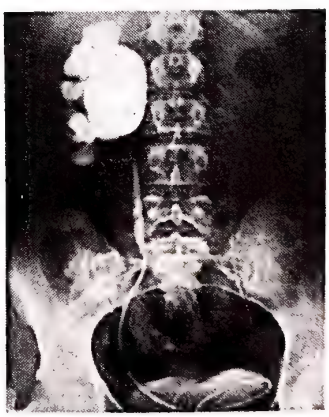


FIG. 1341.—Retrograde pyelogram of a hydronephrosis showing a greatly enlarged pelvis and dilated calyces.

James Christie Anderson, Contemporary. Consulting Surgeon, Royal Hospital, Sheffield, England.
Wilfred Hynes, Contemporary. Surgeon, Plastic and Jaw Department, United Sheffield Hospitals, Sheffield, England.

vein overlying the pelvi-ureteric junction can be divided, but an artery in this situation, whether aberrant or not, should be preserved. The anastomosis is made in front of such an artery. The upper end of the ureter is divided a short distance below the pelvi-ureteric junction, or any narrow segment of ureter. The redundant part of the renal pelvis, together with the ureteropelvic junction is resected as shown in fig. 1342 A, a flap of the lower part of the pelvis being retained. The upper two-thirds of the opening thus created in the renal pelvis is closed with a 0000 plain catgut suture traversing all coats (fig. 1342 B). The upper end of the ureter is slit for 2–3 cm and its anterior edge is anastomosed to the anterior edge of the pelvic flap by a continuous suture of 0000 plain catgut (fig. 1342 C). A ureteric catheter is passed into the ureter for a short distance; this is merely a temporary expedient to keep the deep sutured layer out of the way while the superficial edges are drawn together (fig. 1342 D) in the same manner as were the deep. The catheter is withdrawn just before the anastomosis is completed.

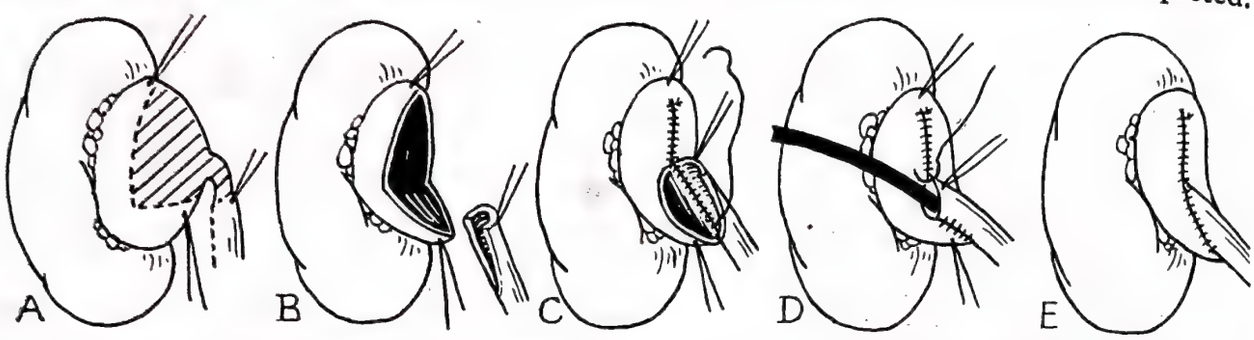

FIG. 1342.—The Anderson-Hynes plastic reconstruction of a hydronephrosis Note the placement of the stay sutures.

Intubated Ureterostomy (Davis).—Longitudinal incision of a narrowed segment of ureter, leaving a T-tube across the split to allow regrowth round the tube is a simple and effective treatment when the pelvis is not greatly enlarged.

RENAL CALCULUS

Ætiology.—The subject is a complicated one, and the following is an epitome of current opinion. (Compare with the ætiology of gallstones, p. 886.)

1. **Dietetic.**—A deficiency of vitamin A causes a desquamation of epithelium. The cells form a nidus around which the stone is deposited. From a study of economic conditions in districts where urinary calculi are common, it is evident that the inhabitants suffer from dietetic imbalance. This is more applicable to bladder calculi.

2. **Altered Urinary Solutes and Colloids.**—In hot climates the concentration of solutes will rise. It has been postulated that any reduction of the urinary colloids which adsorb solutes, or excess of muco-proteins which may chelate[1] calcium, predispose to the formation of an insoluble complex.

3. **Decreased Urinary Output of Citrate.**—The presence of citrate in the urine, 300–900 mg/24h (1·6–4·7 mmol/24h as citric acid), tends to maintain in solution otherwise relatively insoluble calcium phosphate and carbonate. The excretion of citrate is under hormonal control and decreases during menstruation.

4. **Renal Infection.**—Infection favours the formation of urinary calculi. Both clinical and experimental stone formation is common when the urine is infected with a urea-splitting streptococcus, staphylococcus, or proteus. The predominant bacteria found in the nuclei of urinary calculi are a staphylococcus and *Esch. coli*.

FIG. 1343.—In prolonged recumbency the fact that the urine has to travel uphill favours urinary stasis and consequent stone formation. (*After A. C. McEachern.*)

5. **Inadequate Urinary Drainage.**—Stones are prone to occur in patients with obstruction to the free passage of urine.

6. **Prolonged immobilisation** from any cause, e.g. paraplegia, is prone to result in skeletal decalcification and an increased output of calcium in the urine. This, combined with the mechanical effects of recumbency on renal drainage (fig. 1343), favours the deposition of calcium phosphate calculi. In uninfected cases spontaneous dissolution sometimes occurs.

[1] Chelate—to seize hold of. Chētē, Gr. = the prehensile claw of a crab or scorpion.

David Melvin Davis, Contemporary. Professor Emeritus of Urology, Jefferson Medical College, Philadelphia, U.S.A.

7. **Hyperparathyroidism,** although rare, occurring perhaps in 5 per cent. of cases, should always receive consideration. In cases of multiple or recurrent urinary calculi this cause should be eliminated by biochemical tests (p. 620). Hyperparathyroidism results in a great increase in the elimination of calcium in the urine. It has been aptly remarked that these patients pass their skeleton in their urine. A parathyroid adenoma should be removed before the urinary calculi are treated.

8. **Randall's Plaque. Microliths.**—Randall showed that the initial lesion in many cases of renal calculus is an erosion at the apex of one of the renal papillæ. On this erosion are deposited urinary salts = Randall's plaque. It has further been shown that minute concretions (microliths) occur normally in the renal parenchyma and Carr postulates that these particles are carried away, like carbon particles from the bronchi, by lymphatics. Should some of the renal lymphatic vessels become blocked by inflammatory exudate, a subendothelial calculus may form. Later the endothelium becomes ulcerated, leaving the calculus in contact with the urine.

Varieties of Renal Calculi

Oxalate Calculus (Calcium Oxalate).—Popularly known as the mulberry stone, it is covered with sharp projections (fig. 1344). These cause the kidney to bleed, and altered blood is precipitated on the surface of the stone.

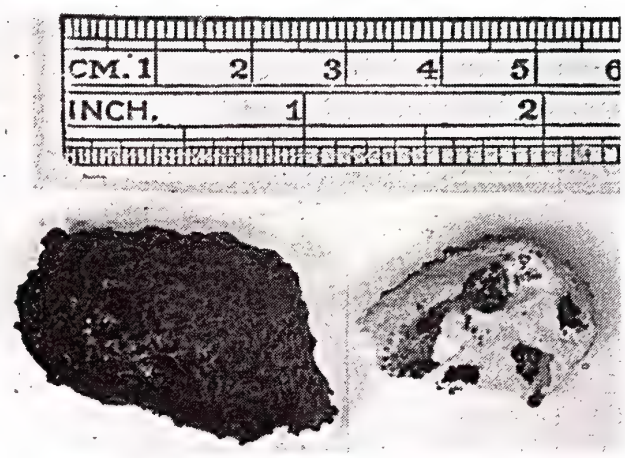

FIG. 1344.—Two oxalate calculi. The larger one removed from the right kidney and the smaller from the left of the same individual. The larger is black, owing to altered blood. The smaller is beginning to be discoloured around its sharp projections. These specimens illustrate clearly the process by which the oxalate calculus changes its complexion.

An oxalate calculus, which is usually single, casts an exceptionally good shadow radiologically, and this is fortunate, for often by virtue of its rough surface it gives rise to symptoms when comparatively small. A calcium oxalate stone is very hard, and on section is laminated concentrically. 'Envelope' crystals can be identified in the urine, viz. →

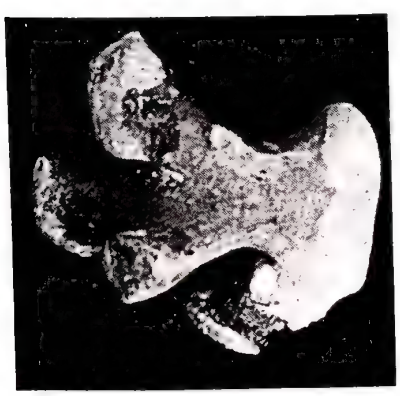

FIG. 1345.—Phosphatic calculus (actual size). Note its branched nature (staghorn calculus).

Phosphatic calculus (usually calcium phosphate, although sometimes combined with ammonium magnesium phosphate and, rarely, composed of the latter only) is smooth and dirty white. In an alkaline urine it enlarges rapidly, and often fills the renal calyces, taking on their shape (staghorn calculus, fig. 1345). Because it is smooth, a phosphatic calculus gives rise to few symptoms until it has attained a large size. By reason of its size rather than its density, it is demonstrated readily by X-rays.

Uric acid and urate calculi are hard and smooth and, because they are usually multiple, they are typically faceted. Their colour varies from yel-

Alexander Randall, 1883–1951. Professor of Urology, University of Pennsylvania, Philadelphia, U.S.A.
Reginald Joseph Carr, Contemporary. Radiologist, Bradford Royal Infirmary, Bradford, England.

low to reddish brown. Pure uric acid calculi are not opaque to X-rays, but absolutely pure uric acid calculi are uncommon; the majority contain enough calcium oxalate crystals to render them opaque. Calculi of ammonium and sodium urate are sometimes found in children. Such stones are yellow, soft, and friable, and unless they contain impurities they do not cast an X-ray shadow.

Cystine calculi are wont to appear in the urinary tract of patients with cystinuria and are sometimes encountered in young girls. Cystinuria is *not* an inborn error of metabolism; it results from a greatly diminished or absent resorption of cystine from the renal tubules. Cystine crystals are hexagonal, white, translucent, and appear only in acid urine (fig. 1346). Cystine calculi are usually multiple and may assume a cast of the renal pelvis and calyces. These calculi are soft, like beeswax, and pink or yellow when first removed. On exposure the colour changes to a greenish hue. They are radio-opaque owing to the sulphur they contain.

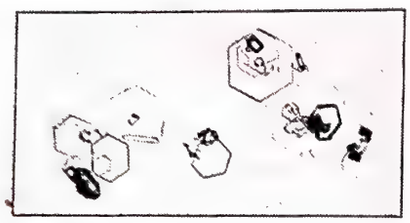

FIG. 1346.—Cystine crystals from the urine of a patient with cystinuria.

Xanthine calculi are extremely rare. They are smooth and round, brick red in colour, and show a lamellar structure.

Indigo calculi are curiosities. Blue in colour, they are derived from indican.

Clinical Features.—Fifty per cent. of patients with renal calculus present between the ages of thirty and fifty. The male/female ratio is 4:3.

The symptoms are not stereotyped and sometimes the diagnosis remains obscure until a radiological examination has been made.

Quiescent Calculus.—Some stones, especially those composed mainly of phosphates, lie dormant for a long period, during which time there is progressive destruction of the renal parenchyma, and uræmia may be the first indication. Secondary infection usually supervenes.

Pain is the leading symptom in 75 per cent. of cases.

Fixed renal pain is located in the renal angle posteriorly (fig. 1347), in the hypochondrium anteriorly, or in both situations simultaneously. It is often worse on movement, particularly on walking upstairs.

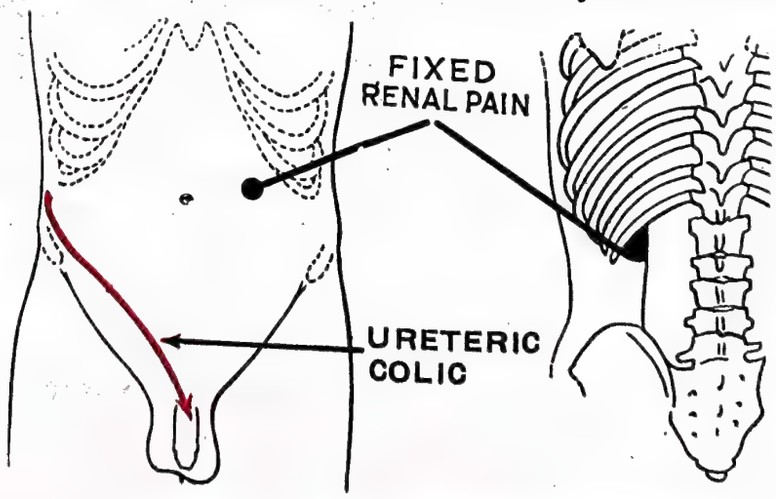

FIG. 1347.—The usual distribution of renal pain.

Ureteric[1] *colic* is an agonising pain passing from the loin to the groin, coming on suddenly, causing the patient to draw up his knees and roll about. It is often accompanied by

[1] See footnote p. 1132.

vomiting and profuse sweating. Strangury[1] may occur if the stone is in the intramural ureter. The pulse quickens, and as the attack progresses the temperature becomes subnormal. An attack of colic rarely lasts more than eight hours. The condition is often due to a stone entering the ureter, but also occurs when a stone in the renal pelvis temporarily blocks the pelvi-ureteric junction. Colic may also be caused by the passage of a shower of oxalate crystals, e.g. after eating an excess of strawberries or rhubarb (p. 1167).

Abdominal Examination.—During an attack of ureteric colic there is rigidity of the lateral abdominal muscles but not, as a rule, of the rectus abdominis. Percussion over the kidney produces a sharp stab of pain; tenderness of the kidney may be apparent on bimanual palpation. Only when a calculus-containing kidney becomes the seat of a hydronephrosis or pyonephrosis of considerable size does it give rise to a palpable swelling.

Hæmaturia.—Infrequently, hæmaturia is a leading, or the only symptom. As a rule hæmaturia occurs in small amounts (enough to render the urine 'smoky') during or after an attack of pain.

Pyuria.—Infection of the kidney is liable to supervene, and pus will be found in the urine in varying amounts. Stones lead to an increase in the number of white cells in the urine even in the absence of infection.

Investigation of a suspected case of Renal Calculus

Radiography.—Before the examination the bowels should be emptied by giving a *vegetable* laxative, for minerals in the intestine cast a shadow (fig. 1348). Radiographs of both kidneys, ureters, and the bladder are taken.

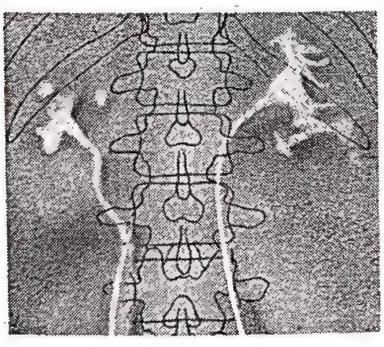

FIG. 1348.—The two shadows in the region of the right kidney were mistaken for calculi. They were due to enteric-coated pills of ammonium chloride.

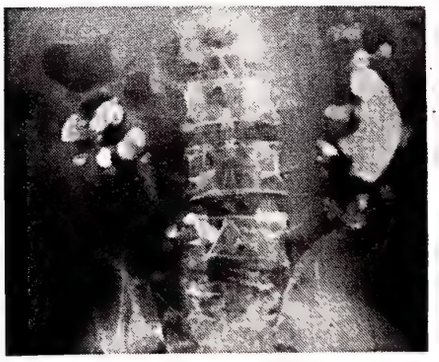

FIG. 1349.—Plain radiograph showing horse-shoe kidney full of stones. The patient, a man of forty-two, stated that he had enjoyed good health until one week previously.

When a renal calculus is branched, there is no doubt concerning the shadow it casts. If a shadow *may* be a calculus in the kidney, exposures are made during full inspiration and full expiration. If the opacity moves with the kidney, and measurements from the lower pole of the kidney to the opacity remain constant, then the shadow is intrarenal.

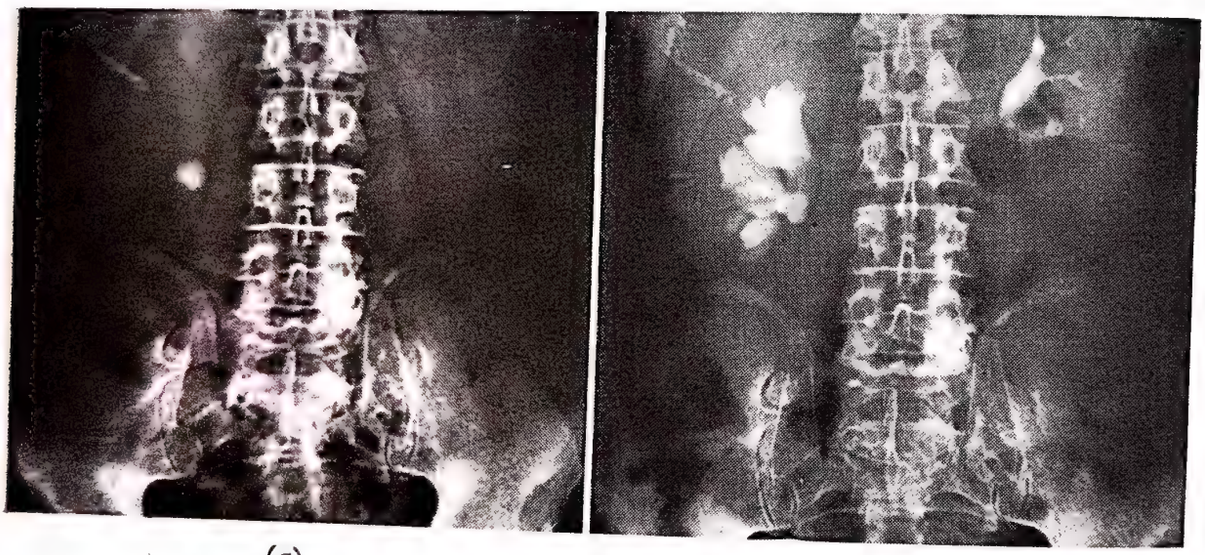
[1] Strangury is the passage of a few drops of urine, often blood-stained, after painful straining.

The following structures and substances from time to time cast a shadow which at first sight may appear to be a renal calculus:

(i) A calcified lumbar or mesenteric lymph node.
(ii) A gall-stone or a concretion in the appendix.
(iii) Drugs (e.g. fersolate) or foreign bodies in the alimentary canal.
(iv) Phleboliths.
(v) The ossified tip of the twelfth rib.
(vi) A chip fracture of the transverse process of a lumbar vertebra.
(vii) Calcified tuberculous lesion of the kidney.
(viii) A calcified suprarenal gland.

A doubtful shadow in relation to the kidney can often be proved to be extrarenal by a *lateral radiograph*. When the shadow can be shown to lie anterior to the bodies of the vertebræ, *ipso facto* it is anterior to the kidney. Such is the finding in calcified mesenteric lymph nodes, gall-stones, and opacities in the alimentary tract.

Excretory pyelography is of value in confirming that the opacity is intrarenal, in determining in which part of the kidney the stone is situated (fig. 1350), and in revealing the function of the other kidney.



(*a*) (*b*)

FIG. 1350.—(*a*) Plain X-ray showing a renal calculus. In which part of the kidney is it situated? (*b*) Same case. Excretory pyelogram. The stone is obstructing the pelvi-ureteric junction. Pyelolithotomy is needed urgently.

The presence of a non-opaque calculus also can be demonstrated by pyelography, for it causes a filling defect in the shadow cast by the medium. A similar defect is seen in papilloma of the renal pelvis (p. 1191). Retrograde pyelography may be required to give a clearer delineation.

Cystoscopy.—A urethral stricture or prostatic obstruction, both of which may be a predisposing factor in renal stone formation, will be revealed by instrumental examination. Unless cystitis is present, the bladder wall looks normal. The urinary efflux from the affected side is increased if the stone is irritating the renal pelvis, or decreased when the pelvi-ureteric junction is blocked or when the parenchyma is severely diseased.

Treatment of Ureteric Colic (p. 1170).

OPERATIONS FOR THE REMOVAL OF RENAL CALCULI

Pre-operative Treatment.—If urinary infection is present, antibiotic treatment is instituted, and continued after operation as necessary. A bacteriology swab for culture should be taken of urine in the renal pelvis.

Operation—General Remarks.—All the operations about to be described have certain features in common. Via a lumbar incision (p. 1192) the kidney is exposed and mobilised. When delivery is impossible, the choice of procedure is more limited and the operation more difficult. An X-ray showing the calculus or calculi clearly should be displayed in an illuminated viewing-box in the operation theatre. The stone or stones removed should coincide in every respect with the X-ray findings.

It is advisable to X-ray the exposed kidney (using a special film encased in a sterile plastic cover). This ensures that no stone or portion of stone within the kidney has been overlooked, and reduces the number of so-called recurrences.

Nephroscopy.—The inspection of the interior of the pelvis and calyces by means of a urethroscope is feasible in some kidneys. The development of rod lens systems, and glass fibres for transmission of increased light, has enabled the production of a nephroscope with flushing system and small forceps with which the interior of calyces can be examined, small calculi picked off, and subepithelial plaque visualised. This teaches one that even a clear X-ray is not proof that kidneys are cleared of foci on which other calculi can form.

At the conclusion of all the operations to be described the kidney is replaced in its bed, the fascia of Gerota closed, and the lumbar wound closed with drainage of the perinephric space. If nephrostomy has been performed, the tube is either brought through the lumbar incision or through a stab incision.

Pyelolithotomy is indicated when a stone (it is usually solitary) lies in the renal pelvis, provided the pelvis is extrarenal. In nearly 50% of cases a renal calculus is so situated. The posterior wall of the renal pelvis is dissected free from its surrounding fat. The kidney is grasped in the left hand so that the tips of the index and middle fingers lie beneath the renal pelvis, making it more prominent, while the thumb anteriorly prevents the stone slipping into one of the calyces. An incision is made on to the stone in the long axis of the renal pelvis. The stone is removed with gall-stone or suitable forceps, care being taken to avoid breaking it. If pyelography showed a stone in a calyx and the renal pelvis is large, the stone can be located by the little finger introduced into the renal pelvis: should the stone be accessible, it can be grasped in forceps and removed by this route. After a stone has been removed via the renal pelvis, a bougie is passed through the pelvi-ureteric junction to calibrate it and to exclude any obstruction lower down. If the kidney is known to be uninfected, the incision in the renal pelvis is closed by interrupted sutures of fine plain catgut. If the kidney is grossly infected, nephrostomy (p. 1144) is performed before closing the incision in the renal pelvis.

Extended Pyelolithotomy (Gil-Vernet) by dissecting in the renal sinus posteriorly, a plane between the pelvis and calyces and the renal vessels leads to the necks of the calyces. Incisions continued into the calyces enable a direct view into the calyx to be obtained in many cases, facilitating the removal of large and small stones. Thermocouple-regulated cooling of the kidney, by ice chips in polythene bags, or liquid nitrogen circulating through coils placed around the kidney, enables the renal pedicle to be clamped to provide a bloodless field and unhurried surgery.

Gil-Vernet, Contemporary. Surgeon, Madrid, Spain.

Nephrolithotomy is frequently indicated if extended pyelolithotomy is employed. It may be necessary when there has been previous surgery, with adhesions making approach to the pelvis difficult. The kidney is cooled, and the renal pedicle is clamped as an incision into the renal parenchyma is accompanied by considerable hæmorrhage. The incision is made just behind and parallel to the most prominent part of the convex border of the kidney (Brödel's line). As the terminal branches of the anterior and posterior renal arteries meet along this line, no large artery is divided, thereby minimising the amount of subsequent cortical necrosis. The incision, usually about 2·5 cm. long, is made over that calyx containing the stone or stones, which are removed with lithotomy forceps. All bleeding points are underrun and tied with 0000 chromic gut, the edges of the opened calyx closed if necessary. The renal incision can be closed by interrupted catgut sutures passing through the kidney substance but not penetrating the calyx, and tied over a piece of Oxycel or muscle to enhance hæmostasis. If infection is present, nephrostomy is carried out by placing a small self-retaining catheter through the incision into the renal pelvis. The incision is then closed on either side of the tube in the manner just described.

Pyelonephrolithotomy is used to remove a stone situated deeply in a calyx, especially if it is present in addition to one in the renal pelvis, and in cases of stones situated in more than one calyx. The pelvis is opened, the little finger is introduced and the calyx containing the stone is palpated. If pressure is exerted on the corresponding convex border of the kidney, even a small stone can usually be palpated. Otherwise, the kidney is punctured with a round-bodied needle so that the point grates on the stone. An incision is made through the parenchyma, and with the finger pressing on the calculus from within, it is grasped by lithotomy forceps introduced through the cortical incision, and withdrawn. If there are stones in other calyces the procedure may be repeated, making two, or even three, cortical incisions. The incisions are closed in the manner already described. If drainage of the interior of the kidney is necessary, the catheter is introduced through the cortical incision or, if there are more than one, through the most dependent.

Partial Nephrectomy.—When the stone is in the lowermost calyx—a fairly common position—and there is considerable damage to the calyx, as in multiple stones, or 'grit' in the renal substance, then lower partial nephrectomy is the best operation (p. 1193). If the damaged calyx is not removed, its dependent position encourages further stone formation.

Nephrectomy (p. 1192) is indicated when the contralateral organ has been proved to be perfectly healthy and the stone or stones have destroyed much of the renal parenchyma. Large branched calculi are notorious for recurring, so nephrectomy is often the best treatment in such cases.

Post-operative Treatment.—The patient should lie on the side of the operation or on his back to encourage drainage and obliteration of dead space in the wound. Wound drains should be shortened after 36–48 hours and removed as soon as any leak has ceased.

If a nephrostomy tube has been inserted then it is wise to give a wide spectrum antibiotic to decrease the risk of infection and possible secondary hæmorrhage.

A high urine output from the kidney, or if a nephrostomy tube is in place, irrigation with Solution G (see below) is a great help in reducing the incidence of 'recurrent' stone.

Treatment of Renal Calculi by Dissolution.—Most renal calculi, because they are irreversible colloidal compounds, cannot be dissolved. The possible exceptions are (*a*) non-infected recumbency calculi of calcium phosphate undergo dissolution with a high fluid intake; (*b*) small cystine stones dissolve in an alkaline urine. Sodium citrate mixture is taken three or four times a day to maintain a urinary pH of between 7·6 and 8·0; (*c*) small phosphate calculi may be dissolved by bringing them in direct contact with solution G:

Solution G:		
	Monohydrous citric acid	32·3 g.
	Anhydrous magnesium oxide	3·8 g.
	Anhydrous sodium carbonate	4·4 g.
	Distilled water	ad 1,000 ml.

The first operation of nephrolithotomy was performed by Ambroise Paré (1510–1590). His patient was a criminal condemned to death by hanging, instead of which Paré removed two stones from his kidney. Fifteen days later the patient was cured, secured his remission, and was given a grant of money.

Max Brödel, 1870–1941. Artist of Pathology and Founder and Director of the Department of Art as Applied to Medicine (the first school of its kind in the world), Johns Hopkins University, Baltimore, U.S.A.

Treatment of Bilateral Renal Calculi.—Usually the kidney with the better function is operated upon first, the operation on the contralateral side being postponed for two or three months. Exceptions to this rule are (*a*) if there is pain on one side, that side is operated upon first, for pain usually signifies that the stone is obstructing the outflow of urine from the kidney, the function of which will become increasingly impaired; (*b*) if there is a pyonephrosis on one side this should be treated by nephrectomy, or, if the patient's condition is poor, by nephrostomy. In cases of bilateral staghorn calculi without infection and with few symptoms especially in the elderly, it is probably wiser not to operate. The patient should drink large amounts of fluid.

Prevention of Recurrence

Frère Jacques, that famous lithotomist of the Middle Ages, used to say, " I have removed the stone, but God will cure the patient." With the advance of knowledge our responsibilities do not end with the removal of the stone; provision must be made to prevent recurrence. Recurrent calculi can be divided into two varieties:

(*a*) *False Recurrence.*—Even a tiny fragment overlooked at the time of the operation is liable to become the nucleus of a new stone. Similarly infection and obstruction are factors in recurrence and should be eliminated in the treatment of the first stone.

(*b*) *True Recurrence.*—Ideally all stone formers should be investigated to exclude metabolic factors. The following investigations in bilateral and recurrent stone formers are essential:

(i) Serum Calcium, measured starving on three occasions to exclude hyperparathyroidism. This series may need to be repeated (p. 621).

(ii) Serum Uric Acid to exclude gout. Elevated serum uric acid levels can predispose to the formation of calcium phosphate stones.

(iii) Urinary urate and calcium and phosphate excretions in 24-hour urine, and screening for cystine.

(iv) Analysis of any stone passed.

(*c*) *Dietary Advice:*

(i) There should be a high fluid intake at all times, regardless of the chemistry of the stones. This is clearly indicated in cystinuria where the liability to stone formation is directly related to the concentration of the cystine in the urine. It is equally important to keep the urine dilute at night.

(ii) **Uric-acid and Urate Calculi.**—Red meats, offal, and fish which are rich in purine should be avoided. Sufficient sodium citrate and sodium bicarbonate are given to keep the urine alkaline. Allopurinol in doses sufficient to overcome a high serum uric acid is essential.

(iii) **Calcium Oxalate Calculi.**—Rhubarb, strawberries, plums, spinach, and asparagus, which are rich in oxalate, should only be taken if they are accompanied by cream or milk, as then oxalates are precipitated as an insoluble calcium salt in the intestine, and are not absorbed. At all times a diet adequate in calcium and magnesium is necessary; calcium oxalate is rendered less soluble in the presence of magnesium ions.

(iv) **Phosphate Calculi.**—Excessive alkalinity of the urine should be treated by giving ammonium chloride or another urinary acidifier. Phosphates in the diet should be restricted. Aluminium gel, 40 ml. t.d.s., p.c. and at bedtime, drastically reduces the incidence of recurrence.

(v) **Cystine Calculi.**—Sulphur-containing proteins such as eggs, meat, or fish are restricted, and proteins with a low sulphur content substituted. Carbohydrates and fats are unrestricted. The urine must be kept dilute at all times as the formation of calculi is directly related to the concentration of cystine in the urine. Fluids must be drunk during the night as well as during the day. Solubility is increased by keeping the urine strongly alkaline, but this is often difficult to achieve. Penicillamine is a costly and by no means always successful drug in preventing recurrent cystine calculi.

(vi) **Recumbency Calculi.**—In patients doomed to long recumbency, sodium phytate taken by mouth forms insoluble calcium phytate, thus removing by the bowel one source of hypercalciuria. Regular timing is essential.

Frère Jacques, 1651–1719. Itinerant Italian lithotomist, after serving as a trooper in the French army, adopted semi-religious habit and cut for stone in the bladder.

(vii) **Idiopathic Hypercalcuria.**—A strict low calcium diet (400 mg daily) should be tried first. 5 mg Bendrofluazide reduces calcium loss in the urine. Water softening to remove calcium in the local water may be required in order to allow a high fluid intake. Sodium phytate taken orally at regular intervals is the last line of treatment.

URETERIC CALCULUS

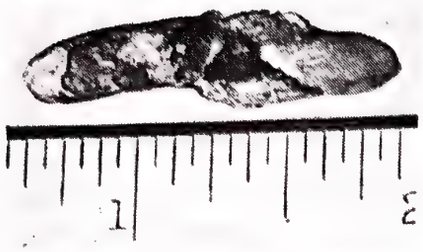


FIG. 1351.—Ureteric calculus removed by operation.

A stone in the ureter nearly always has its birth in the kidney. When it enters the ureter the calculus is rounded or oval in shape. Should it become arrested in its descent to the bladder, in time it becomes enlarged and elongated, resembling in shape a date stone (fig. 1351). In 90 per cent. of cases the stone is single.

Clinical Features.—When a stone descends into the ureter there is an attack of ureteric colic, which is repeated at longer or shorter intervals, until the stone is ejected into the bladder or becomes impacted in the ureter. There are five sites of anatomical narrowing of the ureter where a stone may be arrested (fig. 1352).

Ureteric Colic.—A stone in the upper third of the ureter produces symptoms identical with those of a stone blocking the pelvi-ureteric junction (p. 1162). When a calculus enters the lower third of the ureter, the colic it produces often commences anteriorly at a lower level than the kidney, and is frequently accompanied by pain referred along the two branches of the genito-femoral nerve, to the testis in the male (fig. 1353), the labium majus in the female, and to the anterior surface of the thigh in both sexes. The testis usually becomes retracted by spasm of the cremaster, and tender, the tenderness persisting for some time after the colic has ceased. When the stone enters the intramural portion of the ureter, the pain is referred to the tip of the penis in the male. In both sexes there is strangury. In more than 50 per cent. of cases the stone is passed spontaneously.

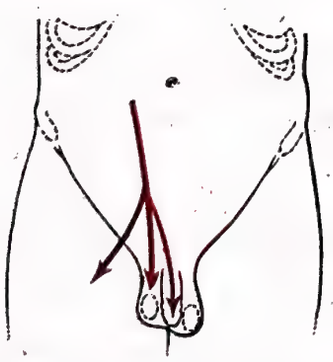

FIG. 1353.—Radiations of ureteric colic produced by a stone in the lower third of the ureter.

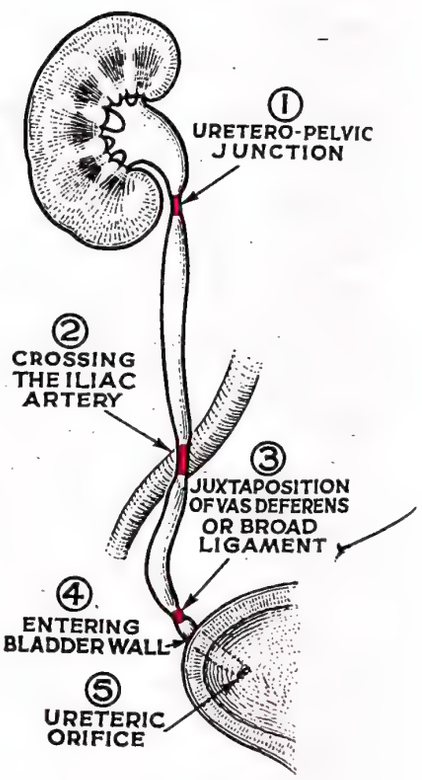

FIG. 1352.—Normal anatomical narrowings of the ureter. (*After C. C. Higgins.*)

Impaction.—When the stone becomes impacted the attacks of colic pass off and give place to a dull pain, usually in the iliac fossa, for impaction usually occurs in the pelvic portion of the ureter. The pain is increased by exercise, and relieved by rest. Such pain varies in intensity and is often associated with backache due to distension of the renal pelvis. Cessation of pain some-

times occurs by the stone forming for itself a false diverticulum in the wall of the ureter by a process of pressure necrosis; subsequent perforation of the ureter occurs but rarely. Severe renal pain persisting for one to two days and then gradually subsiding suggests that complete obstruction has occurred. If an I.V.P. performed one or two weeks later shows no function, the stone must be removed, otherwise complete atrophy of the kidney will occur.

Hæmaturia.—Some degree of hæmaturia occurs after an attack of ureteric colic, and it lasts for a few hours or a day. It is sometimes so slight as to require microscopic identification.

Abdominal Examination.—There is tenderness and often rigidity over some part of the course of the ureter. On rare occasions a stone in the lower end of the ureter can be felt on rectal or vaginal examination. The principal difficulty on the right side is distinguishing the symptoms and signs produced by a ureteric calculus from those of acute appendicitis. The presence of blood in the urine does not necessarily rule out appendicitis, for an inflamed appendix lying in juxtaposition to the ureter can give rise to ureteritis which may cause a small amount of red cells in the urine. Pain on percussion over the kidney is unlikely in acute appendicitis.

Radiography.—Occasionally a typical elongated shadow in the line of the ureter confirms the diagnosis; more often either no shadow is seen, owing to the small size of the stone and the presence of intestinal gas shadows, or a shadow is seen which may or may not be a ureteric calculus.

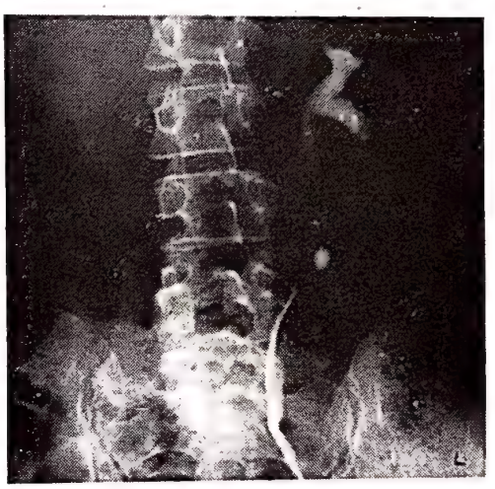

FIG. 1354.—Excretory pyelogram showing stone in the line of the ureter.

Excretory Pyelography.—In, and for some time after, an attack of renal colic there is either no excretion or greatly delayed excretion on the affected side. Films taken later, even up to forty-eight hours after the intravenous injection of Hypaque (diatrizoate) may outline the ureter down to the site of obstruction (fig. 1354). A stone not visible in the plain X-ray may become outlined in the ureter by the contrast solution. After a stone has been impacted for a week or more, a varying degree of hydronephrosis and dilatation of the ureter is often apparent.

If pyelograms taken during an attack of pain show normal excretion on the affected side, then the patient has not got a ureteric colic.

Cystoscopy.—When a calculus is in the upper part of the ureter, the ureteric orifice shows no abnormality. When a calculus has reached the lower third of the ureter, or sometimes when it is in the middle third, the ureteric orifice becomes patulous and its immediate vicinity bespattered with minute petechial hæmorrhages. As the calculus descends to just above the bladder wall, these hæmorrhagic spots coalesce to form larger, bright-red extravasations. The stone having entered the intramural portion of the ureter, the ureteric orifice becomes grossly œdematous. Finally, the pouting calculus may be seen (fig. 1313).

The passage of a ureteric catheter provides much information, and in conjunction with radiography confirms the diagnosis. Usually a catheter fails to pass the obstruc-

tion and a radiograph shows the tip of the catheter abutting on the lower margin of the calculus. However, when the urinary efflux is increased, a catheter sometimes passes into the renal pelvis without hindrance, or, if arrested, after partial withdrawal and reinsertion (fig. 1355).

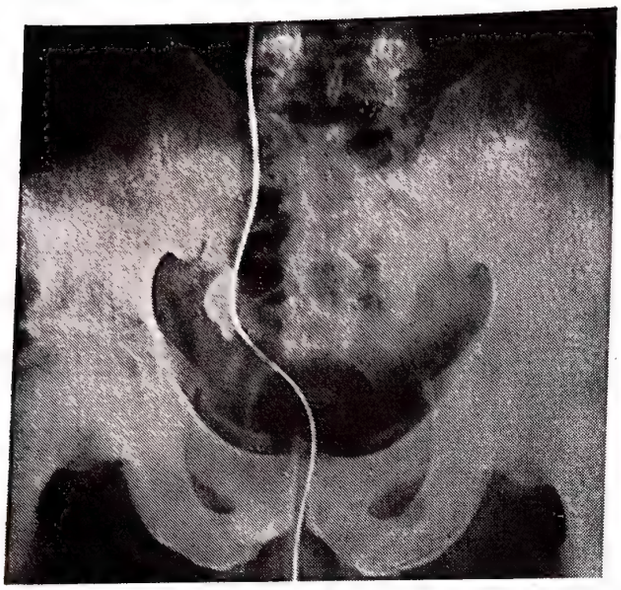

FIG. 1355.—Stone in the ureter. Catheter passed alongside the stone.

Retrograde pyelography is seldom required. The only indications for its employment are when there is doubt concerning a shadow being a ureteric calculus and excretory pyelography shows absence or ineffective delineation of the corresponding renal pelvis and the ureter. It sometimes proves a means of displaying the presence of a ureteric calculus non-opaque to X-rays.

Treatment.—1. Of the Colic. Morphia (15 mg) is the best drug to relieve severe pain and does not produce spasm in ureteric muscle. The stone produces spasm and one dose of probanthine (15 mg) should be given at the same time. Repeated doses of probanthine can easily produce retention of urine by paralysis of the detrusor muscle of the bladder.

2. Of the Stone.

(i) **Expectant.** Provided the urine is sterile, most small calculi will pass naturally. This may take many months. Progress of the stone is observed by plain X-rays every six to eight weeks, and occasional pyelography to see that the function and appearance of the kidneys are satisfactory.

(ii) **Removal of the stone** may be required if:

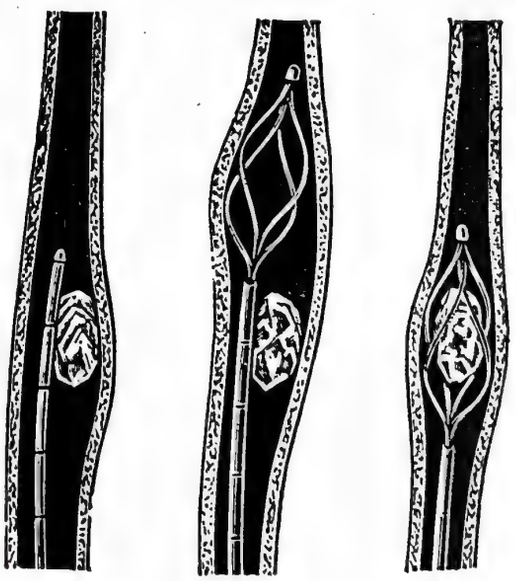
(*a*) Repeated attacks of colic produce no advance of the stone.

(*b*) The stone is enlarging but not moving.

(*c*) Complete obstruction of the kidney occurs, or a hydronephrosis is increasing.

(*d*) The urine is infected.

(*e*) The stone when first seen is thought to be too large to pass.



(*a*) (*b*) (*c*)

FIG. 1356.—Dormia stone catching basket in use. (*a*) basket introduced past stone. (*b*) opened and (*c*) enclosing stone ready for withdrawal. (*Porgès, Paris*).

Instrumental Treatment

(*a*) *Ureteric catheterisation.*—A small stone half a centimetre or less in diameter arrested in any part of the ureter often passes after ureteric catheterisation.

(*b*) *Dormia Basket* (fig. 1356).—This is a stone dislodger and can be used for stones in the lower third of the ureter.

Dormia, Contemporary. Assistant Professor of Urology, University of Milan, Italy.

(*c*) *Ureteric Meatotomy.*—The ureteric orifice is the narrowest part of the whole ureter. By enlarging the opening a stone is often enabled to pass. However, this procedure almost invariably leads to urinary reflux afterwards and should therefore be avoided.

(*d*) *Intra-ureteric Manipulation* with stone catchers, loop catheters and corkscrew stone dislodgers should never be used in mid or upper ureter.

Operative Treatment

Uretero-lithotomy.—The patient should be submitted to radiography just prior to the operation, in order to detect any change in the position of the calculus.

(*a*) **Stone Impacted in the Upper Third of the Ureter.**—An incision similar to that for exposing the kidney (p. 1192) is made; it can be prolonged downwards if necessary.

(*b*) **Stone Impacted in the Lower Two-thirds of the Ureter, but above the Spine of the Ischium.**—With the patient in the dorsal position, an incision is made from a point 4 cm above the anterior superior iliac spine to the middle of the inguinal ligament. The flank muscles are divided in the direction of their fibres. The peritoneum is displaced medially by gauze dissection until the dilated ureter is found adhering to its under-surface. The stone is sought by palpation, and, if possible, is milked upwards or downwards to a convenient point for extraction. The ureter is incised longitudinally and the stone withdrawn by a scoop or forceps. If the stone is impacted firmly, the only course is to incise the ureter directly over it, a practice to be avoided whenever possible, for the mucous lining is ulcerated at the site of impaction, and healing is impaired. The incision in the ureter is closed by sutures of 0000 plain catgut passing through the muscular coats only. The lower end of the wound is drained down to the incision in the ureter.

(*c*) **Stone Impacted in the Juxtavesical or Intramural Portions of the Ureter.**—A midline, sub-umbilical extraperitoneal approach is employed, with the patient in Trendelenburg's position. The peritoneum is stripped from the dome of the bladder and from the side wall of the pelvis. A dissection is then made between the posterior surface of the bladder and the wall of the pelvis. Often at this stage the stone will be felt. If this is not possible, the ureter must be identified where it crosses the iliac vessels, and traced downwards. Once the stone has been located it is removed as described above.

After removal of a stone at any site, a ureteric catheter or bougie should be passed to prove the patency of the distal ureter.

Idiopathic retroperitoneal fibrosis.

This condition is rare. The patient, who typically has complained of backache for many months, suddenly becomes anuric. In other circumstances when kidney disease has been suspected pyelography reveals rapidly developing unilateral or bilateral hydronephrosis associated with a rising blood urea. Characteristically the ureters are nearer the mid-line than normally and this is due to an area of fibrosis centred over the bifurcation of the aorta which strangulates the ureters. The cause is largely unknown. Some cases have been noted following the use of methysergide for the treatment of migraine, and methyl-dopa may also cause the condition.

Treatment.—In the anuric patient, if an attempt at ureteric catheterisation is successful, the catheters should be left *in situ* to relieve the obstruction. If this fails, bilateral nephrostomy is necessary although the use of the artificial kidney (p. 1143) may be beneficial.

In non-urgent cases the involved ureter or ureters should be freed from the fibrous mass by sharp dissection and fixed laterally to the psoas muscles to prevent recurrence. Should this prove impossible an ileal loop ureter should be constructed (p. 1232).

INFECTIONS OF THE KIDNEY

Ætiology.—Renal infections arise in the following ways :

1. *Hæmatogenous.*—From infected tonsils, carious teeth, or from cutaneous infections, particularly boils or a carbuncle, and in the case of tuberculosis from affected lymph nodes in the neck, chest or abdomen.

Friedrich Trendelenburg, 1844–1924. Professor of Surgery, Leipzig, Germany.

2. *Ascending the peri-ureteral lymphatics* from the cervix or the prostate.

3. *Ascending the lumen of the ureter* from the bladder in long-standing cases of lower urinary obstruction with dilated ureters, when, as a result of vesico-ureteral reflux, infected urine may be carried from the bladder to the renal pelvis. Motile organisms, e.g. *Esch. coli*, ascend along the dilated ureters.

On complete urinary investigation, which should always be undertaken after the acute phase of the infection has subsided, about 30 per cent. of males and a smaller number of females will be found to have an obstructive lesion in some part of the urinary tract. Moreover, with or without such a lesion, a focus of infection in the genital organs may be demonstrable.

Bacteriology.—By far the most common organisms responsible are those of the coliform[1] group. When *Streptococcus fæcalis* is present, in nearly 40 per cent. of cases it occurs in association with another organism.

In the presence of the common *Esch. coli* infection the urine is acid, as it also is in many types of streptococcal infection. Both staphylococci and *Proteus vulgaris* split urea, releasing ammonia, which causes the urine to become alkaline.

PYELONEPHRITIS

Renal infection, by whatever route it originates, is never confined to the renal pelvis. In hæmatogenous infection the renal parenchyma is attacked first, and the infection spreads to the renal pelvis. In ascending infection the bacterial inflammation is not limited to the renal pelvis; it implicates the calyces, the pyramids, and at least some part of the adjacent parenchyma. It is, therefore, more correct to discard the term 'pyelitis' in connection with the latter type of infection, in favour of the more accurate designation 'pyelonephritis'.

ACUTE PYELONEPHRITIS

Acute pyelonephritis is more common in females, especially during childhood, at puberty, soon after marriage ('honeymoon pyelitis'), during pregnancy, and the menopause. It occurs more often on the right side than on the left, and is frequently bilateral.

Clinical Features.—While there may be prodromal symptoms of headache, lassitude, and nausea, the onset is usually sudden, often commencing with a rigor and, even, vomiting. There is acute pain in the flank and the hypochondrium. In a few cases the pain radiates from the loin to the groin (ureteric colic). The temperature rises to 38·8° or 39·5° C, and is remitting. Soon after the onset, increased frequency of micturition, due to cystitis, sets in, and when, as is often the case, the urine is acid, micturition is accompanied by a scalding pain in the urethra. On examination there is tenderness in the hypochondrium and in the angle between the last rib and the sacrospinalis, accompanied by a varying degree of muscular rigidity. In the early stages, when it is imperative to make a correct diagnosis, the urine is clear macroscopically.

In cases of severe bilateral pyelonephritis, particularly when there is an associated obstruction, there are likely to be symptoms of uræmia.

[1] Coliform organisms comprise *Esch. coli*, *paracolon bacilli*, and *Aerobacter aerogenes*.

Bacteriological Examination of the Urine.—A mid-stream specimen should be collected in a sterile bottle; the urine is centrifuged and examined microscopically. In early acute pyelonephritis there are typically a few pus cells and many bacteria. When pyelonephritis has been present for twenty-four hours or more, the urine is often cloudy and pus cells abound. Quantitative estimations of the cells and bacteria in the specimen are of real value, whereas vague impressions reported as . . . 'many, some, a few' are usually misleading. In all cases the investigation includes an examination of the sediment stained by Gram's method, culture of the specimen, and an investigation of the sensitivity of the organism or organisms to various antibiotics and chemotherapeutic agents.

Severe Cases.—There are repeated rigors and the temperature rises to 40° or 40·5° C, often without a corresponding rise in the pulse-rate. There is vomiting, sweating, and great thirst, and the patient looks and feels ill. The blood culture, if the specimen is taken soon after a rigor, often gives a positive result. After some hours the pain is localised in one or, rarely, both loins. Urine is scanty and highly concentrated, and is frequently teeming with coliform organisms and pus cells, in which case the diagnosis is simplified. In blood-borne infections the organisms and pus cells do not appear in the urine until the infection has spread from the cortex to the medulla—a matter of many hours, or even days. As the abdominal rigidity abates, the enlarged affected kidney may be palpable.

Differential Diagnosis.—When the symptoms and signs are typical the diagnosis is straightforward. In other circumstances there may be difficulty in distinguishing the condition from pneumonia, acute appendicitis, and acute cholecystitis. The urgent need is to differentiate acute appendicitis from right-sided pyelonephritis. The fact that the pain commenced in, and did not pass to the right side, greatly favours the latter condition. Excretory pyelography may prove of assistance, for an early acute pyelonephritis limited to the right kidney the concentration of medium in the renal pelvis and calyces on the affected side may be so poor that no shadow, or a very indefinite shadow, is cast. A radio-isotope renogram using Chlormerodrin (^{203}Hg) 1·25 μc per kg body weight will show scattered areas of diminished uptake (fig. 1310).

Pyelonephritis of Pregnancy.—The condition usually develops between the fourth and sixth months of gestation. It is commoner in women who have had recurrent bouts of cystitis or pyelonephritis in the past. In 90 per cent. of cases the right side alone is affected. The initiating causes are often chronic urethritis or a cervical erosion. The symptoms do not differ from those of pyelonephritis occurring in the non-pregnant. In about 10 per cent. of cases the disease runs a more severe and protracted course, and occasionally it results in abortion or premature birth. In all patients who have had pyelonephritis of pregnancy, periodic examinations of the urine are necessary during the rest of the pregnancy, the puerperium and for several months afterwards, for if the infection has not been eradicated, recrudescence is liable to occur during this period.

Urinary infection in childhood is not uncommon, and is important to recognise because it frequently involves the kidneys. If recurrent it may lead to severe renal impairment or renal failure in early adult life. In young children there may be no urinary symptoms, although the mother may notice a cloudy or offensive urine. If a child fails to thrive, refuses to eat, has a high fever (temp. 39–40° C) with *rigors or convulsions*, the possibility must always be considered. Pain or screaming on micturition may occur. The older child may complain of loin pain, or suddenly develop frequency and enuresis.

Hans Christian Joachim Gram, 1853–1938. Professor of Medicine, Copenhagen.

Many cases (50%) are associated with an underlying anatomical or congenital abnormality. Once the diagnosis has been confirmed by a clean catch specimen or by a specimen obtained by suprapubic needle puncture of the bladder, a full urological investigation is essential.

Reflux of urine occurs up the ureters during micturition in about 35% of cases with a proven urinary infection. It may be intermittent and is certainly more frequent when infection is present. It can only be demonstrated clearly by micturating ciné-cystography, but this does necessitate catheterisation: this must be performed gently and with strict asepsis, and it is wise to leave a solution of neomycin (50 ml 0·5% freshly made) in the bladder afterwards. Renal function tests and full blood analysis should be done.

Reflux also occurs when the intravesical pressure is high, and the obliquity of the intramural ureter is lost. A thin bladder wall and the presence of a saccule near the ureteric orifice may lead to funnelling of the orifice during ureteric peristaltic retraction.

Mild and moderate reflux up to the upper third of the ureter may not require reimplantation. Severe reflux into the pelvis should be treated by reimplantation to increase the obliquity of the course of the ureter through the muscle wall. Children with reflux should be taught to perform ' double micturition ' in order to limit the urinary stasis if operation is not going to be carried out.

Urinary infection must be treated with the appropriate drug until the clean catch specimen is sterile on culture and free from white cells on microscopy. A repeat urine sample 10–14 days after cessation of treatment must be examined to exclude recurring infection.

ACUTE PYELONEPHRITIS ASSOCIATED WITH RETENTION OF BLADDER URINE

Acute Pyelonephritis with retention of bladder urine occurs most frequently in men suffering from prostatic obstruction or stricture of the urethra, and in cases of fracture of the spine with injury to the spinal cord (p. 457). The retention is not necessarily complete and the patient may be able to urinate, but there is a varying amount of residual urine, from a few ounces to several pints. In most cases the infection is bilateral. Often it follows the passage of a catheter or other instrument, or operations on the lower urinary tract, but it may arise spontaneously. The old name for this condition was ' surgical kidneys ', and in the days of unsterile catheterisation it was frequent and dreaded. At post-mortem examination the kidneys are enlarged and miliary abscesses can be seen beneath the capsules. On bisection there are numerous yellow streaks of pus in the parenchyma radiating from the medulla to the convex border. The renal calyces, pelves, and ureters are dilated.

Treatment of Acute Pyelonephritis

The essential factors in curing pyelonephritis are *early*, *correct* and *prolonged* treatment, and careful follow-up with repeat cultures and white cell counts of the urine after treatment has finished. A full investigation to exclude abnormalities in the urinary tract should be undertaken when the acute attack is controlled.

A mid-stream specimen of urine should be taken and sent for culture and tests of the sensivity of the organisms to antibiotics. Bed rest is important.

If the urine is acid, as it is in the common coliform infections, alkalinisation of the urine has a most beneficial effect in relieving the symptoms and in inhibiting the growth of these organisms. Mist. Pot. Cit. et Hyocyamus, 10 ml. 6 hourly is an old but useful treatment.

When pain is severe, an antispasmodic is given and heat is applied to the affected loin. Morphia, in addition, may be necessary sometimes.

The patient should be instructed to drink large quantities of bland fluid, at least 3 litres in the twenty-four hours. In severe cases with vomiting or

dehydration, intravenous dextrose-saline is given until the dehydration has been rectified and the vomiting has ceased.

While awaiting the bacteriological report and the result of the sensitivity tests, in comparatively mild cases a soluble sulphonamide can be given as directed below, but in severe cases an antibiotic with a wide range of activity, e.g. ampicillin, should be substituted. When the bacteriological report is to hand, the drug of choice should be given.

Three and seven days after commencing the treatment of pyelonephritis the urine must be sent for culture. Even when a full initial course (ten days) of an antibiotic or chemotherapeutic agent has rendered the urine sterile, it is advisable to continue treatment with another drug for a further two to three weeks, or until the hourly white cell excretion rate has fallen to normal levels (less than 200,000 per hour). During this treatment further investigations to rule out abnormalities in the urinary tract should be carried out (p. 1133). Despite the undoubted efficacy of modern antibacterial drugs, none is likely to succeed in sterilising the urine of a patient with an abnormality of the urinary tract. A history of previous urinary infection also reduces the likelihood of a cure, although to a lesser extent (Garrod).

Colomycin, *Gentamicin* and *Carbenicillin* are the best drugs currently available for combating infections with the more resistant strains of *Pseudomonas Pyocyanea*, Proteus, and Klebsiella.

Chemotherapeutic and Antibiotic Agents

Sulphonamides: *Sulphafurazole* (Gantrisin) is capable of high urinary concentration without risk of crystalluria, and is of low toxicity. It is capable of controlling many *Esch. coli* infections and some strains of *proteus* and *Ps. aeruginosa*. The dose is 2 g *statim* followed by 1 g six-hourly until the temperature has remained normal for three days, and cultures of the urine have proved sterile on three consecutive occasions.

Sulphamethiazole (Urolucosil) has similar properties, but unlike other sulphonamides it is unnecessary to insist on a high fluid intake while the patient is taking this drug. The dose is 100 mg four times daily.

Antibacterial Nitrofuran: *Nitrofurantoin* (Furadantin) is a synthetic antibacterial agent. Although when taken by mouth the blood levels remain low, the concentration in the urine is significant; hence it is of value only in genito-urinary infections. It is particularly effective against *Esch. coli*, *A. aerogenes* and *proteus*; often it has proved lethal to antibiotic-resistant strains of these organisms. The average dose by mouth is 5 to 8 mg per kg of body weight. One-quarter of this dose is administered immediately after food three times daily and a further dose with cold milk last thing at night. If nausea or vomiting occurs, the dose must be reduced.

Antibiotics: *Broad Spectrum Antibiotics.*—While these are effective if employed in accordance with bacteriological findings, when it is necessary to continue treatment for a prolonged period (which is not unusual) a number of dangers loom large. Firstly, there are the toxic properties, producing nausea, vomiting, and diarrhœa. Secondly, there is the alteration in the intestinal micro-flora these antibiotics produce, sometimes leading to moniliasis or staphylococcal enterocolitis (p. 16). Thirdly, the frequency with which resistant variants emerge, often in a comparatively short time, is disturbing.

CHRONIC PYELONEPHRITIS

Chronic pyelonephritis is an important, common, and dangerous disease. It is the most frequent cause of death from uræmia. Like its acute counterpart it can be primary, or secondary to abnormality of the urinary tract.

Lawrence Paul Garrod, Contemporary. Professor Emeritus of Bacteriology, St. Bartholomew's Hospital, London.
Theodor Albrecht Edwin Klebs, 1834–1913. Professor of Bacteriology successively at Prague, Zurich and Rush Medical College, Chicago, Illinois, U.S.A.

Pathology.—The inflammation is interstitial, and microscopically scars resulting from the destruction of adjacent parenchyma can be seen. These scars are unevenly distributed and nearly always are more evident in one kidney than in the other. Histologically it can be seen that the brunt of the onslaught has been borne by the renal tubules; they are atrophic, often dilated, and sometimes cystic. In time many of them are destroyed and disappear in scar tissue. On the other hand, the glomeruli retain their normal structure until late in the disease.

Chronic pyelonephritis is almost three times as common in females as it is in males. Two-thirds of the affected females are under forty years of age, while 60 per cent. of the males are over forty.

Clinical Features.—It is possible, but unusual, for chronic pyelonephritis to remain asymptomatic until advanced renal insufficiency appears.

Lumbar pain, dull in character, is present in 60 per cent. of cases.

Increased frequency and dysuria are leading symptoms in most cases.

Hypertension is present in 40 per cent. of cases, being more common in primary than in secondary pyelonephritis. It develops slowly and thus is more in evidence in long-standing cases. In 20 per cent. of cases the hypertension is of the accelerated ('malignant') type.

Constitutional symptoms comprising lassitude, malaise, anorexia, nausea, and headache constitute the main complaint in 30 per cent. of cases. The disease often remains unrecognised in these sufferers, perhaps for years.

Pyrexia. Attacks of pyrexia exceeding 37·8° C are the main symptoms in 20 per cent. of cases. The need to explain these attacks often leads to a thorough investigation including the urinary tract, and the disease is then brought to light.

Anæmia.—A normochromic anæmia due to unsuspected renal impairment may be the presenting feature.

The Urine. *Proteinuria.*—On account of the late destruction of the glomeruli, contrary to glomerulonephritis, the amount of protein passed in the urine is small (less than 3 g daily).

Casts are found infrequently.

White cells are numerous. A fresh three-hour urine should be examined and a count of over 200,000 per hour is abnormal—often it may be as high as several million. Ureteric specimens may reveal considerable difference in this respect between the kidneys, and on the ability of the individual kidney to concentrate and acidify urine.

Bacteriological Examination of the Urine.—Commonly found are *Esch. coli, Streptococcus fæcalis, proteus* and *pseudomonas.*

Treatment is not easy. Two principles must be followed: (1) to eradicate predisposing causes such as obstructions or stones, and (2) by repeated cultures and sensitivity tests to control and, it is hoped, ultimately to eradicate the infection with repeated courses of suitable drugs. In secondary cases, even if the cause can be removed, the renal pelves have frequently lost their musculature and are fibrotic and non-contractile. Moreover,

once the parenchyma has been damaged it is a locus of predilection for blood-borne organisms. Consequently chemotherapy and antibiotics confer as a rule only temporary benefit. The longer the infection has persisted, the more difficult is it to eradicate. When prolonged treatment is required, there is a definite place for the following inexpensive drug.

Mandelic acid and its salts are often curative in coliform infections and those caused by streptococcus fæcalis. Ammonium mandelate 2 g (or better, mandamine, which is mandelic acid and hexamine combined), together with a capsule of 1 g ammonium chloride, is given six-hourly. Fluids are restricted to 1·5 litres in the twenty-four hours. It is essential that the urine be kept acid (pH 5·3 or less). Contraindications to this form of therapy are impairment of renal function and infections producing ammoniacal decomposition of the urine.

In nearly 50 per cent. of patients with pyelonephritis due to infection by one organism only, in whom infection persists in spite of treatment with antibacterial drugs, it is found that the original organism has been replaced by another, e.g. *Streptococcus fæcalis*, instead of *Esch. coli*.

It is highly important to eradicate distant foci of infection whenever possible. In occasional cases when the disease is unilateral and associated with the accelerated type of hypertension, nephrectomy is sometimes curative. Partial nephrectomy, removing a badly damaged portion of renal tissue, may be necessary by helping to sterilise the urine and free the patient of pain.

Recurrent Dialysis.—In advanced cases, diminishing renal function may require institution of recurrent dialysis using an artificial kidney. Difficulty in controlling hypertension or renal infection may necessitate bilateral nephrectomy.

Transplantation of a kidney from a donor or a cadaver may be possible (p. 1317).

Investigation of a case of Pyelonephritis

The following investigations are carried out in chronic cases a week or more after treatment with antibacterial drugs, and in acute cases after the infection has subsided with treatment. These investigations are to discover any cause of obstruction to the upper or lower urinary tract, and/or a source of infection, which is present most often in the genital organs or the urethra.

(*a*) *The Clinical Examination is Repeated.*—The kidneys are palpated for tenderness and enlargement, and the bladder for chronic retention of urine. In middle-aged or elderly males the prostate is examined for enlargement or fibrosis. In male children, atresia of the meatus or meatitis is sought. Inspection of the cervix uteri often displays cervicitis or cervical erosion. Examination of the secretion expressed by prostatic massage sometimes accounts for the presence of infection. If no infection is found in these situations, a possible focus in carious teeth or infected tonsils is sought.

(*b*) *Renal Function Tests.*—To assess the glomerular and tubular function (p. 1133).

(*c*) *Excretory Pyelography.*—The plain film of the urinary tract may reveal the presence of a urinary calculus. In chronic pyelonephritis, and after an attack of severe acute or recurring acute pyelonephritis, changes in the pyelographic shadow or shadows will be manifest. Some of these are similar to those of early hydronephrosis, but they are more unequally distributed. Although the calyces become flattened or clubbed, this is more in evidence in one part of the kidney than another. Persistent poor definition in one group of calyces is presumptive evidence of chronic infection. In cases of longer standing the renal pelvis becomes slightly dilated, but, unlike hydronephrosis, the dilatation of the calyces predominates. The most important X-ray sign is narrowing of the cortex, often localised, and giving rise to depressed

scars seen as notches in the outline, or considerable contracture of one pole. Nephrotomography can be very helpful in demonstrating these scars.

(*d*) *Cysto-urethroscopy*.—After the instrument has been passed, residual urine, if any, is measured. Examination of the urethra may show chronic urethritis or the presence of a stricture. In the female urethro-trigonitis is commonly found. Hitherto unconfirmed obstruction to the prostatic urethra by an enlarged middle lobe or contracture of the bladder neck may be demonstrated. Evidence of cystitis is the most common finding. Sometimes the ureteric orifice, or orifices in bilateral cases, is seen pouting, œdematous, or gaping. Delay in efflux is usual on the affected or more affected side. Ureteric catheters are passed and specimens collected from each kidney. These specimens are examined for cells and bacteria. By these means it is ascertained whether the infection is bilateral or unilateral. In male children valves in the posterior urethra, or a contracture of the bladder neck, are sometimes revealed.

(*e*) *Micturating Cine-cystography*, using a cine-camera coupled to an X-ray image intensifier, may reveal reflux of urine up one or both ureters. This can be a transient phenomena due to infection. It is commonly a factor in childhood.

HYPERTENSION AND A UNILATERAL RENAL LESION

Renal ischæmia regularly produces increased arterial tension, as ischæmia of the renal parenchyma leads to the formation of a vasopressor substance. Too often cases are labelled essential hypertension without thorough investigation. Sometimes in a case of hypertension a unilateral diseased kidney is demonstrated and nephrectomy is followed by permanent lowering of the blood pressure. The most amenable lesion in this respect is chronic pyelonephritis with a short history of high blood pressure. Occasionally patients with a renal neoplasm, or renal calculi with infection, have been permanently benefited, in so far as hypertension is concerned, by removing the diseased kidney. Renal artery stenosis is a cause of hypertension (fig. 128). Direct arterial surgery (p. 133 and p. 145) may be curative.

PYONEPHROSIS

The kidney is converted into a multilocular sac containing pus or purulent urine, with a varying amount of renal parenchyma in its walls. A pyonephrosis can result from infection of a hydronephrosis, follow acute pyelonephritis or, most commonly, arise as a complication of renal calculus (calculous pyonephrosis). As a rule the condition is unilateral.

Clinical Features.—The classical triad of pyonephrosis is anæmia, fever, and a loin swelling. When the condition arises as an infection of a hydronephrosis the swelling may be a large one. When the pyonephrosis is open, an evening rise of temperature to 37·2° or 37·7° C is usual; if the pyonephrosis becomes closed, the temperature is higher. Pyuria, when present, gives rise to cystitis, and sometimes symptoms of that condition are the chief complaint.

Investigation.—A plain X-ray may show a calculus. Excretory pyelography shows the same vagaries as advanced hydronephrosis, in that the appearance of the shadow of the dilated renal pelvis and calyces is long delayed and may be absent. Cystoscopy often reveals cystitis with a purulent efflux from the ureter of the affected side. In closed cases the bladder may be normal and a ureteric catheter either becomes arrested, usually at the pelvi-ureteric junction, or passes the obstruction and gives exit to pent-up purulent urine.

Treatment.—Infection in an obstructed hydronephrotic kidney should be treated as an emergency. Antibiotics should be given, and the kidney drained by a large urethral catheter as a nephrostomy tube. In cases known

to be due to stone, the stone should be removed. Where obstruction is known to have destroyed most of the renal substance, and function on the other side is good, nephrectomy should be performed. Should the capsule prove to be densely adherent to the surrounding structures subcapsular nephrectomy (p. 1193) is performed. When a pyonephrosis arises in a single kidney, or the condition is bilateral, permanent nephrostomy may be the best possible measure. Drainage by an 'ileal conduit' to bladder or the skin is another possibility (p. 1232).

CARBUNCLE OF THE KIDNEY

The source of origin of the organism is usually a cutaneous lesion, such as a boil, carbuncle, whitlow, or an abscess of the breast, and the *Staphylococcus aureus* is conveyed to the kidney via the blood-stream. Occasionally a blow on the loin determines the issue, when injury to the kidney produces a small hæmatoma.

Morbid Anatomy.—On splitting open the kidney there is a necrotic mass of tissue, usually localised, involving the parenchyma (fig. 1357).

Clinical Features.—There is an ill-defined, tender swelling in the loin, persistent pyrexia and leucocytosis, signs that closely simulate a perinephric abscess. In early cases the urine contains neither pus cells nor organisms, but after a few days staphylococci can sometimes be isolated. Pyelography often shows compression or obliteration of a group of calyces, an appearance that does not differ from adenocarcinoma of the kidney.

Treatment.—Antibiotics have cured some early cases. When the response to antibiotic therapy is not dramatic the kidney must be exposed, the carbuncle incised, and the necrotic material removed. Hæmorrhage is not excessive and can be controlled by pressure with a moist warm pack. A drainage tube is passed down to, but not into, the resultant cavity and the wound is closed around the tube. Antibiotics are continued for at least ten days. Primary nephrectomy is indicated only when the major part of the kidney is involved by the carbuncle.

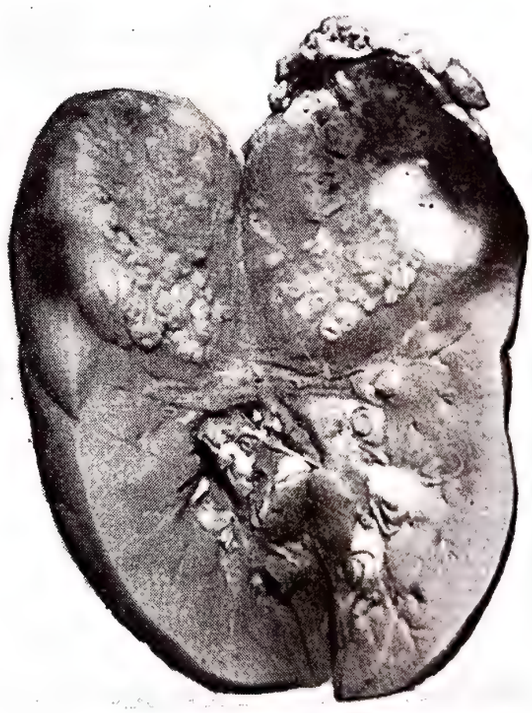


FIG. 1357.—Carbuncle of the kidney.
(*J. G. Yates-Bell, F.R.C.S., London.*)

PERINEPHRIC ABSCESS

The most common causes are depicted in fig. 1358. Other causes are infection of a perirenal hæmatoma, and perforation of the renal capsule from undue delay in operating upon a pyonephrosis or a renal carbuncle. A tuberculous perinephric abscess can arise from an advanced pyonephrosis or from tuberculosis of a nearby vertebra.

Clinical Features.—The classical symptoms and signs of a perinephric abscess are a high, swinging temperature, rigidity, tenderness, and fullness in the loin (fig. 1359). If the suppuration commences in the lower part of the perinephric fat, local signs present early, but when the suppuration is confined to the upper portion of the perinephric fat which lies beneath the lower ribs, it produces no visible swelling, and even rigidity and tenderness may be

absent. The leucocyte count is always raised, often to 20,000/mm³ (20×10^9/l). As a rule no pus or organisms are present in the urine.

Radiography shows obscuration of the psoas shadow, with one or more of the following additional signs—scoliosis with concavity towards the abscess, and elevation and immobility of the diaphragm on the affected side.

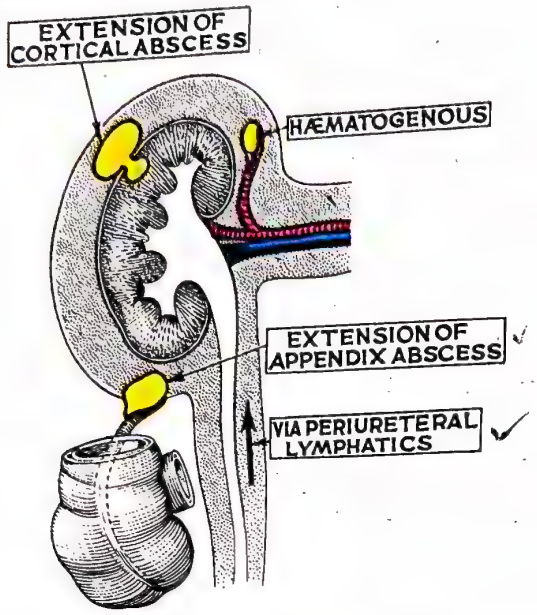

FIG. 1358.—Sources of perinephric abscess.

FIG. 1359.—A large perinephric abscess.

Mathé's Sign.—Absence of the downward displacement that occurs in the erect posture in every normal kidney. Two radiographs, one in the lying posture and one in the erect posture, during excretory pyelography are required. In established cases the kidney can be shown to be displaced forwards if a lateral view is obtained.

Treatment.—Under antibiotic cover a lumbar incision is made large enough to enable the surgeon to open up pockets both above and below the kidney. The surface of the kidney is palpated for an unruptured cortical abscess, which, if present, should be incised. A specimen of pus having been obtained for bacteriological examination, the wound is closed with ample drainage. Appropriate antibiotic treatment follows.

RENAL TUBERCULOSIS

Ætiology and Pathology.—Tuberculosis of the urinary tract cannot arise except as a blood-borne infection from a distant focus, which, in many cases, is impossible to locate.

When clinically recognisable, in the great majority of cases renal tuberculosis is apparently confined to one kidney. A group of microscopical lesions coalesce and discharge pus and tubercle bacilli along one set of tubules, and the pyramid which gives exit to the discharge becomes ulcerated (fig. 1360 A).

Course : *Tuberculous bacilluria* is a convenient term to designate a very early lesion of the renal cortex when no abnormality in the affected kidney can be detected, even by retrograde pyelography. It indicates the presence of active tuberculosis disease which may progress, and as such must be treated in the same way as the demonstrable lesions.

Charles Pierre Louis Mathé, Contemporary. Formerly Urologist-in-Chief, St. Mary's Hospital, San Francisco, California, U.S.A.

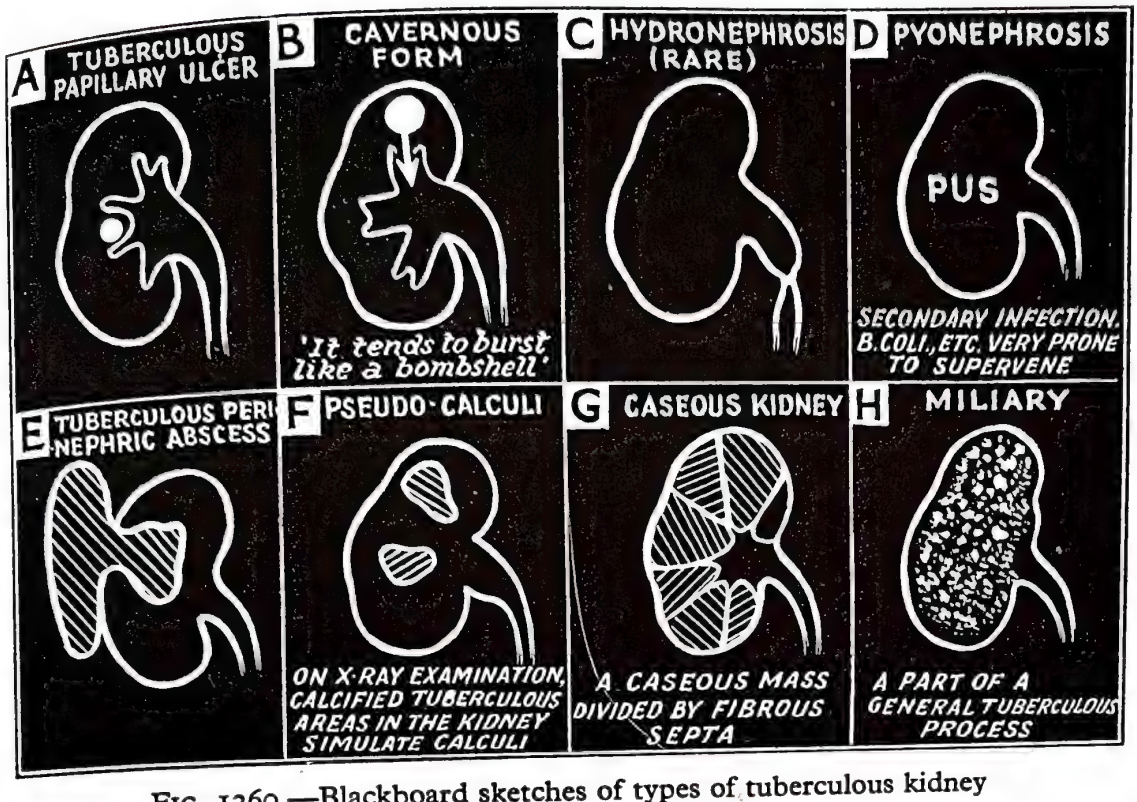

FIG. 1360.—Blackboard sketches of types of tuberculous kidney (macroscopic pathology).[1]

A macroscopical lesion progresses rather slowly, and other similar lesions appear in the same kidney. The infection can be confined to the affected kidney for months or years, causing one or other of the changes depicted in fig. 1360 C to G. More often the disease spreads along the ureter (tuberculous ureteritis) to give rise to tuberculous cystitis in both sexes and prostatitis, vesiculitis and later epididymitis in the male.

In the male, renal and genital tuberculosis can be associated before the bladder and posterior urethra are involved, in which event the genital infection probably occurs in the following way. An urgent desire to micturate causes the internal sphincter to open, while at the same time, because there are no immediate facilities for emptying the bladder, voluntary closure of the external sphincter is called into play. At that moment infected urine is forced under pressure into the mucosal crypts of the prostate and the common ejaculatory ducts (Wells).

Clinical Features.—Renal tuberculosis usually occurs between twenty and forty years of age. Men are affected twice as commonly as women, and the right kidney somewhat more commonly than the left.

Frequency.—The earliest symptom is increased frequency of micturition. Often this is the only symptom. It is progressive, the patient complaining that (over a period of months) the frequency has increased both by day and by night. Frequency is occasionally due to polyuria as the result of the renal tubular inflammation: it is usually due to patchy tuberculous cystitis.

Pyuria.—In early cases the urine is pale and slightly opalescent. The presence of pus cells without organisms in an acid urine is very suggestive of tuberculous urinary infection (Bacteriological examination, p. 1182).

[1] G is known also as the 'putty kidney' and by the French as the 'cement kidney'. It is nature's method of performing (ineffective!) autonephrectomy.

Charles Alexander Wells, Contemporary. Professor Emeritus of Surgery, Liverpool, England.

Painful Micturition.—Once tuberculous cystitis has set in, micturition becomes increasingly painful. First there is suprapubic pain if the bladder cannot be emptied immediately; later a burning pain accompanies micturition, and when secondary infection has occurred there is superadded agonising pain after micturition referred to the tip of the penis or to the vulva, often associated with terminal hæmaturia (strangury).

Renal pain is often absent, but sometimes the patient complains of a dull ache in the loin.

Hæmaturia.—In 5 per cent. of cases the disease is ushered in with painless hæmaturia occurring from an ulcer situated on a renal papilla. During the hæmorrhage, and after it has ceased, investigations may or may not demonstrate the presence of a renal lesion and tubercle bacilli in the urine. In the latter event more typical symptoms commence some months later. Apart from a few drops of blood at the end of micturition in cases complicated by severe cystitis, macroscopical hæmaturia occurs only occasionally.

A tuberculous kidney is œdematous and friable, and is therefore more likely to be damaged by trauma than is the normal pliable kidney.

Constitutional Symptoms.—A continuous slight loss of weight is usual. Evening pyrexia to 37·3° C occurs when the disease is fully established. A high temperature is indicative of a secondary infection or disseminating tuberculosis.

On Examination.—It is unusual for a tuberculous kidney to be palpable.

When a patient with renal tuberculosis has an enlarged kidney which can be felt, it is by no means certain that this kidney is the one that is diseased, for compensatory hypertrophy sometimes renders the healthy kidney both large and tender.

The prostate, vesicles, vas, and epididymis should be examined for nodules or thickening, which may indicate tuberculous invasion.

Investigation :

Bacteriological Examination of the Urine.—Prompt examination must be made of an early morning specimen before contaminants can overgrow. When, after staining a specimen of the sediment with Ziehl-Neelsen's stain, acid-fast bacilli are found, it is highly probable that they are tubercle bacilli, but the proof lies in culture or guinea-pig inoculation, either of which is reliable. **Most important—specific therapy should never be started until a positive culture has been obtained.** If this precaution is neglected, an exacting course of treatment may be started for a non-tuberculous condition, and at a later stage it is impossible to prove or disprove the diagnosis.

In few fields of medicine is the diagnosis more exact. The microscope demonstrates tubercle bacilli in 72%, the guinea-pig test in 94%, and the culture medium in 98% of cases.

A Plain X-ray may show calcification in healing foci. In gross disease this may be a rim around a caseous mass, or complete dense spheres. In minimal lesions specks of calcification may be scattered in one part of the cortex or pyramid. Ureteric calcification is late except at the lower end, and here, in males, the vesicles may also show patchy calcification.

Franz Heinrich Paul Ziehl, 1857–1926. Neurologist, Lübeck, Germany.
Freidrich Carl Adolf Neelsen, 1854–1894. Prosector, Stadt-Krankenhaus, Dresden, Germany.

Excretory pyelography (fig. 1361).

Changes in the Pyelogram commence with loss or dysfunction of one or more calyces, and irregular density in the nephrogram. Spasm or œdema may obliterate a calyceal neck, and if this becomes severe a hydrocalyx will develop. Complete obstruction leads to an abscess displacing adjacent calyces and the appearance of a space-occupying lesion. The bladder tends to become round and spastic when involved, and ulceration may produce spasm and flattening of the bladder in this area. Ureteric fibrosis leads to loss of the natural curves of the ureter, and a wider, straighter and shorter line between kidney and bladder.

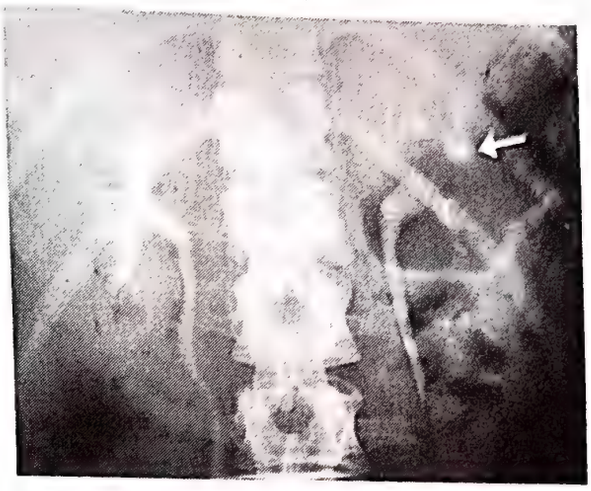

FIG. 1361.—Excretory pyelogram showing a small localised lesion with hydrocalyx. Healing took place under conservative treatment. (*Professor E. Wildbolz, Berne.*)

In late cases, the contralateral ureter becomes dilated also; this is not necessarily an indication of disease on the opposite side, for the dilatation may be due to the cicatrised bladder causing obstruction to the ureter in its intramural course.

Cystoscopy.—When increased frequency is the only symptom and it has not been present long, the bladder and the ureteric orifices are normal.

A unilateral cloudy efflux is sometimes observed. Either more frequent efflux or a delay in excretion of indigo-carmine is indicative of the side that is diseased. In 10 per cent. of cases there is an absence of efflux on the affected side, and no pathological changes in the bladder. These are examples of a closed ureter leading to so-called autonephrectomy, or a pyonephrosis.

Œdema causes pallor around a ureteric orifice and is the earliest cystoscopic sign of vesical involvement. Infiltration follows, and the mucous membrane of the affected ureteric orifice pouts. Tubercles appear, usually lateral to the ureteric orifice, and later in the dome of the same half of the bladder. By confluence of a circumscribed group of tubercles, a tuberculous ulcer, which has an irregular periphery, may form. In long-standing cases, as a result of sclerosing peri-ureteritis, which causes shortening of the ureter, the ureteric orifice becomes displaced upwards and its mouth remains open (the so-called 'golf-hole' ureteric orifice). As the disease progresses, the capacity of the bladder steadily diminishes. At any stage, if a secondary infection supervenes, the intense generalised inflammation of the bladder wall obliterates many of the characteristic features of urinary tuberculosis just described above.

Retrograde pyelography may be necessary when investigating a suspicious pyuria if renal function is poor and tubercle bacilli have not been seen in the Ziehl-Neelsen film. Appearances, such as shagginess of a calyx or an abscess of the parenchyma connected to a calyx by a narrow neck, are often displayed by this method when excretory pyelograms appear normal. Retrograde pyelography is also of great assistance

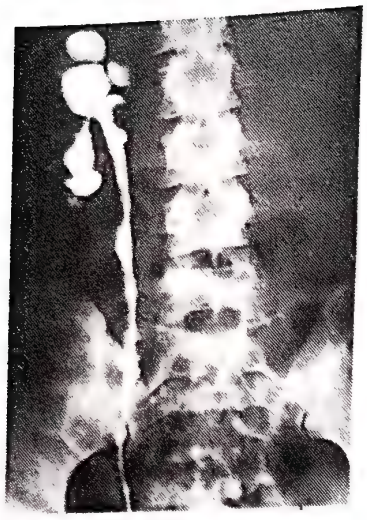

FIG. 1362. — Retrograde pyelogram showing advanced tuberculosis of the right kidney and ureter.

in cases of unilateral renal tuberculosis too advanced to concentrate dye given intravenously (fig. 1362). Remember, however, that the diagnosis depends on finding bacilli and *not* on the pyelographic appearances.

Examination of the Lungs.—A radiograph is necessary to exclude active or previous pulmonary tuberculosis.

Treatment.—(See p. 32). It is essential to have the patient under observation when commencing treatment. The liability to serious side-effects from the drugs used will usually become obvious within the first three weeks. Streptomycin must be given with great care and controlled by serum levels if renal function is impaired. Ideally the first six months, at least, should be spent in a 'sanatorium' where the patient becomes adjusted to taking rather unpleasant drugs in large amounts (as other patients are doing the same), and the problem of the patient who asserts that he is taking the drugs prescribed when in fact he is not, can be overcome.

Other drugs notably Rifampicin which can be taken orally (450–600 mg daily) together with INAH (300 mg daily) have been shown to produce a high cure rate with only six months' treatment. Relapses have been rare. Ethionamide 500 mg daily and Pyrazinamide 2 g daily are other useful drugs. The former has both intra- and extracellular activity while the latter has its main effect within the cell. Rifamycin and INAH are the drugs of choice as they are relatively less toxic and are countered by fewer resistant strains than the other drugs.

Prognosis in renal tuberculosis has improved enormously since the advent of chemotherapy and antibiotic treatment, and if the regimen detailed is carried out properly there should be a very low incidence of recrudescence of infection.

Operative Treatment.—Some lesions are surrounded by so much necrotic and fibrous tissue that antibiotic agents do not reach the organisms in sufficient concentration to kill them. Unilateral lesions of this character, and those in which the disease is more advanced, call for operative treatment, the optimum time for which is after four to six months of antibiotic treatment.

According to circumstances one of several operations is carried out. It must be emphasised that conservative surgery should be the aim, and several conservative procedures may prove necessary on one or both kidneys and ureters during the course of the disease. The fact that a horseshoe kidney is involved does not alter this principle, neither does the fact that one kidney may have been removed already.

1. **Renal Cavernotomy** (Hanley).—As the primary lesion of the calyx heals (fig. 1360 A and B) fibrosis tends to cause a stricture at the neck of the calyx. Radiological disappearance of such a cavity should be viewed with suspicion, and usually indicates that there is a closed pyocalyx which remains infected, as its avascularity prevents the drugs from reaching the tubercle bacilli present. Sometimes such a pyocalyx will

re-open and discharge its contents some six months after starting treatment, but if this does not occur after a year and a calyx is radiologically 'missing', a drainage operation must be undertaken.

The kidney is approached as described on p. 1192 and after clearing the perinephric fat, the abscess is aspirated with a syringe and wide-bore needle. The roof of the abscess is removed with scissors and its caseous contents swabbed out until healthy granulation tissue is reached. Any bleeding from the cut edges is controlled with fine catgut stitches (fig. 1363). The wound is closed without drainage. As the cavity is closed off from the pelvis (if it is not, the operation is unnecessary), there is no leakage of urine. Multiple abscesses in both kidneys can be dealt with in this way.

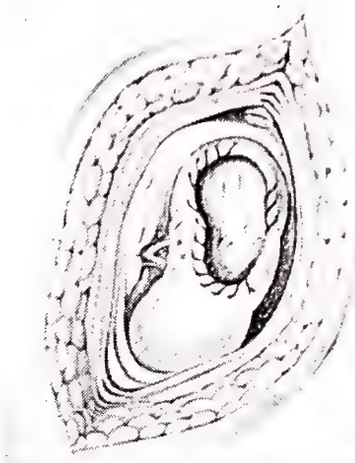

FIG. 1363.—Renal cavernotomy completed. *(After H. G. Hanley, London.)*

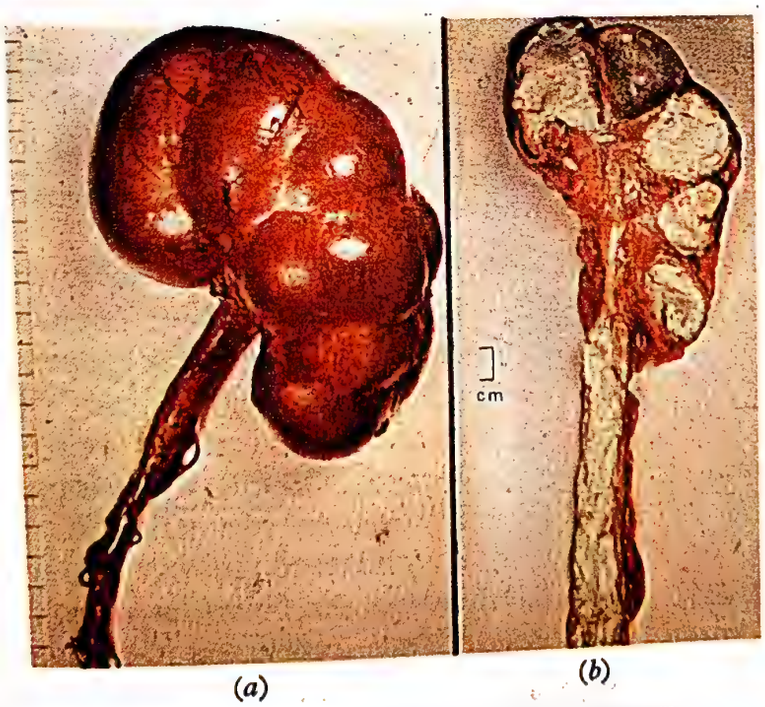
2. **Nephro-ureterectomy.**—The indication is a unilateral lesion with gross impairment of renal function on the affected side.

In such advanced cases the ureter as well as the kidney usually proves to be diseased, and nephro-ureterectomy (fig. 1364), in which, through a separate incision, the ureter is divided and ligated at its entrance to the bladder before commencing lumbar nephrectomy, is the operation of choice. By total removal of the ureter a possible source of continued infection of the bladder is removed, and the incidence of post-operative wound infection and sinus formation is reduced.

3. **For Hydronephrosis.**—This is due to tuberculous cicatricial contracture and healing of the bladder around the lower end of the ureter or at the pelvi-ureteric junction. A procedure similar to the Anderson-Hynes operation (p. 1159) should be performed.



(a) *(b)*

FIG. 1364 (*a* and *b*).—Nephro-ureterectomy. Tuberculous pyonephrosis.

4. **For Systolic bladder** (*syn.* 'thimble bladder' (fig. 1401)).—This is due to healing by fibrosis and often leads to extreme frequency of micturition. The best operation is the type of ileo-cystoplasty, described by Hanley, in which a 15 cm opened-out loop of terminal ileum is sutured to the bladder, from which the dome has been removed to provide a maximum opening.

Howard Granville Hanley, Contemporary. Surgeon, St. Paul's Hospital, London.

ABACTERIAL PYURIA

That sterile pyuria indicates urinary tuberculosis is almost axiomatic. Nevertheless, a small group of cases of abacterial pyuria is definitely non-tuberculous. The symptoms simulate renal tuberculosis very closely, and it is only when repeated examinations of the urine, and in the male the seminal fluid, fail to reveal *mycobacterium tuberculosis* or other bacteria, and cultures and guinea-pig inoculations are negative, that the diagnosis can be made. Pyelography occasionally shows slight dilatation of the renal pelvis and ureter of one or both sides; more usually this examination is negative. Cystoscopy reveals a severe cystitis and often diminished bladder capacity. Occasionally amœbiasis is responsible.

Treatment.—Aureomycin usually cures the condition in three days. In cases resistant to this treatment 0·3 g of neoarsphenamine intravenously weekly for four weeks is often successful. In rare instances, when amœbiasis is responsible, treatment with emetine hydrochloride will eradicate the infection.

NEOPLASMS OF THE KIDNEY

Benign Neoplasms

Adenoma.—Pea-like cortical adenomas are sometimes found at necropsy. They give rise to no symptoms, and are only of academic interest.

Angioma may give rise to profuse hæmaturia.

Truly benign tumours of the kidney are so rare that a good rule is that *all neoplasms of the kidney which can be recognised clinically should be considered malignant and treated as such.*

Malignant Neoplasms

Clinically neoplasms of the kidney are divided into two classes:

In children between the ages of one and seven.
In adults after the age of forty.

Between the ages of seven and forty malignant neoplasms are unusual.

RENAL NEOPLASMS IN CHILDREN

FIG. 1365.—Wilms's tumour

Max Wilms, 1867–1918. Professor of Surgery, Heidelberg, Germany.

Wilms's tumour (*syn.* nephroblastoma) is a mixed tumour containing epithelial and connective tissue elements arising from embryonic nephrogenic tissue, situated originally in one or other pole of the kidney. In infancy such tumours are very occasionally bilateral. Far more common is a unilateral tumour. They usually occur during the first four years of life. Cases arising under one year seem to have a much better prognosis.

Pathology. — *Macroscopically.* — On section the neoplasm is a greyish-white or pinkish-white colour; its consistence varies with the rapidity of the growth, i.e. the more rapid the growth, the softer the tumour (fig. 1365).

Microscopically it is composed mainly of two types of cells—epithelial and connective-tissue. Cartilage, bone, and smooth or striped muscle fibres are occasional findings. The epithelial and connective-tissue cells exist side by side, but one type is usually predominant. Thus the tumour is composed of mixed cellular elements, some of which are radio-sensitive and some radio-resistant. Consequently, the radio-resistant elements show a continuance of activity in spite of radiotherapy.

Clinical Features:

Abdominal Tumour.—The symptomatology is always the same. An abdominal tumour appears and progresses rapidly, while the general health deteriorates. Examination of the abdomen reveals a mass which may be enormous; the bulk of the tumour is on one side of the abdomen. Wilms's tumour tends to grow within a capsule, pushing the rest of the kidney aside; thus the reniform shape of the kidney is lost early.

Pyrexia.—Half these patients have some elevation of temperature, which disappears if the tumour is removed.

Hæmaturia is a sign of ill omen. It denotes that the previously encapsulated tumour has burst into the renal pelvis, and all patients suffering from a Wilms's tumour with this sign die within nine months (Scott).

Pyelography shows gross deformity of some of the calyces.

Metastases.—Wilms's tumour metastasises early, mainly by the blood-stream to the lungs, less commonly to the liver, rarely to bones, and exceptionally to the brain. Lymphatic dissemination is much less common.

Differential Diagnosis.—From a practical standpoint there is but one swelling with which Wilms's tumour can be confused, and that is retroperitoneal neuroblastoma, but as the treatment is precisely the same such differentiation is an academic exercise. However, if radiography reveals bone metastases, this distinctly favours a neuroblastoma. Although these abdominal tumours arouse considerable diagnostic interest, for fear of accelerating dissemination, multiple examinations by, for instance, a class of students, must be forbidden.

Treatment.—*Immediate nephrectomy and post-operative radiotherapy.* The earlier nephrectomy can be carried out, the better. A few hours may be necessary to correct anæmia by transfusion. Radiotherapy should be commenced immediately after operation, and 200 rad given daily to a total of 4,000 to 4,500 rad.

Prognosis.—Under the age of one year 80 per cent. survive five years, over this age it drops to 30 per cent. Recurrences usually occur within a year, so a child surviving eighteen months is probably cured.

Bilateral Cases and Inoperable Cases.—Radiotherapy should be given to the renal areas. There is some hope that chemotherapeutic agents and particularly actinomycin D may prove of value in these cases.

RENAL NEOPLASMS IN ADULTS

1. **Grawitz tumour** (*syn.* adenocarcinoma; hypernephroma) is the commonest neoplasm of the kidney (75 per cent.). It arises in the cortex, possibly from a pre-existing adenoma, probably *per primam* in cells of the uriniferous tubules.

Lyall Stuart Scott, Contemporary. Surgeon, Urology Department, Victoria Infirmary, Glasgow, Scotland.
Paul Albert Grawitz, 1850–1932. Professor of Pathology, Greifswald, Germany.

Pathology.—A tumour of moderate size is spherical in shape, and it often occupies one or other pole, the seat of election being the upper pole; less often it is in the central portion of the kidney. On section it is characteristically yellow (due to lipoid); less often it is dull white, or semi-transparent. Hæmorrhagic areas are often seen. The tumour is divided into numerous lobules by fibrous septa (fig. 1366). The larger the tumour the more extensive is central hæmorrhage and necrosis.

FIG. 1366.—Adeno-carcinoma of the kidney.

Microscopical Structure.—The most common appearance is solid alveoli of cubical or polyhedral clear cells, with deeply stained small rounded nuclei and abundant cytoplasm containing lipoids, cholesterol, and glycogen. The cells may also be arranged in the form of papillary cysts or tubules. In a much smaller percentage the cells are granular (dark). Clear and dark cells can co-exist in different parts of the same tumour. In all cases the stroma is scanty but rich in large blood-vessels, the walls of which often appear, in places, to consist of tumour cells.

Spread.—As the tumour enlarges, it encroaches upon a group of calyces and is prone to grow into the renal veins. Pieces of growth becoming detached are swept into the circulation, to become arrested particularly in the lungs to produce 'cannon ball' secondary deposits, and in bones. Occasionally, when a secondary growth appears in a long bone, it remains the only metastasis for perhaps a year or more.

While spread by the blood-stream predominates, spread by lymphatics occurs also. If the tumour bursts through the renal capsule into the perirenal tissues, it then metastasises to the lymph nodes in relation to the hilum of the kidney, and from there to the para-aortic and other lymph nodes.

Clinical Features.—Men are more often affected than women, the ratio being 2 : 1. Typically the first sign is intermittent hæmaturia. Clot colic may follow. Dragging pain in the loin is sometimes a leading symptom. Occasionally the first manifestation is a palpable renal swelling. In the adult male a rapidly developing varicocele is a rare but impressive sign.[1]

FIG. 1367.—Arteriogram showing vascular 'blush' due to a metastasis from a Grawitz tumour.

Atypical Cases.—(*a*) In 25 per cent. of cases the primary growth remains 'silent', the patient presenting because of secondary deposits such as a painful enlargement of a bone (fig. 1367), a spontaneous fracture, persistent cough, or hæmoptysis.

(*b*) Occasionally persistent pyrexia (37·8°–38·9° C) is the only symptom, there being no infection to account for the temperature. It is presumably

[1] A left-sided varicocele is more likely, as the left spermatic vein joins the left renal vein.

due to absorption of blood and necrotic material. Such pyrexia usually disappears after nephrectomy: should it persist metastases are present.

(*c*) In a small group of cases the patient presents on account of lassitude and is found to be extremely anæmic, and anæmia being out of proportion to that which could be expected from the hæmaturia, if such be present.

(*d*) 'Polycythæmia' occurs in 4 per cent. of cases. The sedimentation rate is *always raised* above the 1 to 2 mm found in idiopathic polycythæmia vera. The blood count will return to normal after nephrectomy, but a return of the polycythæmia has been known with development of metastases.

(*e*) A nephrotic syndrome has been the presenting feature in some cases of hypernephroma.

(*f*) Endocrine disturbances. Renin secreting tumours producing hypertension have been recorded.

Early Diagnosis.—By the time a patient has the classical triad of symptoms, viz. hæmaturia, pain, and a palpable renal tumour, he nearly always has metastases. It is therefore of paramount importance to endeavour to make an early diagnosis, and any one of these symptoms calls for a thorough renal investigation. Patients with hæmaturia should be examined cystoscopically while the bleeding is in progress. If blood is seen issuing from one ureteric orifice, and there is a clear efflux from the other, the information gained is of considerable importance, but is by no means conclusive evidence of a renal neoplasm. Extremely suggestive is bleeding occurring from a palpable kidney. When blood is not seen issuing from a ureter, but an enlarged middle lobe of the prostate or a papilloma of the bladder is discovered, it must not be assumed that the source of the hæmorrhage has been found. Investigation must proceed until each kidney has been proved either to be normal or culpable.

Pyelography.—The early diagnosis rests almost entirely on pyelography.

Excretory pyelography may be inconclusive in early cases, because of lack of precise definition, and in late cases because there is poor or absent concentration of the medium, but at all times it is of great value in determining the function of the contralateral kidney. The presence of a projection in the cortical outline is important.

Tomography during the nephrogram phase can be helpful in outlining the periphery and may distinguish cyst and tumour.

Retrograde pyelography is often required because of the better delineation it affords. The principal pyelographic changes are:

(*a*) Filling defects due to invasion of one or more of the minor or major calyces. Very characteristic is failure of the medium to enter one major calyx.

(*b*) Elongation and compression of one or more calyces and sometimes of the renal pelvis causing the 'spider-leg' deformity (fig. 1368). In congenital cystic kidneys the 'spider legs' are broader, more clearly cut, and involve most if not all of the calyces; also, the condition is bilateral.

(*c*) Displacement of the renal pelvis and the distorted calyces downwards

in growths occupying the upper pole. Growths of the lower pole often displace the ureter inwards.

(*d*) In advanced cases (which may give no shadow on excretory pyelography) the interior of the calyces and renal pelvis are so encroached upon that they are represented by a few, irregular, widely separated shadows.

FIG. 1368.—Pyelogram in a case of hypernephroma of the left kidney. The only symptom was one attack of painless hæmaturia.

Chest X-ray.—A radiograph of the thorax should always be taken before deciding the best course of treatment. It is not rare for a hitherto unsuspected metastasis or metastases in a lung to be revealed in this way.

Aortography, usually by the retrograde route, will show an avascular area in the case of cyst, and abnormal vessels and pooling in the case of tumour.

Bone Scans should, if possible, be carried out as this may reveal metastases which fail to show on X-ray.

Differential Diagnosis.—(*a*) Hæmorrhage into a hydronephrosis, (*b*) congenital cystic kidney with hæmaturia, or (*c*) a solitary cyst of the kidney can closely simulate a renal neoplasm, or (*d*) aneurysm of a renal artery.

Treatment.—In cases without metastases the treatment is nephrectomy with removal of the perinephric fat.

The incision is a matter of personal preference, the objective being to gain wide exposure of the enlarged kidney and especially of its pedicle. The abdominal approach (p. 1193) is best for accomplishing the following manœuvre.

Preliminary Division of the Renal Pedicle.—It is advisable to deal with the renal pedicle before manipulating the kidney, otherwise blood-borne metastases may occur as a direct result of the operation. Before undertaking ligation and division of the renal pedicle the renal vein and vena cava should be palpated delicately between the finger and thumb for a tumour-thrombus which, if present, calls for opening the vein and extracting the thrombus.

In other respects the details of the operation are those described on p. 1192.

When an extremely large tumour is encountered a paramedian incision is easily enlarged by a transverse cut.

Radiotherapy:

Pre-operative irradiation sometimes renders a large tumour smaller but, because of the uncertainty and the delay in operation entailed, pre-operative irradiation is not often advised.

Post-operative irradiation has been said by some authors to improve results, but other series have shown the exact opposite. It should be used if the tumour could not be completely removed at operation.

In inoperable cases radiotherapy often results in dramatic regression of a metastasis, but too often the improvement is only temporary, and there follow other metastases that are less radio-sensitive.

Cytotoxic chemotherapy (e.g. methotrexate, vinblastine) may have a place during surgery to kill circulating cells, and, in conjunction with super-voltage therapy, in treating metastases.

Medroxyprogesterone acetate (Provera) (200 mg two or three times a day) has been considered helpful (Bloom)[1].

Immunotherapy.—Grawitz tumours may be a hopeful field for research into immunotherapy. Reports of cures by removal of single metastases, and the disappearance of metastases after removal of a primary do suggest considerable host resistance in a tumour which is liable to spread by the blood stream. Attempts are being made to culture tumour cells removed at operation, inactivate them, and produce an antigen for administration to the patient if recurrences develop later.

Prognosis.—Even some of the largest neoplasms have been followed by a permanent cure. In operable cases 44% of the patients are alive and well after three years, and 30% after five years. If there is macroscopic involvement of the renal vein or its branches, the prognosis is poor.

2. **Papillary Tumours of the renal pelvis** (fig. 1369) resemble those in the bladder but are less common. They tend to invade the kidney proper, and to take on malignant characteristics. Spread downwards by seeding may give rise to multiple ureteric and bladder tumours, but a diffuse metaplasia may be the result of some carcinogenic agents in the urine (p. 1222).

Clinical Features.—Hæmaturia is often continued for months at a time. A renal swelling is absent, except in rare cases where the pelvi-ureteric junction

FIG. 1369.—Papillary tumour of the renal pelvis.

FIG. 1370.—Pyelogram showing a filling defect of the renal pelvis due to papilloma.

becomes occluded and a hydronephrosis results, in which event there is lumbar pain. Clot colic may occur.

Pyelography reveals a characteristic filling defect of the renal pelvis (fig. 1370).

[1] This is based on the demonstration that female hamsters do not readily produce hypernephromas whereas males can be made to do so readily by dosing them with œstrogens, and that progesterone protects a male hamster from this effect.

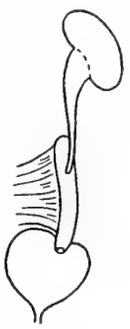
Harris Julian Gaster Bloom, Contemporary. Consultant Radiotherapist, Royal Marsden Hospital, London.

Treatment.—Nephrectomy with extended ureterectomy is the correct treatment. The intramural portion of the ureter along with the ureteric orifice must be excised in continuity by sleeve resection of the bladder wall.

3. **Squamous-celled carcinoma of the renal pelvis** is the least common variety of malignant disease of the kidney. In some instances it appears to be preceded by leukoplakia, and in most cases a stone or stones are present.

Unless the stone gives rise to symptoms, this is the most elusive of all renal neoplasms, for it causes indefinite abdominal pain which finally becomes localised in the region of the involved kidney. Hæmaturia is slight, or to be found only on microscopical examination of the urine. Excretory pyelography shows a kidney excreting little or no medium. Retrograde pyelography sometimes reveals a deformed renal pelvis. Owing to diagnostic difficulties, by the time nephrectomy is performed there are often widespread metastases that are radio-resistant. This neoplasm has the worst prognosis of any renal neoplasm.

Primary neoplasms of the ureter are rare, and similar to those of the renal pelvis. The symptoms are identical with those of a neoplasm of the renal pelvis, although hydronephrosis, hæmonephrosis, and pyonephrosis are more frequent accompaniments. Occasionally a portion of a papillomatous growth can be seen protruding from a ureteric orifice. Usually the diagnosis is made by pyelography.



Papillary tumours of the ureter should be treated by nephro-ureterectomy, as the epithelium frequently shows changes of carcinoma in situ at many sites. The intra-mural ureter should be removed, or the epithelium destroyed by fulguration. Only rarely is it justifiable, because of reduced renal reserve, to perform resection of the ureter, and replacement by an ileal conduit viz.——————→
On the whole, the prognosis of tumours of the ureter is very poor, largely on account of late diagnosis.

EXPOSURE AND REMOVAL OF THE KIDNEY

The kidney lies in a deep recess beneath the rigid bulwarks of the thoracic cage and, having regard to the possibility of a short renal pedicle, no single incision will meet all requirements.

The Oblique Lumbar Incision (Morris).—The patient is placed in the lateral 'kidney' position (fig. 1371), and is held in this position by a broad band of adhesive strapping, which is fixed to one side of the table and passed over the pelvis to the other side. The arm-rest also steadies the patient and relieves the chest of the weight of the arm, which would otherwise embarrass respiration. Morris's classical incision commences 1·25 cm below and lateral to the angle made by the twelfth rib with the outer border of the sacrospinalis, and it passes downwards and outwards towards the anterior superior iliac spine (fig. 1372) and all muscular layers are incised until the extraperitoneal fat is reached. An alternative and more favoured approach is to make the incision over the 12th rib and then either to resect the rib or, by displacing the upper half of the periosteum, to 'drop' it into the lower part of the wound. Care must be taken when removing periosteum not to open the pleural cavity. The pleura will be seen lying on the diaphragm after removing the rib. The extraperitoneal fat has a free posterior border and this is displaced forwards to display the perinephric fascia, which is then incised to reveal the perinephric fat

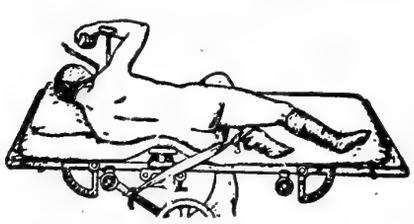


FIG. 1371.—Position on the operating table for exposure of the kidney by Morris's incision.

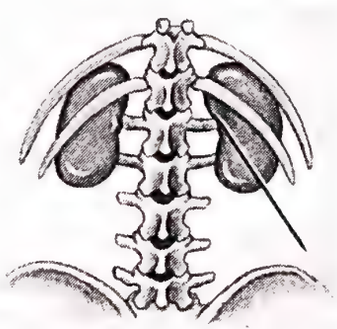

FIG. 1372.—Morris's incision.

Sir Henry Morris, 1844–1926. Surgeon, Middlesex Hospital, London.

surrounding the kidney. To perform nephrectomy the kidney is lifted from the posterior leaf of the perinephric fat, the fingers of one hand being inserted behind the pelvis and the vessels. Fat and fascia are dissected away from these structures as they lie on the operator's fingers. The vessels are ligated individually and the ureter is divided at a convenient site. The wound is closed in layers with a corrugated drain placed beside the pedicle.

If the pleura has been breached, the anæsthetist should expand the lung fully before the pleura is closed, at the end of the operation. An X-ray should be taken to check that the lung is re-expanded. Any residual pneumothorax may need to be aspirated.

Transabdominal nephrectomy is frequently employed for the removal of renal tumours, as it gives an unrivalled approach to the renal vessels which must be tied before the tumour is handled, in order to prevent cells being displaced into the circulation by the manipulations. A transverse or paramedian incision is used.

Subcapsular Nephrectomy.—In order to prevent damage to densely adherent structures such as the duodenum, colon, and spleen, the kidney may be removed by incising the capsule along the convex border and dissecting it free to the hilum, where it is again incised to allow access to the renal pedicle.

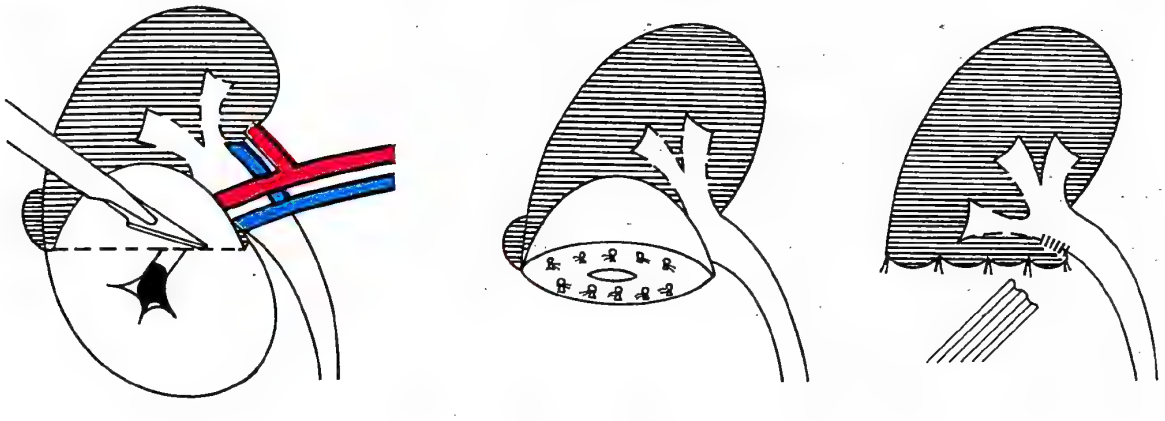

FIG. 1373.—(A) Capsule preserved and reflected; clean cut across parenchyma. Isolation of the affected calyx. (B) Hæmostasis by suture of individual vessels. (C) No attempt to approximate the cut surface of the renal parenchyma, just cover the surface with the capsule.

Partial Nephrectomy (Semb).—A wide lumbar exposure with resection of the twelfth rib is required. Bleeding is controlled by compression of the appropriate branches of the renal vessels. The stages of the excision are shown in fig. 1373.

Carl Boye Semb, 1895–1971. (*See footnote, p. 722*).

CHAPTER 55

THE URINARY BLADDER

SURGICAL ANATOMY AND PHYSIOLOGY

Surgical Anatomy.—Possessing an anterior, superior and posterior surface and being lined by transitional epithelium, the average bladder is capable of holding between 400 and 500 ml. of urine without over-distension. The bladder wall is made up of a muscular coat of unstriated muscle, known as the **detrusor muscle,** the fibres of which are arranged in three more or less distinct strata. *The internal layer* is thin, and its fasciculi have a reticular[1] arrangement. *The middle layer* is thicker than the others, and consists of densely interlaced fasciculi running mainly in a circular direction. When hypertrophy of the musculature of the bladder occurs it is the fasciculi of this layer that stand out and give rise to the characteristic trabeculation of the bladder wall (fig. 1429). While this layer is virtually absent within the limits of the trigone, its fibres are so well marked below that structure as to warrant their being accorded the dignity of the term **sphincter vesicæ.** The **trigonal muscle** is a separate entity derived from a prolongation of the longitudinal layer of each ureter. In the trigone the muscular strands from each side decussate, and eventually are inserted into the wall of the posterior urethra. *The external layer* is composed mainly of longitudinal fibres. Some of the fibres of this layer are prolonged in the pubo-prostatic ligaments (see below).

Supports of the Bladder.—Several parts of the related pelvic fascia are described as **true ligaments of the bladder.** The rectovesical portion of the pelvic fascia supports the bladder posteriorly. At the base of the bladder this fascia is united closely to the muscular tunic, but it thins out rapidly as it is reflected upwards. The two lateral true ligaments of the bladder are indistinct, but the anterior, or **pubo-prostatic ligaments,** are well defined, and are of great surgical importance. Each stretches from the front of the prostate and adjacent portion of the bladder to the lower part of the periosteum of the pubis.

The urachus and obliterated hypogastric arteries, together with the folds of peritoneum overlying these structures, are called the **false (median and lateral umbilical) ligaments of the bladder.** Condensation of fascia around the blood-vessels passing to the bladder is known as the **superior and inferior vascular pedicles.**

Arteries.—The superior and inferior vesical arteries are derived from the anterior trunk of the internal iliac artery. Branches from the obturator and inferior gluteal arteries, and in the female from the uterine and vaginal arteries, also help to nourish the bladder.

Veins form a plexus on the antero-inferior surface of the bladder; in the male the prostatic plexus (fig. 1427) is continuous with the vesical plexus, which drains into the internal iliac vein.

Lymphatics accompany the veins, and drain into the lymph nodes along the internal iliac vessels. Some lymphatics from the fundus pass to lymph nodes situated at the promontory of the sacrum.

Physiology.—Micturition is partly a reflex and partly a voluntary act. The nerves concerned in micturition are:

The sympathetic fibres, which arise in segments twelfth dorsal to third lumbar. These fibres pass via the presacral nerve and the sacral sympathetic chains to the inferior hypogastric plexus, and thence to the bladder.

---

[1] Reticular (Lat. *reticularis*) = resembling a net.

The parasympathetic innervation, which is derived from the anterior primary divisions of the second, third and fourth sacral segments. These fibres pass through the pelvic splanchnic nerves to the inferior hypogastric plexus, from which they are distributed to the bladder.

The somatic innervation also comes from the second, third and fourth sacral segments as the pudendal nerves which pass, not to the bladder itself, but to the sphincter urethræ (striated muscle).

While the sympathetic nerves convey afferent painful stimuli of over-distension *from* the bladder to the brain, it is unlikely that either set of autonomic nerves convey *to* the bladder any cortical impulses, such impulses being transmitted via the pudendal nerves to the sphincter urethræ, relaxing the latter. At the same time stretching of the muscle fibres by distension of the bladder initiates a reflex which is mediated through the parasympathetic nerves, and the detrusor muscle contracts. The neurogenic theory therefore ascribes the act of micturition to a stretch reflex which, if the time or place are not propitious, can be inhibited by cerebral control (fig. 1374).

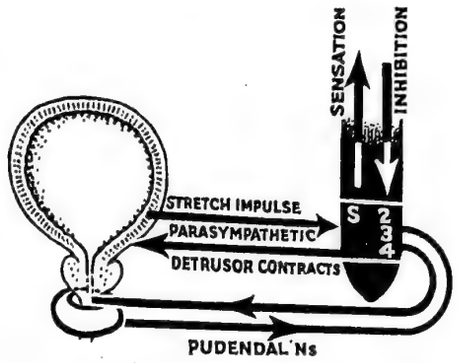

FIG. 1374.—The nervous control of the bladder. The sympathetic innervation has been omitted for the sake of simplification.

ECTOPIA VESICÆ (*syn.* EXSTROPHY OF THE BLADDER)

Ætiology.—Incomplete development of the infra-umbilical part of the anterior abdominal wall, associated with incomplete development of the anterior wall of the bladder, is the embryological origin of the condition.

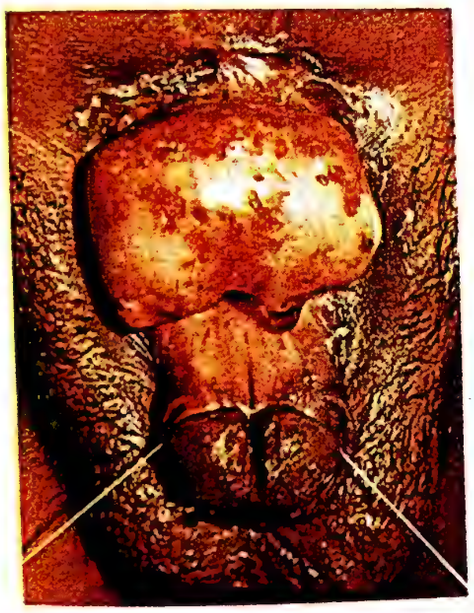

FIG. 1375.—Ectopia vesicæ in a male. A drop of urine is seen at the left ureteric orifice, the corona glandis being retracted by threads. (*G. D. Adhia, F.R.C.S., Bombay.*)

Clinical Features.—Ectopia vesicæ occurs once in 50,000 births, and may be complete or incomplete. In the more common complete variety, because of the pressure of the viscera behind it, the deep-red posterior bladder wall protrudes through the defect (fig. 1375). If the exposed mucous membrane, which bleeds readily, is drawn gently upwards, the paler, wet trigone is displayed, and effluxes of urine from the ureteric orifices can be seen. There is a well-defined line of demarcation between the protruding mucous membrane and the adjacent skin, and, especially after reducing the extruded bladder wall beneath the mucocutaneous junction, the firm edge of the hernial ring can be felt. Usually the umbilicus is absent. There may be umbilical and inguinal herniæ. The rectal sphincter is often lax. The sex ratio is about four males to one female.

In the male, the completely epispadiac penis is broader and shorter than normal, and not infrequently bilateral inguinal herniæ are present; the prostate and seminal vesicles are rudimentary or absent, whereas the testes are normal and descend more often than not. *In the female*, the clitoris is cleft and the labia minora are separated anteriorly, exposing the vaginal orifice. In both sexes there is separation of the pubic bones

(fig. 1376), which are connected by a strong ligament, and, except for the fact that the patient has a waddling gait, this bony defect causes no disability; indeed, in those female sufferers who become pregnant, it facilitates delivery. The linea alba is as wide as the separation of the pubic bones. In the rare incomplete form the pubes are united and the external genitalia are more normal.

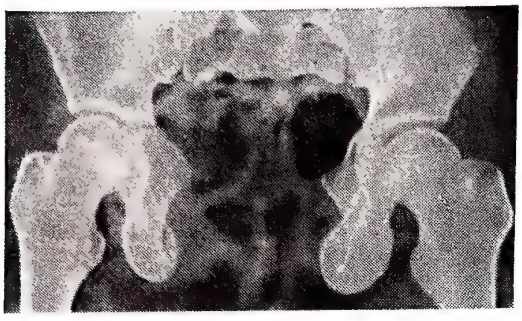

FIG. 1376.—Showing the separation of the pubes in a case of ectopia vesicæ. (*The late Professor Grey Turner, London.*)

The lot of a patient with ectopia vesicæ is particularly unfortunate. A portable urinal seldom keeps him dry for long, and the odour of urine always accompanies him. Frequently the everted vesical mucous membrane becomes ulcerated and painful. It undergoes metaplastic changes, and sometimes becomes the seat of an adenocarcinoma. Attempts to prevent recurrent attacks of ascending pyelonephritis by chemotherapeutic and antibiotic agents are only partially successful; 50 per cent. of those afflicted die of renal failure before the age of thirty.

Treatment

(*a*) *Diversion of urine* (p. 1229), into the colon, followed some months later by cystectomy. The operation is undertaken between four and six years of age.

(*b*) The best long term results would seem to follow diversion into an *ileal conduit* (p. 1230), *with excision of the bladder*, at the age mentioned. Renal function is likely to be better maintained than following uretero-colic anastomosis, and there are no problems of rectal control (see clinical features).

(*c*) *Iliac Osteotomy and closure of abdominal wall.*—In recent years, attempts to reconstruct the bladder and sphincters by operation within the first year of life have shown that it is possible to obtain a sound mid-line abdominal scar by commencing the operation with osteotomy of both iliac bones just lateral to the sacro-iliac joints. The bladder can be closed, and the reconstructed urethra displaced behind the pubis, which now meets in the mid-line. However, the ultimate results in respect of continence, freedom from urinary infection, and stone formation are disappointing, though in males the procedure may be a useful method of keeping the patient dry with an appliance. It is better, if this is the intention, to make no attempt to produce continence at the bladder neck.

Results.—Comparatively few who have undergone successful uretero-sigmoidal implantation for ectopia vesicæ live for twenty years. The causes of the untimely demise are (1) stricture at the site of anastomosis and bilateral hydronephroses, (2) recurrent pyelonephritis and (3) hyperchloræmic acidosis (p. 1232). Many different methods of implanting the ureters have been devised (fig. 1423); all aim at reducing the risks of stenosis and reflux.

RUPTURE OF THE BLADDER

Intraperitoneal 20 per cent.
Extraperitoneal 80 per cent.

As the bladder has intraperitoneal and extraperitoneal relations it follows that rupture or perforation results in either intraperitoneal or extraperitoneal extravasation of urine (figs. 1377 and 1378). Intraperitoneal rupture may be due to a blow, kick or fall on to a fully distended bladder and it is more common in the male than in the female. Extraperitoneal rupture is usually caused by a fractured pelvis, occasioned by the all too common road traffic accidents of today. Other causes of rupture or perforation of either type include gunshot wounds, stab wounds, the passage of instruments, endoscopic resection, or diathermy coagulation of bladder tumours.

Intraperitoneal Rupture.—There is sudden, agonising pain in the hypogastrium, often accompanied by severe shock and perhaps syncope. However, especially if the patient was 'drunk and distended', in a few minutes

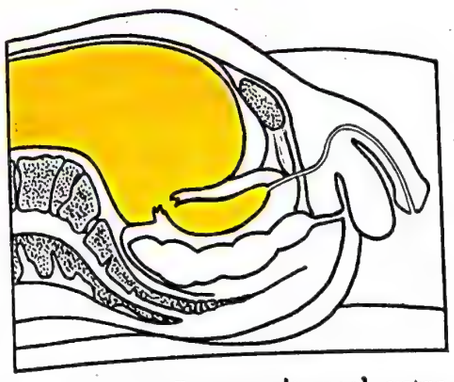

FIG. 1377.—Intraperitoneal extravasation of urine.

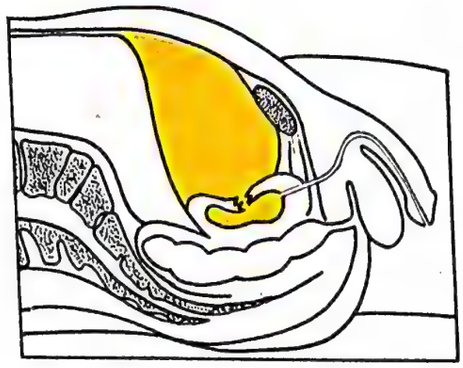

FIG. 1378.—Extraperitoneal extravasation of urine.

the shock subsides and the pain lessens, so that the patient may continue with his orgies, but the abdomen commences to distend. Usually the patient has no desire to micturate. On examination varying degrees of abdominal rigidity and, after a few hours, abdominal distension are present. In spite of the fact that the patient has not passed urine since the accident, there is no dullness above the pubes corresponding to a distended bladder. Usually there is tenderness in the hypogastrium. If the amount of urine in the peritoneal cavity is considerable, shifting dullness can be elicited. Rectal examination often reveals a bulging in the rectovesical pouch. When the urine is sterile, symptoms and signs of peritonitis are delayed for hours.

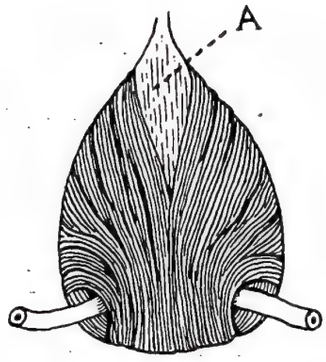

FIG. 1379.—Intraperitoneal rupture occurs within the area A. The tear is nearly always longitudinal.

Extraperitoneal Rupture.—As in many cases this cannot be differentiated from a rupture of the posterior urethra and as the treatment is the same, this injury is dealt with on page 1261.

Confirming a Suspected Diagnosis.—A plain X-ray taken in the erect position may show the ground glass appearance of fluid in the lower abdomen. Intravenous pyelography may confirm a leak from the bladder. A peritoneal 'tap' may be of value. If doubt still exists and if there is no sign of fracture then retrograde cystography can be performed safely. With careful asepsis a small (14F) catheter is passed. Usually some blood-stained urine will drain. A solution made from 60 ml. of 35% Hypaque or Conray with 120 ml. of normal saline for intravenous use is injected into the bladder and radiographs taken.

Treatment.—When there are reasonable grounds for suspecting rupture of the bladder, operation should be undertaken without delay.

Intraperitoneal Rupture.—Lower laparotomy is performed. Urine is removed by suction, after which the patient is placed in Trendelenburg's position. The edges of the rent, which is usually situated in the posterior part of the dome of the bladder (fig. 1379), are trimmed and sutured by two layers of interrupted catgut stitches, and the operation completed by stitching a large Malécot catheter into an extraperitoneal suprapubic incision in the bladder. The latter ensures intravesical tension being kept at a minimum during

Friedrich Trendelenburg, 1844–1924. Professor of Surgery, Leipzig, Germany. In 1839 Dr. Walther, a General Practitioner of Pittsburg, successfully sutured an intraperitoneal rupture of the bladder of a blacksmith.

healing of the sutured tear. Unless obvious infection is present the peritoneum can be closed without drainage. The abdominal wall is repaired around the Malécot catheter, not omitting drainage of the prevesical space. Following the operation, antibiotic therapy is given until the urine is proved sterile after removal of the catheter in 8–10 days.

Prognosis.—When operation is performed within twelve hours the mortality is approximately 11%; when operation is delayed to twenty-four hours the mortality rises to 55%. As in the days of ancient Greece, when the condition was regarded as inevitably fatal, without operation the mortality is 100%.

WOUNDING OF THE BLADDER DURING OPERATION

Operations in which the bladder is liable to be injured are (1) inguinal or femoral herniotomy (especially during the performance of the low operation for strangulated femoral hernia); (2) hysterectomy (particularly panhysterectomy by either the abdominal or vaginal route) and (3) excision of the rectum. In all these operations, to minimise this accident the bladder must be emptied *after* the patient has been anæsthetised. If the injury is recognised at the time of its infliction, the bladder must be repaired in two layers and urethral catheter drainage maintained for seven days. If it is not so recognised, the treatment is similar to that of rupture of the bladder.

When accidental perforation of the bladder occurs during endoscopic resection of a bladder tumour, or the prostatic capsule is perforated during transurethral prostatectomy, for practical purposes the perforation is always extraperitoneal. When the accident is recognised at the time, drainage of the bladder with a large urethral catheter, and the administration of antibiotics, usually suffice.

RETENTION OF URINE

Retention of the urine is either acute or chronic, the latter leading ultimately to retention-with-overflow.

Acute retention

Ætiology.—The most frequent causes are:

In the male	*In the female*	*In the male child*
Prostatic enlargement. Urethral stricture. Post-operative retention.	Retroverted gravid uterus. Disseminated sclerosis. Hysteria.	Meatal ulcer with scabbing.

Other causes:

Following spinal anæsthesia.	Acute urethritis or prostatitis.
Blood-clot in the bladder.	Urethral calculus (p. 1276).
Rupture of the urethra (p. 1260).	Phimosis
Neurogenic (injury or disease of the spinal cord).	Certain drugs (p. 1201).
Fæcal impaction in the rectum.	Muscular atony from advanced age.

Clinical Features.—The patient has not passed urine for some hours, and is unable to do so. The swelling caused by a full bladder often can be

Achille-Etienne Malécot, 1852–?. He invented his catheter while Interne des Hôpitaux de Paris.

seen in a thin person; it is somewhat tender to palpation, and dull to percussion above the symphysis pubis. Spasms of acute pain occur periodically as the muscle of the bladder contracts. An attempt is made to elicit the cause of the retention; this is most frequently due to vascular engorgement of an already enlarged prostate (p. 1236), but the floor of the urethra should be palpated for the induration characteristic of a stricture, and the reflexes in the lower limb and perianal sensation, tested.

Treatment.—It is of paramount importance never to relieve, or attempt to relieve, acute retention and forthwith send the patient home. He must always be admitted and kept under observation for at least twenty-four hours. Once the patient is in suitable surroundings, the effect of administering a dose of Omnopon to relieve anxiety, and a hot bath to diminish internal congestion, is tried. In many cases the patient is able to pass urine into the bath. If this fails, catheterisation is attempted. This should always be performed with full aseptic ritual (p. 1239). A small (12F) pre-sterilised plastic catheter (Jaques), is employed; if this is unsuccessful, a Tieman's catheter (fig. 1380) should be tried. If the catheter is to be left indwelling, a Gibbon catheter (fig. 1385), or a small Foley catheter (fig. 1381) should be

FIG. 1380.—Tieman's catheter.

FIG. 1381.—Foley's catheter.

used. Failure of the catheter to find its way past an enlarged prostate may be due to a middle lobe projection. Catheterisation may be accomplished then by using a coudé[1] or bi-coudé catheter (18F), or by inserting a curved introducer down a Foley catheter. The bladder is then emptied completely and the catheter removed.

All catheters (and gum-elastic bougies) are calibrated in the French scale (F.),[2] and as the narrowest part of the urethra is the external urinary meatus, unless there is reason to believe that the urethra is strictured, it is usual to choose a catheter with a diameter a little less than that of the orifice, viz.⟶ ● 10F. ● 16F. ● 12F. ● 18F.

If, after a reasonable attempt with catheters, the bladder has not been entered, one of four courses may be adopted according to circumstances.

1. **Suprapubic Puncture.**—Suprapubic puncture with a lumbar puncture needle or an 'intracath' (p. 91) is a useful method of relieving acute retention when catheterisation has failed. If the bladder is allowed to refill after it has been punctured, leakage into the prevesical space may follow.

2. **Suprapubic Catheterisation** (Riches' Technique).—A catheter is inserted into the bladder suprapubically through a 1·25 cm. incision made under local anæsthesia 2·5 cm. below the level at which the anterior surface of the bladder curves upwards and backwards to form the dome. The fibres of the linea alba are divided in the

[1] coudé (adjective) = bent; coude (noun) = elbow.
[2] The French scale is also known as Charrière's scale, so called after Joseph Charrière (1803–1876), a Paris surgical-instrument maker.

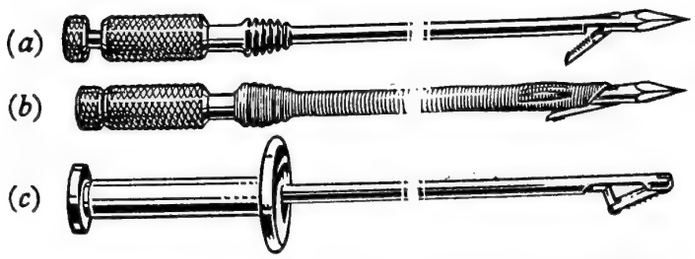

FIG. 1382.—(*a*) Riches' suprapubic catheter introducer; (*b*) the catheter stretched on the introducer; (*c*) the advancer.

length of the incision. After the special catheter has been mounted on its introducer (fig. 1382 (*a*), (*b*)) it is passed through the incision until its sharp point touches the surface of the bladder, and the instrument is passed into the bladder with a short, sharp thrust directed backwards and downwards. The introducer is removed and the advancer (fig. 1382 (*c*)) is passed down the lumen of the catheter and its expander is opened. Thus the catheter is carried towards the trigone, and the advancer is removed. A stitch secures the catheter to the skin, and this is reinforced with a strip of adhesive plaster.

3. **Immediate Prostatectomy.**—Possibly immediate prostatectomy in cases of benign enlargement of the prostate in fit patients.

4. **Urethral instrumentation** (p. 1270), in the case of a urethral stricture.

Chronic retention

In such cases the distension of the bladder is painless. The blood urea must be estimated before any attempt is made to relieve the retention. If it is below 70 mg% (12 mmol/l), treatment is as outlined for acute retention. Above this figure slow decompression is advisable (p. 1240).

Retention with overflow

In this condition the patient has no control of his urine, small amounts passing involuntarily from time to time overflowing from a bladder which is distended. It may follow a neglected acute retention, or chronic retention.

Retention with overflow is referred to also under '<u>incontinence</u>' (p. 1203) and '<u>prostatic enlargement</u>' (p. 1238).

The general principles which govern the treatment of this condition are similar to those of acute retention, but decompression of the bladder must be carried out very slowly (p. 1240).

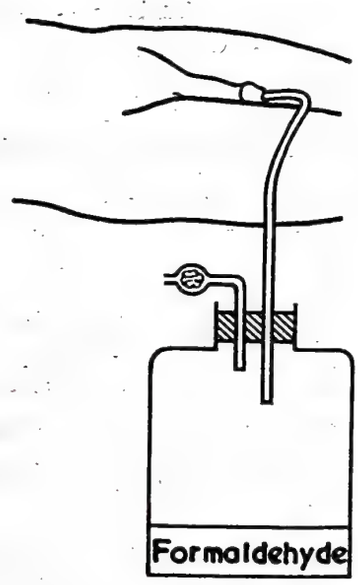

FIG. 1383.—The essentials of continuous bladder drainage. The indwelling catheter has been introduced, using aseptic and antiseptic precautions (p. 1239). The sterile connecting tubing leads to the collecting bottle. This bottle should contain a suitable disinfectant, e.g. formaldehyde to keep the contents sterile. Alternatively, a closed sterile plastic container fitted with a non-return valve may be used.

THE INDWELLING CATHETER AND THE CLOSED SYSTEM OF CATHETER DRAINAGE

The incidence of ascending infection is nearly halved by connecting the catheter (urethral, suprapubic or perineal) to sterile tubing conducted to a sterile collecting bottle (fig. 1383), and employing irrigations only if clot retention occurs. When a catheter has been *in situ* for five or more days, some degree of urethritis is likely to supervene, though this has been much reduced by the use of catheters made from various non-irritant plastic substitutes for rubber. To change the catheter in the presence of urethritis entails a grave risk of infection from the anterior to the posterior urethra, and thence to other parts of the urogenital system (fig. 1384).

Sir Eric William Riches, Contemporary. Consulting Surgeon and Urologist, The Middlesex Hospital, London.

SPECIAL FORMS OF RETENTION OF URINE

Post-operative Retention of Urine.—Retention of urine can be encountered after any operation. It is common after operations on the anal canal and perineal region, and is due to reflex spasm of the urinary sphincters. After operations on the pelvic viscera, retention of urine is so common that it is usual to forestall it by inserting a catheter before or at the conclusion of the operation.

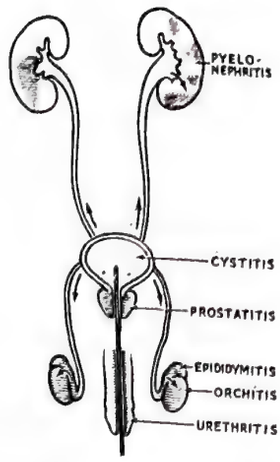

FIG. 1384.—Complications liable to follow changing a urethral catheter in the presence of urethritis. (*After C. G. Scorer, F.R.C.S., London.*)

When the patient is an elderly male, prostatic obstruction, hitherto latent, should be suspected. Many patients cannot urinate while lying or sitting in bed. Another extremely common cause is sedation: when a sufficient quantity of an analgesic drug to relieve pain is administered, frequently the desire to micturate is suppressed until the sympathetic nerve fibres are stimulated from overdistension of the organ.

Treatment.—If the male patient, while supported, is permitted to sit on the edge of his bed, he is often able to empty his bladder. The sound of running water is often helpful. Parasympathetic stimulating drugs, e.g. Carbachol, may be prescribed, but they should be avoided after operations on the gastrointestinal tract. If after a reasonable trial the patient cannot pass urine, he or she must be catheterised.

Acute Retention due to Drugs other than Sedatives.—A number of the newer drugs are prone to induce or precipitate retention of urine. Propantheline bromide, used to decrease secretion and motility in peptic ulcer, antihistamine drugs, antihypertensive drugs, anticholinergic drugs and I.N.A.H. compounds (chemotherapeutic agents for tuberculosis) have all been reponsible for producing acute retention of urine. Indeed, ' drug retention ' has become a clinical entity.

Retention due to Lesion of the Spinal Cord (p. 457).—The bladder, the nervous control of which is disrupted because of a complete or incomplete lesion of the spinal cord, passes through various stages of dysfunction.

The Atonic Neurogenic Bladder.—Immediately following the injury the detrusor muscle becomes paralysed, the bladder neck sphincter contracted tightly and the external sphincter relaxed. The only factor permitting any evacuation of the bladder is the elasticity of its walls. In lesions situated above S.2 (fig. 1374) to below D.4–6, because the sympathetic innervation of the bladder is intact, the patient can appreciate when the bladder becomes filled to capacity. If allowed to do so, the bladder becomes greatly distended and paralytic overflow incontinence ensues. This phase (due to *spinal shock*) lasts for days, weeks or even months. As recovery from spinal shock takes place, depending on the level of the lesion, *automaticity* or *autonomy* of bladder function occurs, but before it does so it passes through two intermediate phases.

(*a*) *Phase of Ineffectual Emptying Contractions.*—Contractions of the detrusor muscle occur, but because the sphincter vesicæ remains in spasm, small quantities only of urine are voided frequently. This phase is of a few hours' duration.

(*b*) *Phase of Hypertonicity.*—The detrusor passes into spasm. The internal sphincter relaxes physiologically and the external sphincter reflexly.

The Automatic (*syn.* **Reflex**) **Bladder.**—When the lesion is situated above the centre of micturition the bladder empties reflexly every one to four hours, the amount of residual urine varying from case to case. When the filling reaches a certain point the detrusor muscle contracts reflexly—a condition similar to that seen in early infancy.

The Autonomous Bladder results when a lesion is situated at a level that will destroy the centre for micturition (fig. 1374), or a lesion in the cauda equina. Emptying of the bladder is dependent upon the precarious and inefficient control by the nerve plexus situated between the muscular strata of the bladder wall. Continual dribbling is the outcome, but the bladder can be emptied by manual compression. Residual urine, however, is never absent and dilatation of the ureters and, eventually, of the renal pelves and calyces results.

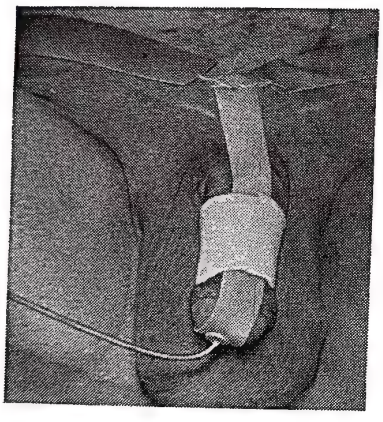

FIG. 1385.—Portex Gibbon catheter in place.

Treatment.—The most practical solution of the problem of how best to relieve retention of urine during the vigil of the period of atonicity, is to pass, with the strictest aseptic precautions, a catheter of Portex tubing 1·5 mm in diameter which is so designed that it can be retained by its wings in both the male (fig. 1385) and in the female (Gibbon). It is advisable to introduce the tubing at the earliest possible time, as there is evidence that over-distension prejudices the eventual development of detrusor contractions (Ross). Especially important is early drainage in the female, for otherwise wet beds favour the development of bedsores. Should the tubing become blocked with mucus, it can usually be freed by suction applied with a syringe to its distal end. A high fluid intake (3 litres in 24 hrs.) must be insisted upon.

The state of automaticity is heralded by return of bulbo-cavernosus reflexes (erections) and anal reflexes, and should the catheter tubing become blocked, urine will be passed alongside the catheter.

With the return of detrusor activity *bladder training* is commenced. At first the catheter is clipped off and released at regular, but lengthening, intervals. Later the catheter is removed, and reflexes are initiated by the patient lifting himself in his chair or bed, again at regular intervals by the clock. Drinks are given during the day, but none after seven p.m. (19.00 hrs.).

Enhancing or Initiating Automaticity in Refractory Cases.—Cysto-urethrography is invaluable in determining (1) spasm of the bladder neck, (2) contracture

Norman Otway Knight Gibbon, Contemporary. Surgeon, Sefton Hospital, Liverpool, England.
James Cosbie Ross, Contemporary. Consulting Surgeon, Royal Southern Hospital, Liverpool, England.

of the prostatic urethra, (3) prostatic shelf obstruction and (4) spasm of the external sphincter.

Transurethral resection of narrow strips of the vesical neck and prostatic urethra between five and seven o'clock is often very successful in types of obstruction 1, 2 and 3. Pudendal neurectomy sometimes abolishes spasm of the external sphincter. For this operation the patient is placed in the jack-knife position (p. 1055) and the pudendal nerves are exposed as they leave Alcock's canal and resected. The effect of section may be tested by local anaesthetic block of the nerves. Usually it is wiser to sacrifice one nerve at a time. An alternative attack is to cut the internal sphincter in two places by the per-urethral route.

The State of Autonomy.—Manual expression of urine by the patient, if he has the use of his arms, plus contracture of the abdominal muscles, if they are not paralysed, is the only (but often tolerably successful) method of avoiding life-long urethral or suprapubic catheter drainage.

Persistent Retention of Urine following Excision of the Rectum.—In 10 per cent. of cases retention of urine persists for three months or more. Probably, owing to the absence of cystometric substantiation of damage to the parasympathetic nerve supply to the bladder, the retention is due to mechanical factors, notably sagging of the bladder into the space formerly occupied by the rectum. In most cases the retention can be cured by transurethral resection of the prostate. Usually the prostate is not enlarged, and consequently the resection can be carried out easily and quickly. Therefore, if after two weeks the patient is unable to empty his bladder and his general condition is satisfactory, transurethral prostatic resection should not be postponed. Thus the patient is spared what would probably be a long period of invalidism and the risk of urinary infection.

INCONTINENCE OF URINE

Incontinence of urine — the patient is either unaware that urine is passing, or if aware of it, is unable to prevent the leakage of urine from the urethra. The history is most important and in many cases will indicate the cause.

Enuresis — incontinence of urine due to involuntary acts of micturition in children without detectable neurological or urological disease. Usually the condition presents as failure to acquire normal control but in about 15 per cent. of cases it may commence after control has been acquired. In such instances there is usually an illness or psychological factor which reveals the condition. In both the underlying state is a persistence of the infantile pattern of bladder activity—sudden forceful contraction and emptying in response to a certain distension, an impairment of the sensory awareness of bladder content with lack of inhibitory control from higher centres.

Nocturnal enuresis is much more frequent than diurnal. Diagnosis may be made confidently if the history is typical; there is no dribbling between acts, there is no abnormality on clinical examination and the urine is completely normal. It is important to remember that retention and overflow (p. 1238), always due to obstruction at the bladder neck or in the urethra, may present at *any age* as bedwetting. Control by day may be adequate but there will be frequency and urgency.

Treatment.—Drugs to inhibit bladder irritability (belladonna) and to tighten the sphincter (ephedrine) may help. Diurnal enuretics should be

Benjamin Alcock. Professor of Anatomy, Cork, Ireland (1849–1855). He was dismissed from his post for a breach of the Anatomy Acts and disappeared in America.

encouraged to pass urine by the clock and gradually lengthen the duration between acts. At night the child should be wakened regularly. In cases of 'onset' enuresis after a dry period, the social and psychological aspects of the family must be investigated. Older children may respond to an alarm which is activated by urine passing on to a pad.

Stress Incontinence — leaking of urine on coughing or sneezing or lifting heavy weights. It is due to weakness of urinary sphincters. Common in women after childbearing, it may also follow operations on the bladder neck and prostate, to relieve obstruction.

Operative Treatment.—In patients with considerable bulging of the anterior vaginal wall (cystocele), anterior colporrhaphy frequently improves continence. In the absence of a cystocele an operation to rectify sagging of the bladder neck can be undertaken in cases in which there is little or no improvement after a course of exercises.

Everard Williams' operation for stress incontinence is simple, and gives as good results as more complicated procedures. A Foley's catheter having been introduced into the bladder, the bladder neck and adjoining portion of the urethra are exposed via the retropubic route. The lower part of the bladder and the intrapelvic portion of the urethra are mobilised, but there is no necessity to separate the urethra from the vagina. Three chromic catgut sutures are introduced on either side, each traversing the wall of the urethra or that of the bladder neck, being careful not to penetrate the mucous membrane. The sutures are then passed through the fascia covering the deep surface of the pubic bones near the symphysis. When the sutures are tied they suspend the bladder neck and the proximal part of the urethra.

Dribbling of Urine and Normal Micturition.—This occurs when there is a ureteric fistula (p. 1213) or an aberrant ureter opening into the urethra beyond the sphincters (in male), or into the vagina in females. The history is diagnostic, and intravenous pyelography may reveal the absent upper calyces on one side. These segments are very liable to infection. Treatment is by excision of the aberrant ureter and portion of kidney which feeds it.

Total Incontinence:

Here there is complete loss of control. The urine dribbles away all the time and the bladder is usually empty. Excluding all fistulæ (p. 1213) the causes of this condition are:

Congenital.—Severe epispadias.

Traumatic.—Damage to pelvic muscles and nerves, as in fractured pelvis or after prostatectomy.

Infective.—Acute exfoliative membranous cystitis as in chemical irrigation. Chronic tuberculosis.

Neoplastic.—Fixation of sphincters: Carcinoma of Prostate and Cervix.

Neurological.—Meningo-myelocoeles, Multiple Sclerosis (usually retention and overflow).

Management of Incontinence.—The aim is to keep the patient dry, free of odour, to lessen the incidence of skin excoriation, and to protect the kidneys from the effects of infection and back pressure.

Appliances in women are usually unsatisfactory. An indwelling catheter drained constantly into a leg urinal is usually a satisfactory solution although in some instances diversion via an ileal conduit is necessary (p. 1232).

In men, a condom urinal, or a Cunningham penile clamp (fig. 1386) may be

Harry George Everard Williams, 1892–1970. Obstetrician and Gynæcologist, Charing Cross Hospital, London.

satisfactory, and they avoid an indwelling catheter. Regular pyelographic checks to confirm the absence of retention and back pressure effects are essential.

Some of the conditions listed above may be amenable to specific surgical treatment. Thus a gracilis muscle sling may be attempted for epispadias or a post prostatectomy incontinence (fig. 1387). This usually needs to be activated by an electrical stimulator for complete success. Severe contraction of the bladder if sphincters are normal can be helped by a cystoplasty using ileum to enlarge it.

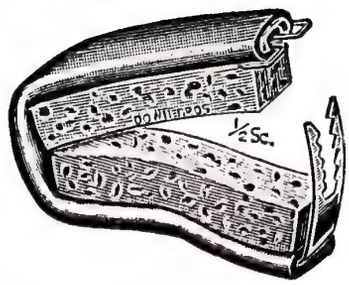

FIG. 1386. — Cunninghams' penile clamp.

In neurological disease it is usually necessary to divert the urine into an ileal loop (p. 1232) if there is evidence of increasing dilation of the upper tract, particularly in the presence of recurrent infections. The bladder need not be removed but should be washed out after the operation and 1 g neomycin instilled. It should also be washed out two or three times in the post-operative period; after this it rarely produces any symptoms.

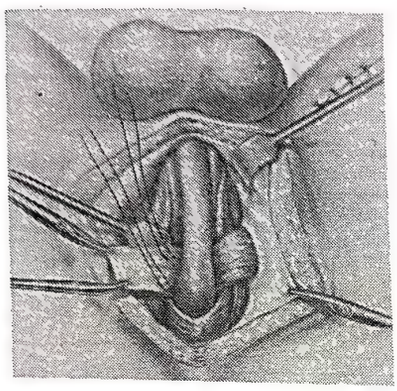

FIG. 1387.—Transplantation of the gracilis muscle to make a new sphincter urethræ.

Uretero-ileostomy (p. 1232).—The collection of urine from an artificial bladder into an ileostomy bag especially if the ileostomy has been given a spout of 2·5 cm long, is so much more water-tight than a portable urinal worn over the genitalia. The incidence of pyelonephritis is so much less, that the substitution of an artificial for a normal non-functioning bladder is a change for the better, not only for the patient but for those with whom he or she lives (the uriniferous odour is reduced, sometimes to vanishing point). The operation is particularly successful in cases of incontinence due to spina bifida (Wells).

Urodynamic study (fig. 1388) has thrown a great deal of light on cases of urgency and incontinence. The principle is to record the pressure within the bladder during filling, and emptying, and at the same time to record the patient's subjective symptoms, and observe the activity of the bladder with an image intensifier. A catheter is passed along the urethra into the bladder together with a small fine pressure tube. A similar pressure tube is placed in the rectum to record intra-abdominal pressure. Via transducers the pressures in the bladder and abdomen are recorded as waves on heat sensitive paper. A third pen records true intravesical pressure by a subtraction performed electronically.

Using a television camera to ' observe ' the pressure traces it is possible to display this on the screen of the image intensifier alongside the bladder and also to record all action and a commentary on video-tape.

VESICAL CALCULUS

Definition.—*A primary vesical calculus* is one that develops in sterile urine; it often, but not necessarily, originates in a kidney and passes down the ureter to the bladder, where it enlarges.

A secondary vesical calculus occurs in the presence of infection.

A vesical calculus can occur also by the deposition of urinary salts upon a foreign body in the bladder.

Charles Alexander Wells, Contemporary. Professor Emeritus of Surgery, Liverpool, England.

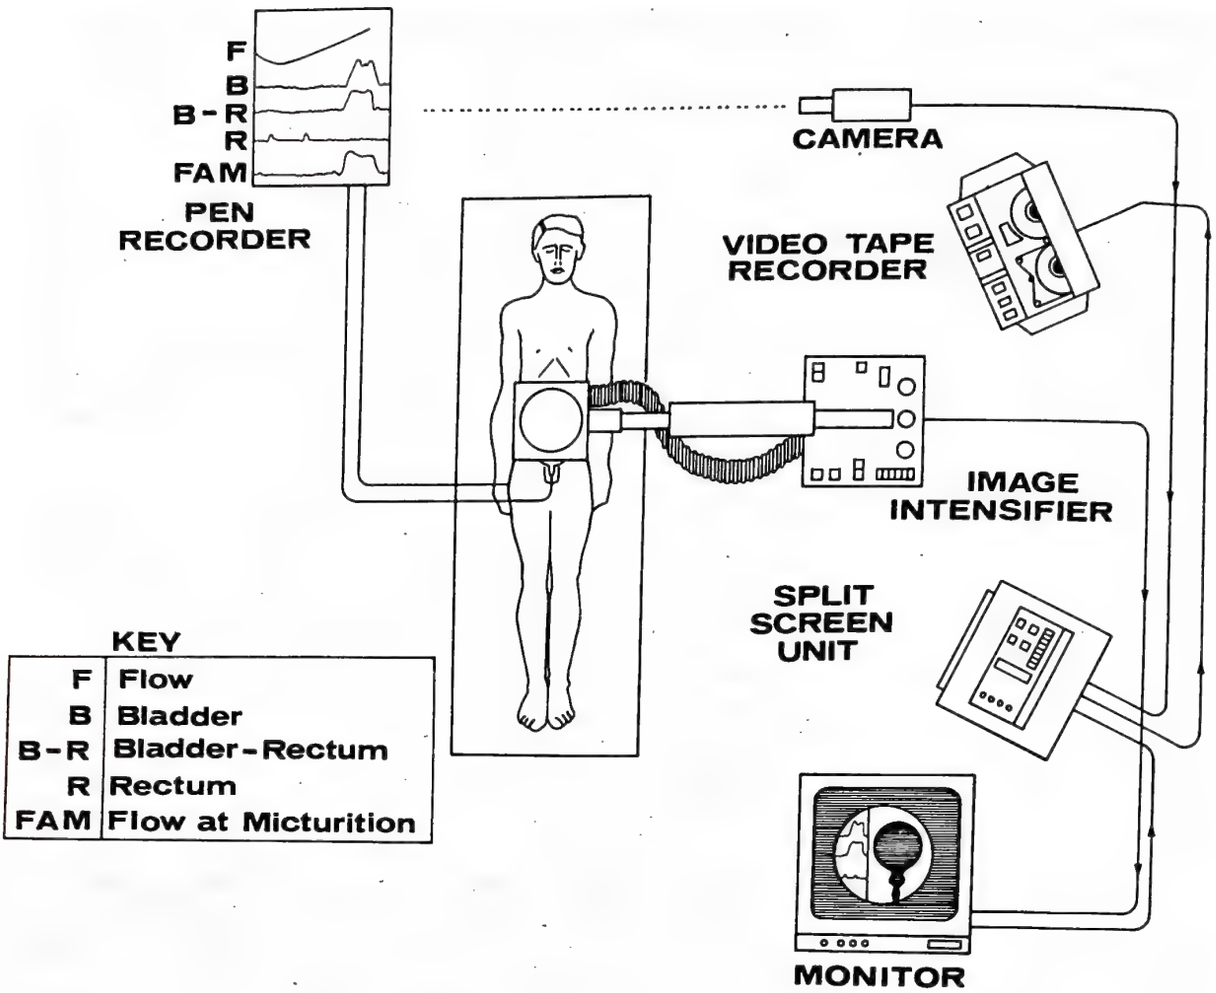

FIG. 1388—Urodynamic study (p. 1205).

Incidence.—Until the twentieth century vesical calculus was one of the most prevalent disorders among the poorer classes, and the incidence was especially high in childhood and adolescence. Owing to improved diet, especially an increased protein-carbohydrate ratio, primary vesical calculus is comparatively rarely encountered. The most remarkable fall in incidence is among children.

FIG. 1389.—'Jack-stone'[1] calculus. This type of vesical calculus is typically found in a post-prostatic pouch.

Composition and Cystoscopic Appearance.—Most vesical calculi are composite, but have one component in excess, and assume the appearance of that variety (see also p. 1161).

1. *Oxalate calculus* is a primary calculus that grows slowly. Usually it is of moderate size, and is solitary. Its surface is uneven (mulberry type; sometimes it bristles with spines (fig. 1389). Although calcium oxalate is white, the stone is usually dark brown or black because of the incorporation of blood pigment into it.

2. *Uric acid and urate calculi* are round or oval, fairly smooth, and vary in colour from pale yellow to light brown: they may be

[1] 'Jack-stone' = the kernel of the fruit of the jack tree. These fruit stones are used for a game played by children in the U.S.A.

single or multiple. These stones also are primary: they are not opaque to X-rays.

3. *Cystine calculus* occurs only in the presence of cystinuria (p. 1162), and is radio-opaque due to its high sulphur content.

4. *Triple Phosphate calculus* is composed of ammonium, magnesium and calcium phosphates and occurs in urine infected with urea-splitting organisms. It tends to grow rapidly. In some instances it occurs on a nucleus of one of the foregoing types of calculus; much more rarely on a foreign body. In others the nucleus is composed of desquamated epithelium and bacteria. It is dirty white in colour, and of chalky consistency.

A vesical calculus is usually free to move in the bladder. It gravitates to the lowest part of the organ, which, when the patient is erect or sitting, is the bladder outlet. In the recumbent position (as also at cystoscopy) the stone occupies a position behind the inter-ureteric ridge. Less commonly the stone is wholly or partially in a diverticulum or a post-prostatic pouch, and in either case the stone may be partially or completely hidden from view.

Clinical Features.—Males are eight times more often affected than females.

(*a*) *Latent.*—When a stone is situated in a post-prostatic pouch or a diverticulum of the bladder, it is usually discovered unexpectedly at cystoscopy or on X-ray examination.

(*b*) *Typical.—Frequency* is the earliest symptom. Unlike other forms of frequent micturition, it is not much in evidence during the night. After micturition the patient does not feel satisfied that the bladder is empty.

Pain is most in evidence in cases of spiculated oxalate calculus. It occurs at the end of micturition, and is usually referred to the tip of the penis or to the labia majora; more rarely to the perineum or suprapubic region. Pain and discomfort are much in evidence during exertion, and are aggravated by jolting movements (e.g. riding in a vehicle). If the patient lies down, the symptoms tend to pass off because the stone falls away from the sensitive portion of the bladder, the trigone. Thus he usually sleeps peacefully through the night. In young boys, screaming and pulling at the penis with the hand at the end of micturition are indicative of vesical calculus.

Hæmaturia is characterised by the passage of a few drops of bright red blood at the end of micturition, and is due to the stone abrading the vascular trigone—a fact that also accounts for the pain.

Interruption of the urinary stream by the stone blocking the internal meatus, occurs occasionally, and may be remedied by a change of posture.

Acute retention of urine from a vesical calculus is extremely uncommon in adults, but not so in children.

(*c*) *Masked.*—The symptoms of a concomitant persistent cystitis may overshadow those that might be occasioned by the stone.

Rectal or vaginal examination, when accompanied by abdominal palpation, occasionally enables a vesical calculus to be felt. Unless the stone is large, rectal examination is negative in the adult male, but in a

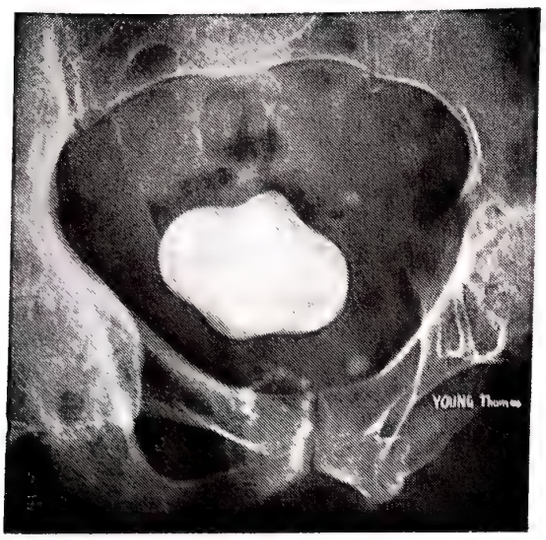

FIG. 1390. — Radiograph showing a vesical calculus.

female or child a calculus of moderate size may be palpable.

Examination of the urine will reveal blood, and possibly pus or crystals typical of the calculus, e.g. envelope-like in the case of an oxalate stone, or hexagonal plates with cystine calculi.

Radiography.—In at least 92 per cent. of cases vesical calculus can be demonstrated on an X-ray film (fig. 1390). If the stone is not opaque, a filling defect may be visualised. Radiographs of the whole of the urinary tract should be taken, after which excretory pyelography is carried out; the former will reveal or disprove the presence of opaque renal or ureteric calculi, while the latter will help to determine the normality or otherwise of the kidneys.

Cystoscopy is essential for evaluation of the case. Frequently, on introducing the sheath of the cystoscope, a significant 'click' will be felt when a free-lying stone comes in contact with the instrument. As described already, cystoscopy usually determines the composition of the calculus. Stones non-opaque to X-rays, e.g. uric acid, can be seen.

In all cases the whole of the bladder wall is inspected: in primary calculus aseptic cystitis is basal; in secondary calculus bacterial cystitis is universal. In appropriate cases the exit of the bladder is examined for prostatic enlargement or contracture of the bladder neck.

Treatment:

Litholapaxy.—In most cases crushing the stone with a lithotrite is highly satisfactory. However, the contraindications to the method are as follows:

Contra-indications to Litholapaxy

- **Urethra**
  - Prostatic obstruction.
  - A urethral stricture that cannot be dilated sufficiently.
  - When the patient is below ten years of age.
- **Bladder**
  - Vesical diverticulum.
  - Cystitis that fails to respond to treatment.
  - Contracted bladder.
  - Other conditions requiring operation, e.g. enlarged prostate, new growth.
- **Stone**
  - A very large stone.
  - A very small stone, which should pass naturally.
  - Too hard to crush—an oxalate calculus.
  - Too soft to crush—a cystine calculus.
  - A stone encrusting a foreign body.

Technique.—For several days before the operation a suitable drug is administered to reduce infection. While blind litholapaxy is preferred by those who have had much experience with the solid lithotrite, its only advantage is that, by reason of its

solidity and greater strength, harder stones can be crushed than is the case with an instrument that contains a light and telescope incorporated in its shaft. A cystoscopic lithotrite (Canny Ryall, Riches) enables the stone, and such fragments as are necessary, to be seized under vision. The instrument, with its obturator in place, is introduced into the bladder, and rotated so that its closed jaws point downwards. The obturator is removed and the bladder is irrigated with water or glycine solution by means of two 200-ml. syringes until the lotion is returned clear. The bladder is then filled with not more than 300 ml. of the solution, and after inserting the telescope, the stone is seen. The screw on the handle of the instrument is turned, and the jaws thereby opened. The distal blade is hooked over the centre of the stone (fig. 1391) and by rotating the screw handle the proximal movable blade is advanced so that the stone is grasped firmly. The ocular end of the lithotrite is depressed, thereby lifting the calculus away from the bladder wall. After withdrawing the telescope slightly, to prevent damage to the light bulb, the screw is turned slowly, breaking the stone. Large fragments are crushed into small ones by repeating the manœuvre. With the jaws closed, the lithotrite is rotated so that the jaws point upwards, and after removing the telescope and allowing the lotion to escape, the instrument is withdrawn.

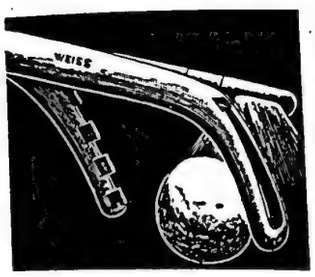

FIG. 1391.—A cystoscopic lithotrite.

FIG. 1392.—An evacuating cannula

FIG. 1393.—Modified Bigelow's evacuator.

Evacuation of the Fragments.—An evacuating cannula (fig. 1392), the largest that the urethra will take, is passed, and 200 ml. of lotion are introduced into the bladder. The evacuator (fig. 1393), filled with lotion and with its tap closed, is fitted on to the cannula. The tap is opened and the bulb is elevated so as to depress the beak of the cannula towards the base of the bladder, after which the bulb is compressed slowly. The bulb is then permitted to expand, and the returning lotion carries with it sand and fragments of the stone which, being heavier than the lotion, drop into the glass receptacle. Compression of the bulb and aspiration is continued until no further fragments fall. The beak of the cannula is turned to the left and to the right, and suction is applied in these situations. To save time in emptying and refilling two evacuators can be used. If at any time the bulb fails to expand, this may be due to blocking of the eye by bladder mucosa, in which event release can be effected by further compression of the bulb and slight rotation of the instrument. Blockage of the cannula by fragments of the stone can sometimes be remedied in the same way, but more often they must be dislodged by detaching the evacuator and passing the obturator of the cannula. When no more fragments can be aspirated, the evacuator is detached and the bladder is irrigated until the lotion is returned clear. The cystoscopic lithotrite is reintroduced, and if no fragments remain, a Foley's catheter is passed. After the patient has been returned to bed the catheter is connected to a sterile bottle. Usually the catheter can be removed in twenty-four hours. As soon as it is assured that the patient is passing urine without difficulty, he can return home. Suitable drugs should be given until the urine is sterile.

Suprapubic Lithotomy.—The alternative to litholapaxy is removal of the stone through a suprapubic incision, after which the bladder is closed and drained by a urethral catheter.

Lithotomy in Special Circumstances.—A stone associated with an enlarged prostate can be removed in the course of a suprapubic or retropubic prostatectomy. When the stone is associated with contracture of the bladder neck, it can be removed in the course of an open operation for that condition.

Frère Jacques de Beaulieu, 1651–1714, was the most famous Journeyman Lithotomist; he mainly practised the perineal operation using a bread-knife.

Edward Canny Ryall, 1865–1934. Surgeon, All Saint's Hospital, London.

A very small stone sometimes can be removed by means of an evacuator after passing the largest-sized cannula commensurate with the calibre of the urethra. For stones too large to pass through the cannula but small enough to pass through the urethra, removal by seizing the stone in the jaws of a cystoscopic rongeur (fig. 1394) is ideal.

FOREIGN BODIES IN THE BLADDER

A piece of catheter or bougie may become broken and remain in the bladder. The variety of foreign bodies which have been removed from the bladder is astonishing, e.g. manicure sticks, hair-clasps (fig. 1395), hairpins and candle-grease. The presence of such objects in the bladder is usually accounted for by urethral masturbation, or attempts to produce a miscarriage. Occasionally a foreign body enters through the wall of the bladder, e.g. a piece of rubber tubing after cystostomy; unabsorbable sutures used in an extravesical pelvic operation. The diagnosis rests on cystoscopy, and in the case of radio-opaque foreign bodies on radiography.

FIG. 1394.—Young's cystoscopic rongeur.

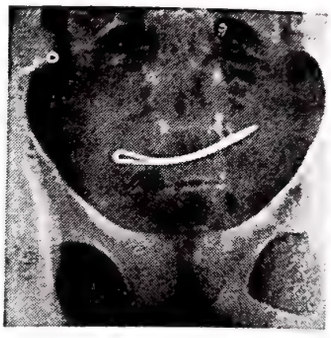

FIG. 1395.—A hair-clasp in the bladder.

Complications of a Foreign Body in the Bladder:

1. Cystitis, which is the most common complication.
2. Perforation of the bladder wall.
3. Vesical calculus.

Treatment.—A small foreign body can be removed per urethram by means of an operating cystoscope or Young's cystoscopic rongeur. When the foreign body is heavily encrusted, penetrating the bladder wall, or accompanied by severe cystitis, the suprapubic route should be chosen. Paraffin wax can be dissolved by the introduction of equal parts of xylol and water into the bladder for half an hour.

DIVERTICULUM OF THE BLADDER

Definition.—It is most important to distinguish a saccule from a diverticulum of the bladder. The normal intravesical pressure at the commencement of micturition is about 35 cm of water (25·7 mmHg or 3·4 kPa). Pressures as great as 100 cm (73·5 mmHg or 9·8 kPa) are reached by a hypertrophied (trabeculated) bladder (fig. 1429) endeavouring to force urine past an obstruction. This pressure causes the mucous lining between the inner layer of hypertrophied muscle bundles to protrude, so forming multiple saccules. If one or more, but usually one, saccule is forced through the whole thickness of the musculature of the bladder wall it becomes a diverticulum.

Ætiology

(*a*) **Congenital diverticulum** is rare. It may be situated in the middle line anteriosuperiorly, and represent the unobliterated vesical end of the urachus. It empties with the bladder, and is symptomless. Others in the usual situation on the base of the bladder can occur without obstruction and may require excision because of the risk of chronic infection or stone formation in a young adult.

(*b*) **Pulsion Diverticulum.**—The causative obstructive lesion, in order of frequency, is contracture of the bladder neck, benign enlargement of the prostate, fibrous prostate, urethral stricture and congenital valves of the posterior urethra.

Hugh Hampton Young, 1870–1945. Director, James Buchanan Brady Urological Institute, Baltimore, Maryland, U.S.A.

Pathology.—Usually the mouth of the diverticulum is situated above and to the outer side of one ureteric orifice. Exceptionally, it is near the middle line behind the interureteric ridge. The size varies from 2–5 cm, but may be larger. It is lined by bladder mucosa and the wall is composed of fibrous tissue only (compare traction diverticulum p. 1212). A diverticulum enlarges in a downward direction and sometimes may obstruct a ureter.

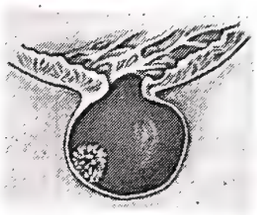
Complications

1. **Recurrent Cystitis.**—As the pouch cannot empty itself there remains a stagnant pool of urine within it. Once infected, the infection persists and continues to reinfect the bladder. In long-standing cases peridiverticulitis causes dense adhesions between the diverticulum and surrounding structures. Squamous cell metaplasia and leukoplakia occur in 15–20% of cases.

2. **Vesical calculus** due to stagnation and infection is present in 20% of cases, most often in the bladder, sometimes in the diverticulum as well, less often in the diverticulum only. On rare occasions a dumb-bell calculus fills the diverticulum and projects into the bladder.

3. **Hydronephrosis and hydroureter,** consequent upon compression of the lower end of the corresponding ureter, are liable to be followed by pyelonephritis and pyonephrosis.

4. **Neoplasm** arising in a diverticulum is an uncommon complication (7–8%). Unless the diagnosis is made at a very early stage, the prognosis is poor, because extravesical invasion through the thin wall of the sac occurs so readily.



Clinical Features.—An uninfected diverticulum of the bladder may cause no symptoms whatsoever. The patient is nearly always a male (95 per cent. of cases), usually over fifty years of age.

There are no pathognomonic symptoms of a vesical diverticulum; they are those of lower urinary tract obstruction, recurrent cystitis, and pyelonephritis. Hæmaturia (due to cystitis, vesical calculus, or, rarely, a neoplasm) is a leading symptom in one-third of cases. In a few cases micturition occurs twice in rapid succession (the second act may follow a change of posture), and when the first specimen is clear and the second cloudy, diverticulum of the bladder should be strongly suspected. In cases of chronic retention of urine, two swellings may be recognised rising out of the pelvis, one being the bladder and the other the diverticulum.

FIG. 1396.—Cystoscopic appearance of the orifice of a diverticulum and trabeculation of the bladder.

Cystoscopy is the usual means of discovering the diverticulum. Most often its orifice is seen as a clear-cut hole about the diameter of a lead pencil, the depths of which are black and unilluminated (fig. 1396). With inadequate distension of the bladder, sometimes the mouth of the diverticulum is seen closed, when the mucous membrane around the potential orifice is thrown into radiating pleats (fig. 1397); therefore, when searching for a diverticulum, it is important to have the bladder fully distended. In heavily infected cases much irrigation is necessary before a clear view of the bladder wall can be obtained.

The differential diagnosis of a diverticulum from sacculation of a trabeculated bladder is not difficult, for the orifice of the saccule is relatively large, and the shallow interior can be seen. It is sometimes possible to pass an endoscope into a diverticulum and examine its interior.

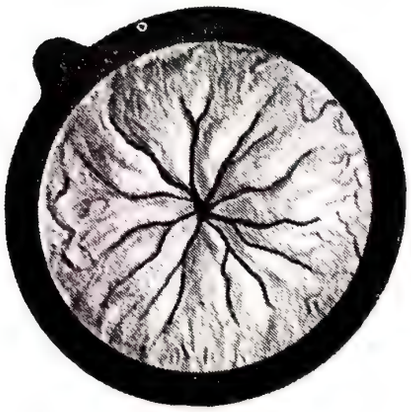


FIG. 1397.—Occasional appearance with inadequate distension of the bladder.

Excretory pyelography will not only exclude or reveal implication of the upper urinary tract, but in many instances the accompanying cystogram will give information regarding the size of the diverticulum.

Retrograde cystography is employed only when the former fails to show the pouch clearly. The bladder is emptied of urine, and filled with a non-irritating radio-opaque medium. Radiographs taken before and after micturition show the dimensions and position of the diverticulum clearly (fig. 1398).

Indications for Operation. — A vesical diverticulum gradually increases in size, and once infected the infection cannot be permanently eradicated. Therefore, unless the pouch is small and uninfected, it should be removed, usually when the associated lower urinary tract obstructive lesion is treated.

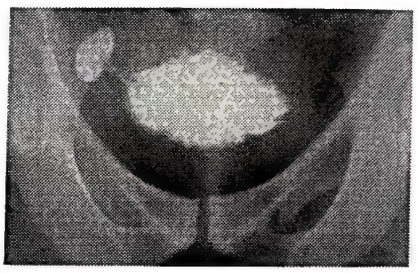

FIG. 1398.—Diverticulum of the bladder shown by cystography.

Pre-operative Treatment.—When the urine is infected, suitable pre-operative antibiotic treatment is given. In the presence of gross sepsis and retention of urine, it is necessary to resort to an indwelling urethral catheter, and give bladder washes.

Combined intravesical and extravesical diverticulectomy is the operation that is practised most frequently. Cystoscopy is performed, and a large ureteric catheter is passed up the ureter on the affected side, and left in place, 240 ml. of lotion remaining in the bladder. With the patient in the Trendelenburg position, the anterior bladder wall is exposed through a suprapubic incision. The peritoneum is dissected upwards, and that side of the bladder bearing the diverticulum is cleared from surrounding structures with the fingers until some part of the pouch is brought into view. The bladder is then incised in the middle line near its dome, and emptied by suction. The interior of the diverticulum is packed with a strip of gauze, and with the fingers of one hand in the bladder and the recti muscles retracted widely, the diverticulum is freed from surrounding structures by gauze and sharp dissection. Usually the neck of the diverticulum can be separated from the ureter, and when the pouch is free it is severed from its attachment to the bladder with a diathermy knife. The resulting defect is closed in two layers. The cystostomy incision is sutured around a Malécot catheter, and the abdominal wall is closed, leaving a drainage tube in the extravesical space which housed the sac.

An alternative method, if the sac is densely adherent, is to carry the incision in the bladder down to the rim of the diverticular orifice, then to detach the diverticulum, together with its fibrous rim. The incision in the bladder is closed and the diverticulum left in position with a corrugated drain into it for two to three days. The track fibroses rapidly after removal of the drain.

TRACTION DIVERTICULUM OF THE BLADDER (*syn.* HERNIA OF THE BLADDER)

A portion of the bladder protruding through the inguinal or femoral hernial orifice occurs in 1·5 per cent. of such herniæ treated by operation (Sir Cecil Wakeley). The

Sir Cecil Pembrey Grey Wakeley, Contemporary. Consulting Surgeon, King's College Hospital, London.

condition is relatively frequent in femoral and direct inguinal herniæ. The disposition of the diverticulum in the hernia varies, and in order of frequency is:

(*a*) (*b*) (*c*)

FIG. 1399.—(*a*) Intraperitoneal (*b*) paraperitoneal (see fig. 1275) (*c*) extraperitoneal hernia of the bladder.

Clinical Features.—In a few cases, in order to empty the bladder completely, the patient finds it necessary to exert pressure on the hernia. Suspicion of a bladder hernia can be confirmed by cystoscopy or cystography.

Accidental Wounding of the Bladder during an Operation for Hernia.—When recognised at the time, the wound in the bladder should be closed by a double layer of catgut and an indwelling catheter is retained for a week or so. If the accident is not recognised at the time and unless early operation is undertaken to repair the rent and drain the prevesical space or peritoneal cavity, as the case may be, together with suprapubic cystostomy, the outlook is grave.

URINARY FISTULÆ

A urinary fistula is an abnormal communication between any part of the urinary system and the skin or some internal hollow viscus. The persistence of a fistula on the skin implies the presence of distal obstruction or the presence of chronic infection such as tuberculosis or a foreign body, e.g. stone, or non-absorbable ligature (p. 63).

Congenital Urinary Fistula.—(1) *Ectopia vesicæ* (p. 1195). (2) *From patent urachus.*—If present at birth or commencing soon after, the possibility of obstruction at the bladder neck or urethra must be investigated. In later life infection in a urachal cyst may produce a fistula. Carcinoma in such instances is not uncommon. Treatment in each case is excision of the urachal tract and closure of the bladder once distal obstruction has been dealt with or excluded.

(3) *In association with imperforate anus* (p. 1050).

Traumatic Urinary Fistula.—Perforating or penetrating wounds, damage not recognised during surgery, or poor healing and avascular necrosis following a combination of radiotherapy and surgery may lead to leakage of urine from ureter or bladder through the wound. Also a clot retention occurring after a transvesical prostatectomy or diverticulectomy may lead to dehiscence of the bladder wound and a temporary fistula, which will heal quickly, provided the bladder is kept empty with an indwelling catheter.

Vesico-vaginal fistula "is the greatest misfortune that can happen to a woman, the more so because she is condemned to live with it, and cannot hope to die from it" (Dieffenbach).

Ætiology: 1. *Obstetrical Causes.*—From time immemorial the usual cause has been protracted or neglected labour.

Johann Friedrich Dieffenbach, 1792–1847. Director of the Surgical Division of the Charité Krankenhaus, Berlin.

2. *Gynæcological Causes.*—The operations chiefly concerned with this complication are total hysterectomy and anterior colporrhaphy.

3. *Radiotherapeutic Causes.*—First and foremost is the radium treatment of carcinoma of the cervix uteri; to a lesser extent irradiation of the pelvic viscera for other reasons is responsible.

4. *Direct Neoplastic Infiltration.*—Exceptionally carcinoma of the cervix uteri ulcerates through the anterior fornix to implicate the bladder.

When a wound of the bladder is recognised and repaired at once, leakage is uncommon, but escape of urine will quickly follow if such damage is passed unnoticed. However, most vesico-vaginal fistulæ are the result of ischæmic necrosis of the bladder wall due to prolonged pressure of the fœtal head in obstetric cases. In gynæcological cases the ischæmia is brought about by grasping the bladder wall in a hæmostat, including the bladder wall in a suture, or perhaps even by local œdema or hæmatoma. Leakage due to necrosis of tissue seldom manifests itself before seven days after the operation.

An intractable fistula following radium treatment of carcinoma of the cervix uteri may arise from avascular necrosis years after the apparent cure of the original lesion.

Clinical Features.—There is leakage of urine from the vagina, and, as a consequence, excoriation of the vulva. Digital examination of the vagina reveals a localised thickening on its anterior wall. On inserting a vaginal speculum, urine will be seen escaping from an opening in the anterior vaginal wall. It is usually possible to pass a bent probe from the vagina into the bladder. Cystoscopy is often difficult, owing to the contraction of the bladder from cystitis and the escape of urine from the fistula; however, usually the tip of the probe that has been passed can be seen emerging through an area of granulation tissue.

Differential Diagnosis between a Uretero-vaginal and Vesico-vaginal Fistula.—If a swab is placed in the vagina and a solution of methylene blue is injected through the urethra, the vaginal swab becomes coloured blue. In the case of a uretero-vaginal fistula the vaginal swab is not so coloured. Uretero-vaginal fistula is discussed on p. 1151.

Treatment.—Operation must be postponed for several months to enable viable tissue in the neighbourhood to recover fully, and for scar tissue to consolidate. The fistula is exposed via the vagina; the edges are freshened and a longitudinal repair of tantalum wire used to traverse the bladder wall (not mucosa) and the whole thickness of the vagina. Parallel vaginal incisions may be used to relieve tension on the suture lines. The bladder is drained by No. 4 polythene tubing (Chassar Moir) for fourteen days, unless the urethra is primarily affected, when a suprapubic cystotomy is performed.

FIG. 1400.—Cystoscopic view of a vesico-intestinal fistula. Bubbles of gas can be seen issuing from the orifice of the fistula.

Fistula from Renal Pelvis to Skin or Gut.—Tuberculosis of a kidney may result in destruction of the kidney by caseation, and a chronic sinus leading to duodenum or colon and/or the skin, usually in the iliac fossa, or in the lumbar triangle of Petit. Similarly pyonephrosis and stone may spontaneously discharge into the gut or by a fistula to the skin. Cases of duodenal ulcer involving the pelvis of the right kidney are also on record.

Fistulæ Arising as a Result of Infection.—The commonest cause is diverticulitis of the colon. It may also follow Crohn's disease, appendix abscess, or pelvic sepsis in association with acute salpingitis, or as a result of surgery and radiotherapy within the pelvis.

The onset may not be dramatic, and may well be treated as acute cystitis. The diagnosis can be difficult to make because the acute signs subside, but on cystoscopy a patch of œdema on the left side of the vault is suggestive, and a cystogram may reveal the

James Marion Sims, 1813–1883, while a country Practitioner at Montgomery, Alabama, was the first to succeed in closing a vesico-vaginal fistula.
John Chassar Moir, Contemporary. Emeritus Nuffield Professor of Obstetrics and Gynæcology, Oxford, England.
Burrill Bernard Crohn, Contemporary. Gastro-enterologist, Mount Sinai Hospital, New York, U.S.A.

fistula. However, as the tract is not always patent a negative result may be obtained. The passage of gas per urethram in a patient who has cystitis is most suggestive (providing diabetes is excluded).

Treatment.—A defunctioning colostomy is made above the fistula as the first step. Inflammation is allowed to subside over two to three months. At laparotomy the communication is separated, the hole in the bladder being closed and patched with omentum, and the segment of diseased bowel resected. The bladder is drained by a urethral catheter. The colostomy is closed about 3 weeks later provided a barium enema reveals no leaks.

Cases due to Carcinoma.—By the time a fistula between the bowel and the bladder has developed, as a rule, the growth is inoperable or requires pelvic evisceration for its attempted eradication. As so often these patients are unfitted for this major procedure, it is best to leave the patient with the defunctioning colostomy performed in the first instance. Exceptions do occur, and occasionally it is warranted to undertake segmental resection of the colon and a partial or complete cystectomy.

Urethral Fistulæ occur as the result of infection above a stricture producing a peri-urethral abscess which rupturing into the urethra allows extravasation to occur suddenly into the scrotum and perineum. Urine and infection extend into upper 2·5 cm. of thigh and lower abdominal wall (p. 1264). Widespread cellulitis and tissue necrosis will occur unless diversion of urine is achieved by suprapubic cystotomy, and the tissue planes are freely drained by inguinal and scrotal incisions.

Neoplastic Fistulæ.—Primary bladder tumours may fungate through the abdominal wall when neglected. Only palliative treatment is possible in most of such cases. Involvement of the bladder by growths of cervix, uterus and colon and rectum do produce fistulæ, as may lymphosarcoma of small gut. Carcinoma of the prostate rarely produces a rectal fistula. Treatment in most such cases is difficult and prolonged and in most only palliative relief can be given. It is rarely in the patient's interest to divert the ureters (p. 1229).

CYSTITIS

Both acute and chronic cystitis occur at all times of life, and in both sexes, but they are especially common in women.

Predisposing Causes

1. Incomplete emptying of the bladder, such as occurs in prostatic obstruction, urethral stricture, stenosis of the external urinary meatus, diverticulum of the bladder, pregnancy (and more particularly the puerperium), cystocele, also injuries and diseases of the spinal cord.
2. The presence in the bladder of a calculus, foreign body, or neoplasm.
3. Lowered general resistance from intercurrent disease and avitaminosis.

When cystitis has been brought under control, every endeavour should be made to search for, and if present, treat a primary focus of infection or remove a predisposing cause. In many cases none can be found.

Avenues of Infection

1. *Descending* from the kidney along the lumen of the ureter (pyelonephritis, p. 1172).
2. *Ascending* from the urethra is the usual cause. The shortness of the urethra is held responsible for the comparatively common occurrence of cystitis in females. The passage of urethral instruments is a source of cystitis in both sexes, more especially when residual urine is present in the bladder. This does not necessarily imply that the instrument was unsterile, but rather that instrumentation awakens a latent infection in the posterior urethra.
3. *Lymphogenous.*—The rich lymphatic network at the base of the bladder which communicates with the prostate, the seminal vesicles or the cervix uteri, and the rectum, provides an avenue by which organisms can reach the bladder from these commonly infected structures.

4. *From Adjacent Structures.*—Fistulous communications with the intestine, the vagina, and the Fallopian tube, or by suprapubic cystostomy.

5. *Hæmatogenous.*—Metastasis from a distant focus is exceptional.

Bacteriology.—*Esch. coli* is the commonest infecting organism. Less frequently *Streptococcus fæcalis*, *Staphylococcus aureus*, *Staphylococcus albus*, *B. proteus* or *Ps. æruginosa* is responsible. *B. proteus* and *Staphylococcus albus* are urea-splitting organisms that cause persistent alkalinity of the urine. Tuberculous cystitis is considered under ' Special Forms of Cystitis ', p. 1217.

The presence of pus cells without organisms calls for repeated examinations for the *M. tuberculosis* and the gonococcus (an exceedingly rare cause of cystitis). Having eliminated these possibilities, the condition may be one of abacterial cystitis (p. 1217), or of bladder tumour.

Clinical Features.—The severity of the symptoms varies greatly; those of acute cystitis are usually the more distressing.

Frequency is the outstanding symptom, both during the day and at night. The desire to urinate occurs from every hour to every few minutes, and often it is so urgent that if the bladder cannot be emptied forthwith, incontinence results. In severe cases, because of infection and loss of sleep, the patient looks drawn and haggard.

Pain varies from mild to agonising.[1] When the inflammation is situated in the dome of the bladder, pain is referred to the suprapubic region, while when, as is often the case, the inflammation involves the trigone, pain is referred to the tip of the penis, the labia majora, and the perineum.

Hæmaturia.—The passage of a few drops of blood-stained urine or blood-stained debris at the end of micturition is a frequent accompaniment. Less often the whole specimen is blood-stained, but more so at the end.

Pyuria is always present, except in some cases of trigonitis and interstitial cystitis (p. 1218). If urine is passed into two glasses, the second is the more cloudy.

On examination there is tenderness over the bladder suprapubically, per rectum, or per vaginam.

Initial and midstream urine specimens should be collected in a male as prostatitis may be present, in which case threads will be seen clearly in the initial specimen (p. 1251). In a female, and when the initial urine in the male does not contain threads, a midstream specimen must be subjected to microscopy and culture, and the sensitivity of any organisms assessed.

Treatment should be commenced forthwith, and modified if necessary when the bacteriological report is to hand. The patient is urged to drink plentifully, and while awaiting sensitivity results, one should prescribe either a sulphonamide or nitrofurantoin (100 mg q.d.s.) with Mist. pot. cit et hyocyamus 10 ml. t.d.s. as a bladder sedative. Failure to respond, or early recurrence of infection, indicates the necessity for further investigation to exclude predisposing factors.

Cystoscopy to confirm the diagnosis may be performed in women during the acute phase. The appearances may vary from hyperæmia, sometimes

[1] An Irish surgeon, long since dead, always finished his evening prayers,—" Please God, when you take me, may it not be through the bladder".

with mucosal hæmorrhages, to severe sloughing and ulceration of the mucosa. In men, cystoscopy to exclude predisposing causes should be delayed until the infection has been controlled.

SPECIAL FORMS OF CYSTITIS

Acute Abacterial Cystitis (*syn.* Acute Hæmorrhagic Cystitis).—The patient, a young man or woman, presents with symptoms of severe cystitis. Pus is present in the urine, but no organism can be cultured therefrom. The condition, which sometimes is associated with abacterial urethritis, commonly follows recent venereal exposure. While tuberculous cystitis always must be ruled out by cultural or biological tests, the fact that excretory pyelography shows normal excretion on both sides strongly favours acute abacterial cystitis. In 60 per cent. of cases, by special cultural methods the pleuro-pneumonia-like organism, which frequently accompanies acute abacterial urethritis, is found.

Although this is a self-limiting disease its course can be shortened by the antibiotic therapy recommended for abacterial urethritis (p. 1267). When cystoscopy is performed after the acute symptoms have abated, abundant mucosal hæmorrhages are seen, and presumably at its height the infection causes a hæmorrhagic cystitis.

Urethro-trigonitis is a common form of recurrent lower urinary tract infection in women. Cystoscopy shows increased vascularity of the trigone, œdema of its mucous membrane (most marked towards the apex) and, in severe cases, there is a pseudo-membrane limited to the trigone. Inflammatory polypi may be present at the bladder neck (fig. 1484). Later the urethra becomes narrowed. A cystocele is frequently present.

A primary focus of infection must be sought; the most common being (*a*) the cervix uteri (chronic cervicitis or a cervical erosion) or (*b*) the intestinal tract, notably chronic colonic diverticulitis. No examination is complete without examining the cervix with a speculum, and if the cervix is healthy a barium enema is necessary for evidence of diverticulitis.

Treatment.—In addition to the usual measures, urethral polypi should be destroyed by light fulguration and the urethra dilated, if necessary. Cervicitis or a cervical erosion is treated by excising the glandular tissue of the cervix with a diathermy loop. Diverticulitis is discussed on p. 970.

Tuberculous cystitis is always secondary to renal tuberculosis, and unless treated early is a particularly relentless form of chronic cystitis.

Cystoscopy shows that early tuberculosis of the bladder commences around one ureteric orifice or in the neighbourhood of the trigone, the earliest evidence being pallor of the mucosa, due to submucous œdema. Subsequently tubercles may be seen, and in long-standing cases there is much fibrosis, and the capacity of the bladder is so much reduced that it has earned the name of 'thimble' bladder. This feature can be well shown by cystography (fig. 1401).

FIG. 1401.—Retrograde cystograph showing exceedingly contracted ('thimble') bladder in a case of tuberculous cystitis.

Treatment.—Tuberculous cystitis usually responds rapidly to antituberculous drugs (p. 32), but occasionally, in cases with advanced renal changes, may not subside until the involved kidney and ureter have

been removed. Local treatment of persistent tuberculous cystitis consists of instillations of a substance inimical to *M. tuberculosis*. Among the best is B53, a soap derived from a branched fatty acid, having a high inhibitory index for the *M. tuberculosis*. A correctly buffered 0·5 per cent. solution containing local anæsthetic is instilled and retained for one hour. A fortnight's course can be repeated after an interval of a week.

When the bladder is considerably contracted, but free from ulceration, remarkable relief from the distressing frequency can be achieved by ileocystoplasty (fig. 1402), which is an extremely efficacious method of increasing the capacity of a contracted bladder. When, in addition, tuberculous contracture threatens to implicate the remaining kidney by back pressure, as shown by dilatation of the ureter on excretory pyelography, the ureter is implanted into the newly constructed pouch of intestine (p. 1232) with every hope of conserving renal function as well as rendering the patient symptom-free.

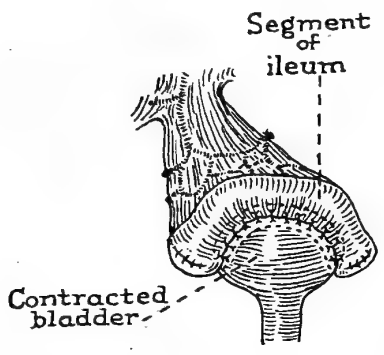

FIG. 1402. — Ileocystoplasty using a 6-inch segment of ileum. (*After D. O. Ferris.*)

Ileocystoplasty.—After pre-operative sterilisation of the intestines (p. 992) a 15-cm segment of ileum with an ample blood supply as demonstrated by transillumination is disconnected, leaving its mesentery intact, and the continuity of the intestine is restored by anastomosis. After closing the ends of the donor segment and opening it longitudinally it is anastomosed to the dome of the contracted bladder (fig. 1402).

Interstitial Cystitis (*syn.* **Hunner's Ulcer;** Elusive Ulcer).—For practical purposes Hunner's ulcer can be said to be a condition peculiar to women. The symptoms commence in the early forties. It can cause more pain, mental anguish and associated neurosis than does carcinoma of the bladder; as a consequence, the incessant painful micturition it occasions sometimes leads to drug addiction and even suicide.

Ætiology is still as obscure as it was when Guy Hunner first described the condition in 1914. Certainly it does not commence as an ordinary pyogenic infection of the mucous membrane, but rather as an infection of the paravesical tissues secondary, it is suggested, to infection of the adnexae, or even to infection from a more distant focus such as the nasopharynx. Some believe the condition is due to an attenuated *M. tuberculosis* which so far has defied isolation. In a number of instances the symptoms have commenced three or four months after a pelvic operation.

Pathology.—As a result of the paracystitis, fibrosis of the vesical musculature ensues, leading to contracture of the bladder and areas of avascular atrophy of the mucous membrane. Finally, ulceration of the mucosa occurs in the least vascular portion of the bladder, namely the fundus. Often the capacity of the bladder is reduced to 30 to 60 ml. The characteristic linear bleeding ulcer is a crack due to splitting of the mucous membrane when the bladder is distended under anæsthesia for cystoscopy.

Microscopically, inflammation of all coats of the bladder is present with granulation tissue in the submucosa underlying the ulcer. The muscularis is hypertrophied and the peritoneum in proximity to the area of maximum disease is thickened.

Clinical Features.—Bladder capacity becoming much reduced, increased frequency, eventually every hour both day and night, is the leading symptom. Pain, relieved by micturition and aggravated by jarring and overdistension of the bladder is the second and most characteristic symptom. In early cases the urine is crystal clear and sterile; in later cases it contains ordinary pyogenic bacteria in under half the

---

B53 (Hinconstarch) is produced in the laboratories of the Irish Medical Research Council.

Guy Leroy Hunner, 1868–1951. Gynæcological Surgeon, Johns Hopkins University, Baltimore, U.S.A.

specimens examined; in the remainder the urine remains sterile. In 60 per cent. of cases hæmaturia is a leading symptom.

Cystoscopy.—The lesion appears in the roof of the bladder as a star-shaped area of intense congestion in which a fissure can be seen when the bladder is distended. The ulcer, if ulcer it can be called, bleeds readily.

Treatment is difficult and unsatisfactory. Local hydrocortisone and irrigation of the bladder with various sedatives have proved valuable. Hydrostatic dilatation under anæsthesia may give relief for some months. Light diathermy fulguration of the ulcer may help. Complete relief may be obtained by urinary diversion, while ileo-cystoplasty after excision of the affected bladder wall, though frequently very satisfactory, is not always permanently successful in relieving all symptoms.

Alkaline encrusting cystitis is due to urea-splitting organisms causing phosphatic encrustations on the bladder mucosa of elderly women. There are symptoms of chronic cystitis and a plain X-ray shows the bladder outline. The encrustations may be curetted and removed via a cystoscope or a suprapubic cystotomy, or controlled by tidal lavage using a dissolvent solution or solution G (p. 1166), or 0·5 per cent. acetic acid.

Cystitis Cystica.—Glands are not found in the normal vesical mucosa. Under the influence of chronic inflammation, the surface epithelium sends down buds, resulting in minute cysts filled with clear fluid, most abundant on the trigone. Most of the cases are seen in women, and the urine usually contains pus, and commonly *E. coli*. An adenocarcinoma may originate in one of these cysts.

BILHARZIASIS OF THE BLADDER

Geographical Distribution.—The disease is endemic in the greater part of Africa, throughout Israël, Syria, Arabia, Iran and Iraq. It is met with frequently in Portugal and in Greece, and in the islands of Madagascar, Mauritius and Cyprus. Dwellers along the valley of the Nile have suffered from time immemorial. The condition also occurs along the shores of some of China's great lakes. Marshes or slow-running fresh water provide a favourable habitat for the particular fresh-water snail (Bullinus contortus), which is the intermediate host.

Mode of Infestation.—The disease is acquired while bathing or standing in infected water. The free-swimming bifid-tailed embryos (cercariæ) of the trematode *Schistosoma hæmatobium* penetrate the skin by their motile and erosive secretory powers. Shedding their tails, which enabled them to swim, they enter blood-vessels and are swept by the blood-stream into all parts of the body. All perish save those that are carried to the liver. Once within the liver the survivors flourish by sustaining themselves on erythrocytes, and they develop into male and female worms. The female is long, smooth and slender and is furnished with two weak suckers anteriorly. The male is broader, shorter (11 mm. in length), bosselated and provided with a strong sucker at either end. Sexual maturity having been attained, the nematodes leave the hepatic nursery and enter the portal vein. Here the male bends into the shape of a canoe and in so doing a gutter (the gynæcophoric canal) is formed along its length. Into the groove a female nestles and, thus conjugating, the pair (fig. 1403) paddle their way against the stream towards the inferior mesenteric vein. The long journey is accomplished in short stages, the male's suckers serving as anchors to the vein wall during periods of rest. *Schistosoma hæmatobium* worms have an affinity for the vesical venous plexus, and to reach it they must pass along the portal-systemic anastomotic channels, the most important in this respect being the venules in relation to the lumbar lymph nodes (Makar); other communications being venules in relation to the lower part of the ureters.

FIG. 1403.—Conjugating male and female *Schistosoma hæmatobium* trematodes. (*After A. Looss.*)

Having reached one of the smaller radicles of the vesical plexus the pair can go no further coupled, so the female, now pregnant but still comparatively slender, parts from the male and moves forward until she enters a submucous venule so small that she completely blocks it. She now proceeds to lay about twenty ova in a chain, and

Theodor Maximilian Bilharz, 1825–1862. Professor of Zoology, Cairo.
Naguib Makar, Contemporary. Emeritus Professor of Urology, Cairo University, Cairo, Egypt.

after each is deposited, by slightly withdrawing herself, the venule contracts upon the ovum. Each ovum is provided with a terminal spine (fig. 1404) which penetrates the vessel wall. Aided by muscular contraction of the bladder, and perhaps by secreting lytic fluid, some of the ova reach the lumen of the bladder; others die incarcerated in the mucous membrane. A heavily infected subject passes many hundreds of ova a day. If the ova reach fresh water, the low osmotic pressure of the new environment causes their envelope to burst, and thus emerges the miracidium, which is ciliated. To survive, the miracidium must reach and penetrate the intermediate host within thirty-six hours. Within the snail's liver the miracidium enlarges and gives rise to myriads of daughter cysts, broods of which are set free on the death of the snail. A single miracidium begets thousands of cercariæ to complete the life-cycle.

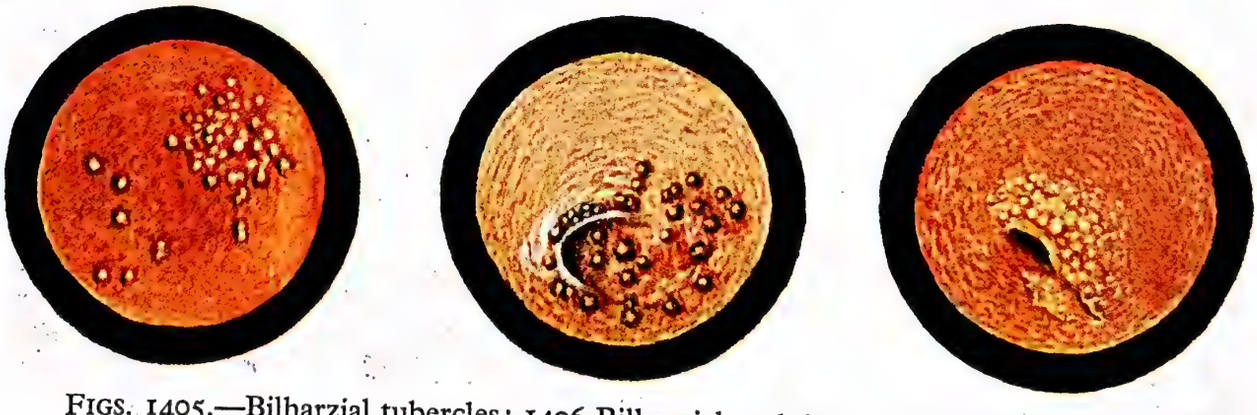
FIG. 1404.—A bilharzia hæmatobium ovum.

Clinical Features.—After penetration of the skin there may arise urticaria, which lasts for about five days and sometimes recurs (swimmer's itch). After an incubation period ranging from four to twelve weeks, high evening temperature, sweating, and asthma, together with leucocytosis and eosinophilia of over 10 per cent., sometimes last several weeks. Usually an asymptomatic period of several months supervenes before the ova laid in the bladder wall find egress and cause the typical early sign and symptom of intermittent, painless, terminal hæmaturia. Men are three times more often affected than women. Native patients of the peasant class rarely consult a doctor for this hæmaturia *per se*, so that many late cases are encountered.

Examination of the Urine.—The last few millilitres of an early-morning specimen of urine are collected and centrifuged. It is essential that all receptacles be absolutely dry. The ovum is recognised without staining under the low-powered microscope. Examination on several consecutive days may be required. Even so, a negative result does not exclude bilharziasis, especially in patients no longer resident in bilharzial districts.

Cystoscopy.—Dependent on the length of time the disease has remained untreated, cystoscopy will reveal one or more of the following:

1. *Bilharzial pseudo-tubercles* are the earliest specific appearance. The pseudo-tubercles are larger, more prominent, more numerous, more yellow and more distinctly grouped (fig. 1405) than those of tuberculosis.
2. *Bilharzial nodules* (fig. 1406) are due to the fusion of tubercles in the presence of secondary infection. They are larger and greyer than the foregoing.
3. '*Sandy patches*' are the result of calcified dead ova with degeneration of the overlying epithelium. They occur in the first instance around one or both



FIGS. 1405.—Bilharzial tubercles; 1406 Bilharzial nodules; 1407 'Sandy patches'. (*After N. Makar.*)

ureteric orifices (fig. 1407). Considerable calcification of this nature is visible on the radiograph.

4. *Ulceration* is the result of sloughing of mucous membrane containing dead ova, or what is even more common, sloughing of a bilharzial papilloma. The ulcer is

Napoleon's troops who served in his march to the Pyramids suffered from hæmaturia.

shallow (fig. 1408), bleeds readily, and its common position is the posterior wall of the bladder.

5. *Fibrosis* is mainly the result of secondary infection. The capacity of the bladder becomes much reduced. Contracture of the bladder neck is also a common result of bilharzial fibrosis.

6. *Granulomas.*—Bilharzial masses are due to an aggregration of nodules. They are sessile, soft and bleed readily when touched.

7. *Papillomas* are distinguished from the foregoing by being more pedunculated (fig. 1409). They vary in size from that of a pea to that of a walnut, and they may be single or multiple.

8. *Carcinoma* is a common end-result in grossly infected bilharziasis of the bladder which has been neglected for years. It usually commences, not in a papilloma, but in an ulcer, and is therefore a squamous-celled carcinoma.

FIG. 1408.—Bilharzial ulcer. (*After N. Makar.*)

FIG. 1409.—Bilharzial papilloma. (*After N. Makar.*)

Treatment[1].—Lesions 1 to 6 inclusive can be expected to heal under general treatment by antimony and other preparations (see p. 1074). It takes many months for dead ova to be expelled, and even after repeated courses and healing of the bladder lesion, living bilharzial worms have been found at necropsy in the portal system. In addition to general treatment, healing of bilharzial ulcers and granulomas is expedited by light diathermy coagulation. Bilharzial papillomas and, of course, carcinoma do not respond to general treatment: these lesions require the same surgical measures as non-bilharzial papillomas and carcinomas, in addition to general treatment.

Other Complications and their Treatment:

(*a*) *Secondary bacterial cystitis* is commonly present in cases of some standing and the treatment of it must be thorough and prolonged.

(*b*) *Urinary calculi*, especially vesical and ureteric, occur more frequently when bilharzial lesions of the bladder are present. Litholapaxy is contraindicated in cases where there is ulceration of the bladder wall.

(*c*) *Stricture of the ureters* affects the last inch of the ureters. These strictures often respond to dilatation, but sometimes transplantation of the affected ureter into another part of the bladder is necessary.

(*d*) *Prostato-seminal vesiculitis*, like tuberculosis of these structures, is made worse by prostatic massage, and general treatment alone must be employed.

FIG. 1410.—Bilharzial contracture of the bladder, with ureteric reflux. (*H. Talib, F.R.C.S., Baghdad.*)

(*e*) *Contracture of the bladder, and contracture of the bladder neck* (fig. 1410), must be treated in the same ways as similar contractures of non-bilharzial origin.

[1] John Brian Christopherson, 1868–1955. Introduced the treatment of bilharziasis by the intravenous injection of tartar emetic in 1918 whilst he was Director of Civil Hospitals at Khartoum and Omdurman, Sudan.

(*f*) *Bilharzial urethral strictures* are often accompanied by fistulæ, and can be cured only by excision of the fistulous tracks and urethroplasty (p. 1272).

NEOPLASMS OF THE BLADDER

More than 95 per cent. of primary tumours of the bladder originate in its mucous membrane; the remainder are connective-tissue growths—angioma (the least uncommon), myoma, fibroma, and sarcoma. These are too rare to merit further description, as also is a phæochromocytoma arising in the bladder wall from accessory adrenal tissue.

Another uncommon benign bladder tumour is an **endometrioma,** characterised by a localised, smooth, vascular projection on the bladder wall, sometimes containing chocolate-coloured cysts; and at other times translucent cysts of a bluish hue. The tumour enlarges and bleeds during menstruation. Treatment is partial cystectomy.

Secondary involvement of the bladder can occur from extension of a malignant neoplasm of a neighbouring organ, particularly the large intestine (sigmoid and rectum), the uterus or an ovary.

On rare occasions the first symptoms of a carcinoma of the pelvic colon are those of cystitis. Cystoscopy reveals a circumscribed area of intense inflammation, usually on the left side of the fundus. If the diagnosis is not made and treatment carried out at this stage, a vesico-intestinal fistula results (p. 1214).

Ætiology: The first suspicion of a chemical cause for bladder tumours was raised by Rehn in 1894 when he recorded a series of tumours in workers in aniline dye factories. However, subsequent investigation has exonerated aniline itself—it was the impurity of B. naphthylamine. It is now recognised that benzidine, alpha-naphthylamine, xylenamine, auramine and magenta are all carcinogenic. The particular industries involved are the dyeing industry, gas workers, the rubber and cable industries and the printing industry. Tumours occurring in workers in these industries are accepted for compensation.[1] Bilharzia, active or inactive, and bladder cancer are commonly found together and probably the former produces chronic irritation and incomplete emptying which produce metaplasia and squamous carcinoma.[2] Fibrosis reduces lymphatic metastases, but produces ureteric obstruction and renal damage. Leukoplakia of the bladder must also be regarded as a precancerous lesion. Despite these facts in the majority of cases the cause of a bladder cancer cannot be determined.

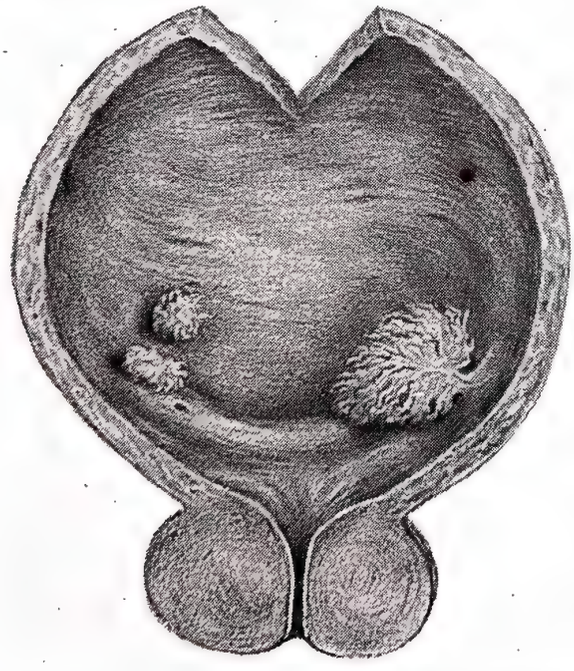


FIG. 1411.—Papillary tumour with daughter implantations ('kiss' cancer).

[1] Workers exposed to this hazard should have a sample of urine centrifuged and examined for red cells and neoplastic cells at three-monthly intervals.

[2] It has been suggested that nitrosamines excreted in the urine of agricultural workers may be an essential factor in the development of carcinoma in those bladders which are affected by bilharzia.

Ludwig Rehn, 1849–1930. Surgeon, Frankfurt on Main, Germany.

Pathology

Benign Villous Tumours.—A papilloma of the bladder commences as a single frond with a central vascular core—later it becomes tufted. From these tufts spring villi—long, finger-like projections composed of three or four layers of transitional epithelium surrounding a capillary vessel with a minimum amount of supporting fibrous tissue. Thus the fully developed papilloma appears like a red sea anemone with delicate tentacles eddying to and fro with each and every movement of the bladder contents.

Diffuse papillomatosis is a term used to signify a condition in which multiple small growths are disseminated over a relatively wide area of the bladder. Pedicle formation is not so pronounced as in the solitary variety. To justify a diagnosis of diffuse papillomatosis, a stage must have been reached when multiplicity has outstripped the ability to keep the bladder clear by endoscopic destruction of the neoplasms.

Malignant Villous Tumours.—Low-grade transitional cell carcinomas have exactly the same macroscopic appearance as the benign villous growths. As the degree of differentiation decreases, the appearance of the growth alters: (*a*) the villi are stunted, closely packed, and swollen, resembling a cauliflower; (*b*) the growth is sessile (90 per cent. of villous tumours are pedunculated); (*c*) the bladder wall immediately adjacent is more vascular and œdematous; (*d*) the surface of the growth may ulcerate, show areas of necrosis, or become encrusted with urinary salts; (*e*) a bladder tumour accompanied by cystitis is nearly always malignant; (*f*) submucosal lymphatic nodules appear around the growth; (*g*) the depth of invasion of the bladder wall increases, and ureteric obstruction may occur.

Multiplicity of the growth is not necessarily a sign of malignancy, provided the daughter growths are limited to two or three and the rest of the bladder mucous membrane is normal. When this number is exceeded and/or a patch of œdematous vascular mucosa is seen the growths must be deemed malignant. Unablated, this neoplasm, like other forms of vesical carcinoma, invades the bladder wall (fig. 1415) and gives rise to regional and distant metastases.

Solid tumours are always malignant and grow rapidly through the bladder wall. The surface, instead of being tufted, is bald from the outset. The tumour, which is sessile, becomes lobulated (fig. 1412), is deep red, and bleeds on being touched. It is liable to become covered with a powder of phosphates. Later the surface becomes ulcerated in places. Lymphatic metastases occur earlier than is the case in malignant villous tumours. Solid carcinoma is the second most common form of carcinoma of the bladder.

FIG. 1412.—Nodular carcinoma of the bladder, sometimes known as the 'bun-shaped' tumour.

A **carcinomatous ulcer** is similar in appearance to a carcinomatous ulcer elsewhere, and occasionally it arises in a patch of leukoplakia. This type of growth occurs in the base of the bladder and on the trigone. This is the most

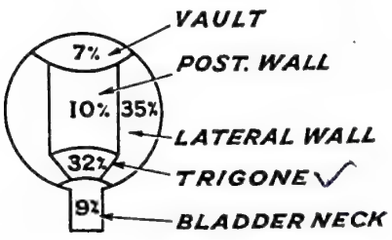

FIG. 1413.—Sites of carcinoma of the bladder. (*American Urological Association Statistics.*)

malignant carcinoma of the bladder. The frequency of carcinoma at various sites is shown (fig. 1413).

Primary adenocarcinoma of the bladder is rare (1 per cent. of cases). It is a highly malignant tumour commencing in the fundus of the bladder of relatively young patients, and is believed to arise in the remnants of the urachus. Secondary adenocarcinoma of the bladder from a primary neoplasm in the stomach, colon, lung, rectum, or prostate is more common than one originating in the bladder.

Metastases.—When a carcinoma has invaded the muscle coat (but no further) it is doubtful if metastasis occurs, though local recurrence is common. On the whole, vesical neoplasms are slow to metastasise and the incidence of distant metastases is relatively low, irrespective of the histological characters of the tumour. On the other hand, once the neoplasm has penetrated the musculature and has reached the prevesical fat, it disseminates by the lymphatics, to reach the lymph nodes along the external iliac and common iliac vessels, thence to the para-aortic and mediastinal lymph nodes. By the blood-stream they can be swept to the lungs, liver, bones or the brain.

Clinical Features.—*Papilloma.*—Painless, profuse, paroxysmal hæmaturia is the only symptom for a long period. The hæmaturia may last for a few hours or a few days, and then it ceases. After an interval of weeks or months, bleeding recurs ; as time progresses the intervals become shorter and the hæmaturia more severe and of longer duration. Eventually the resulting anæmia may be so severe as to necessitate blood transfusion. Clot retention sometimes occurs, as also dysuria if the growth obstructs the internal urinary meatus. Bimanual rectal or vaginal examination is usually negative. In 80 per cent. of cases painless hæmaturia remains the only symptom and sign.

Malignant Neoplasm.—In 95 per cent. of cases the initial symptom is intermittent hæmaturia, which eventually becomes continuous and associated with dysuria. It is a sad fact that in spite of this ominous sign more often than not twelve or more months elapse before the patient presents for treatment, and this is not always the patient's fault. Occasionally (in carcinomatous ulcer) the first symptoms are those of severe cystitis. In all cases sooner or later cystitis supervenes, and painful, frequent, blood-stained micturitions are the dominating symptoms in established cases. As time goes on, strangury occurs at the end of each act of micturition. Loin (renal) pain from an obstructed ureter is not uncommon. A late manifestation, due to nerve involvement, is pain referred to the suprapubic region, the groins, perineum, the anus, or down the thighs.

Investigation:

Examination of the Urine.—Culture is essential. Cytology of a 3-hour specimen of urine is proving accurate in diagnosing tumours and also in assessing the histological grade.

Excretory Pyelography.—Occasionally the preliminary plain film shows a faint shadow of an encrusted neoplasm of the bladder. As a rule in cases of papilloma, excretory pyelography displays normal kidney function. When the neoplasm is obstructing a ureteric orifice, dilatation of that ureter will be apparent. In the case of a large neoplasm a filling defect of the bladder (fig. 1414) is likely to be revealed.

FIG. 1414.—Cystograph in a case of malignant tumour of the right side of the bladder.

Cystoscopy is the mainstay of diagnosis. It should be performed in every case of hæmaturia. The main cystoscopic appearances of bladder tumours have been described under 'Pathology' (p. 1223).

Following cystoscopy, but before any transurethral operation or biopsy is undertaken, the following important examination is made.

Bimanual palpation under general anæsthesia (recto-abdominally in the male and vagino-abdominally in the female), with the patient's abdominal musculature completely relaxed and the bladder absolutely empty, is of salient importance in determining the stage of progression of the neoplasm and the potentialities of a cure by any given method. When a tumour is impalpable, it is most unlikely that it has invaded the bladder wall. While a very large papilloma sometimes can be felt, the tumour is mobile within the bladder (fig. 1415 (T1)). When a localised but

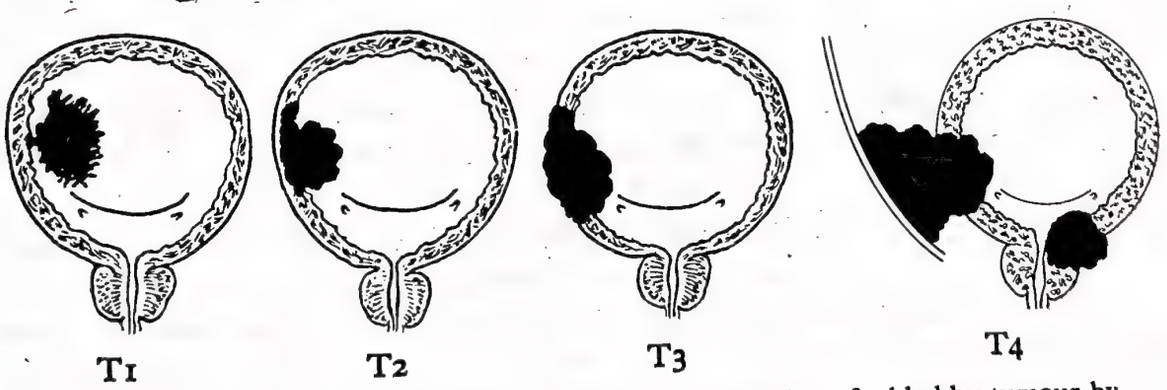

FIG. 1415.—Clinical assessment of the stage of progression of a bladder tumour by bimanual palpation. *(After D. M. Wallace.)*

Staging by the **TNM** classification (cf. p. 48). *Stage T1*—involving subepithelial connective tissue. *Stage T2*—infiltration of muscle superficially. *Stage T3*—full thickness of muscle and possibly perivesical tissues affected, but mobile. *Stage T4*—fixed to adjoining organs or involving prostate

definite thickening can be felt, but which is as movable as one would expect the bladder to be, it is probable that the bladder wall is infiltrated, but not penetrated (fig. 1415 (T2)). On the other hand, if in addition the mass is

larger than would be expected from the cystoscopic appearance but is not fixed, extra vesical spread (fig. 1415 (T3)) has certainly occurred. When a mass is easily palpable, fixed to the bony pelvis (fig. 1415 (T4)) and firm to stony-hard in consistency, palliative measures alone are advisable. The degree of infiltration, as judged by bimanual palpation under anæsthesia, is a more valuable criterion of potential curability than the degree of malignancy revealed by histological studies.

Biopsy.—The removal of a tiny piece of tissue is useless in most instances—the biopsy must be adequate, should include the underlying vesical wall itself, and is best taken with a resectoscope. Alternatively, special biopsy forceps (Riches or Lowsleys), or cystoscopic rongeur forceps (fig. 1394) may be used.

Treatment:

While the treatment of a solitary pedunculated papilloma is standardised except for comparatively minor details in technique, the same being true if a few seedlings are present, as we proceed from the probably malignant to the undoubtedly malignant bladder tumour, so the gulf of controversy as how best to treat the neoplasm widens. At the present time vacillation between ultra-radical operations and wholly conservative measures is to some extent influenced, on the one hand, by the appearance of new isotopes or new methods of applying them, and, on the other, by better methods of diverting the urinary stream after removal of the bladder.

FIG. 1416.—Cystodiathermy of a papilloma of the bladder.

Cystodiathermy.—The widely employed method of destroying benign papillomas is coagulation diathermy applied by an electrode through an irrigating cystoscope. A small solitary papilloma can be treated satisfactorily employing local anæsthesia of the urethra, the patient being ambulatory. For larger growths a general or spinal anæsthetic is given which permits more massive fulguration, but necessitates in-patient treatment. If daughter growths are present, they are fulgurated first. It is of great importance to attempt eradication of the growth at the first treatment.

The patient is cystoscoped again in twelve weeks by which time necrotic tissue should have sloughed off, and the area epithelialised. Further treatment is carried out if necessary. Larger papillomas can be destroyed more quickly by Kidd's diathermy cystoscope, which has a relatively large ball electrode incorporated on the beak of the instrument, viz.→

Excision with a resectoscope is indicated when the tumour is too large to be destroyed at one session of cystoscopic electro-coagulation, and especially for small papillary carcinomas with little or no infiltration. After the main part of the tumour has been sheared away, electro-excision of the base flush with the bladder wall is accomplished. Cautiously a slight gutter is then made beneath the base of the tumour, into the muscle. Avoidance of downward pressure minimises the risk of perforation of the bladder—the leading danger of this excellent method.

Francis Seymour Kidd 1878–1934. Surgeon The London Hospital.

Transvesical Excision of a Large Villous Growth.—The bladder is distended with 1 : 2,000 silver nitrate solution and the viscus is exposed by a suprapubic incision. The contents of the bladder having been evacuated by a trocar and cannula (fig. 1417), which permits suction of the fluid contents so that none is spilled, the edges of the abdominal wall are covered with packs soaked in silver nitrate solution or 60 per cent. alcohol, as a precaution against contamination of the wound by detached tumour cells. The bladder is opened, and the surface of the tumour is lightly coagulated (with the object of preventing detachment of cells). It is then picked up with Fergusson's cupped forceps which surround the tumour. An innocent tumour can be elevated so that there is a substantial pedicle of normal mucous membrane. This is transected with the diathermy needle. After coagulating bleeding-points, the area from which the papilloma sprang is electro-coagulated. In the case of a sessile neoplasm, a diathermy loop electrode (fig. 1418) allows excision of the tumour including a fraction of the muscle layer. This accomplished, the cut surface is lightly fulgurated. The bladder can then be closed with indwelling urethral catheter drainage. Drainage of the prevesical space is necessary.

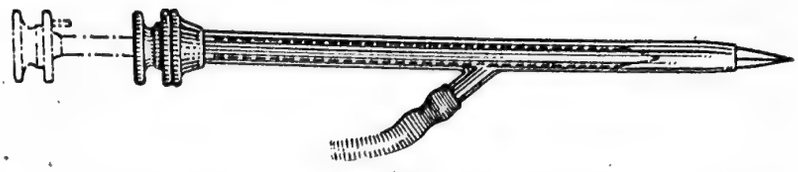

FIG. 1417.

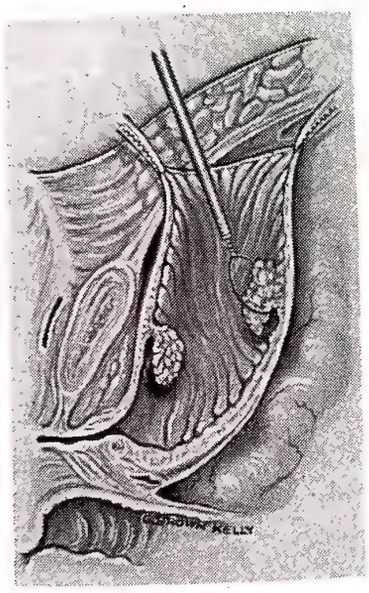

FIG. 1418.—Transvesical excision of a bladder tumour with diathermy loop electrode. (*After A. R. C. Higham.*)

Follow-up.—After the papilloma has been destroyed, endoscopically or by open operation, it is essential that the patient be examined cystoscopically, commencing at three-monthly intervals and, if there is no recurrence, gradually lengthening the interval to one year. In 30 per cent. of cases there is no recurrence. In the remainder there are recurrences, either at the site of the original lesion or in another part of the bladder, but as a rule they can be kept under control with regular cystodiathermy.

Local Radiotherapy.—When the lesion is not anaplastic, is 4 cm. or less in diameter with evidence of local invasion either on the pyelogram (hold-up or dilatation of one ureter), or on bimanual examination, it is wise to add local irradiation to the open diathermy excision described above. This may be achieved with radioactive gold grains or tantalum wire, inserted after the initial breach in the mucosa has been closed with 3/0 chromic catgut sutures.

(*a*) **Implantation of Radioactive Gold Grains** (^{198}**Au**).—The gold grains are inserted by means of a repeater gun, which is loaded with a cartridge containing fourteen grains. This isotope has a half life of two and a half days. The grains are implanted according to physical rules depending on the area to be irradiated. Stereoscopic films taken subsequently enable the physicist to determine the dosage the tumour will receive.

(*b*) **Radio active tantalum wire** (^{192}**Ta**) (Wallace) (fig. 1419) has a long half-life (four months), and it therefore can be stored in the hospital ready for use when required, instead of having to be obtained from an atomic pile for each patient. The wire is bent hair-pin fashion with a loop provided at the blunt end. Through the opened bladder the sharp ends of the wire are drawn beneath the base of the tumour by means of twin, hollow needles, mounted on a boomerang needle introducer which enters and emerges some millimetres from the periphery of the neoplasm. The wire having been inserted, a plastic or rubber catheter is passed from the external urinary meatus and its tip is attached to the loop of wire by a stitch. The bladder is then closed. Again,

David Mitchell Wallace, Contemporary. Professor of Urology, University of Riyadh, Saudi Arabia.

stereo-radiographs enable the physicist to determine how long the wires should be allowed to remain in position. They are removed by withdrawing the catheter.

Deep X-ray Therapy.—The advent of penetrating radiation such as Cobalt 60, and the linear accelerator which enables a high depth dose to be obtained easily, has greatly improved this method of treatment. It is now possible to irradiate the bladder to a high dose level and largely spare the rest of the pelvis, particularly the skin. Undifferentiated carcinomas are best treated by this method and the local results are now good. It is important, however that the tumour should be accurately localised, employing cystography.

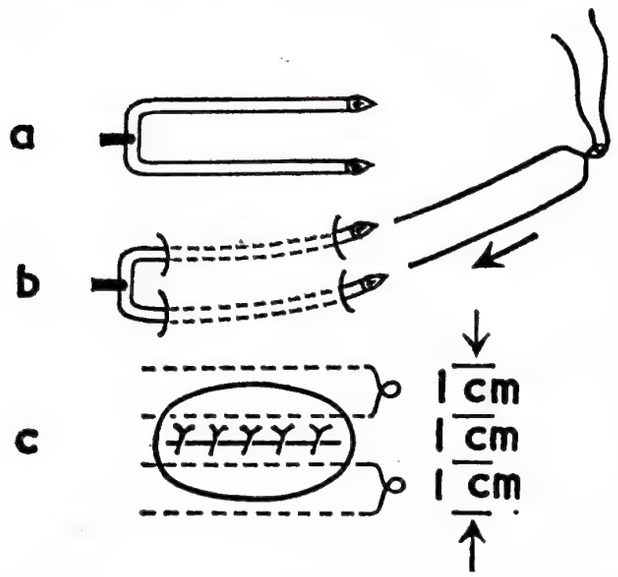

FIG. 1419.—Insertion of radioactive tantalum wire. (a) The curved twin hollow needles. (b) Insertion of the wire loop via the curved needles. (c) Position of wires relative to site of tumour pedicle.

Excision of a Part or the Whole of the Bladder:

Partial Cystectomy (*syn.* Segmental Resection).—Its disadvantage is that many malignant tumours of the bladder are situated near the trigone, where the operation is inapplicable. That part of the bladder containing the growth, together with a surrounding inch of the whole thickness of healthy bladder wall, is excised. When the neoplasm is situated near a ureteric orifice, the ureter should be divided before the excision is carried out, and after the excision has been completed, reimplantation of the ureter into the bladder is performed. The operation is of most value in small lesions involving muscle in the vault of the bladder.

Subtotal Cystectomy.—Like total cystectomy, the operation is conducted intraperitoneally. The whole of the bladder is mobilised to the entrance of the ureters into the bladder wall posteriorly and to within a finger's-breadth of the internal urinary meatus anteriorly. A new bladder is then constructed, utilising a segment of ileum with its blood-supply intact, the graft being split along its length. This operation has a very limited application; usually a growth extensive enough to necessitate it has encroached on the trigone.

Total Cystectomy.—The indications for total cystectomy are somewhat controversial. Provided the patient is fit to withstand this operation it would be justifiable to undertake it in the following circumstances: (1) Profuse papillomatosis uncontrolled by other methods; (2) Recurrence or residual growth after adequate radiotherapy; (3) Carcinoma involving the bladder neck in either sex; (4) Recurrences in a small contracted bladder that has resulted from oft-repeated conservative operations; (5) Recurrence after partial cystectomy.

Operation.—With the bladder empty, a lower left paramedian incision is made, and the incision is carried down far enough to expose the symphysis pubis. The peritoneum having been opened, the iliac and para-aortic lymph nodes and the liver and the kidneys are palpated. Having decided to proceed, the operating table is tilted and the ureters are isolated and divided as low as possible in the same way as described on p. 1232. A suitable catheter is passed along the lumen of each ureter, and the urine is allowed to drip into a bottle placed away from the operation area. Hæmorrhage is reduced by ligating the anterior division of the internal iliac arteries.

The bladder and its overlying peritoneum, together with the prostate and all the fascia and fat surrounding these structures (including the uterus in the female), and the urethra, are removed *en bloc*.

One of the most important steps of the operation is to find the correct plane of cleavage between the prostate and the rectum. This is accomplished by following the vas deferens proximally. *En route* this will lead to the superior and inferior vesical vascular pedicles, which are ligated and divided.

For total cystectomy to be truly radical, the lymph vessels and nodes of the pelvis

at least up to the bifurcation of the common iliac artery should be included, but of necessity this increases the operating time.

Diversion of Urine.—For methods of diversion see below.

URINARY DIVERSION

This chapter closes with an account of the principles of this important subject, and includes indications, the methods employed and their attendant problems, and some operative details.

Indications.—Diversion of the urine may be either (*a*) a temporary expedient to relieve distal obstruction, or (*b*) a permanent procedure when (1) the bladder has been removed, (2) the sphincters of the bladder have been damaged or have lost their normal neurological control, (3) there is an incurable vesico-vaginal fistula, (4) there is an irremovable obstruction, and (5) in cases of ectopia vesicæ (p. 1195).

Methods of Urinary Diversion (fig. 1421).

The diversion may be achieved by any of the following methods, but the choice in each case will be decided largely by the primary disease.

Pyelostomy or nephrostomy, or urethrostomy (with indwelling catheters).

Cutaneous ureterostomy.

Suprapubic cystostomy (with in-dwelling catheter).

Cutaneous vesicostomy (cystostomy).

Suprapubic displacement of the urethra.

Uretero-sigmoidostomy (*a*) in continuity, (*b*) making a rectal bladder and colostomy.

Trigono-colostomy (*a*) in continuity, (*b*) into an isolated conduit.

Ureteric transplantation into an isolated ileal or colonic conduit.

Diversion of urine immediately raises the following problems:—1. the collection of the urine, 2. stricture-formation at any anastomosis, and 3. reflux and reabsorption of urinary solutes. The problems of infection are intimately related to all three.

Collection of the Urine

(*a*) **Catheters.**—In the past, indwelling catheters have been used for permanent diversion. They invariably result in infection and they often become blocked by phosphatic encrustation. There is now *no place for permanent catheter drainage* of the kidneys or ureters. For temporary drainage the tubes should be of latex or soft silastic (polyvinyl plastics are irritant and predispose to a stricture).

Bladder Drainage.—In elderly patients unfit for prostatectomy and in some terminal cases of carcinoma of the prostate, an indwelling Foley catheter (fig. 1381), changed every three weeks, is a satisfactory method of drainage. Alternatively, a St. Peter's Hospital suprapubic drainage apparatus (fig. 1420) incorporating a straight

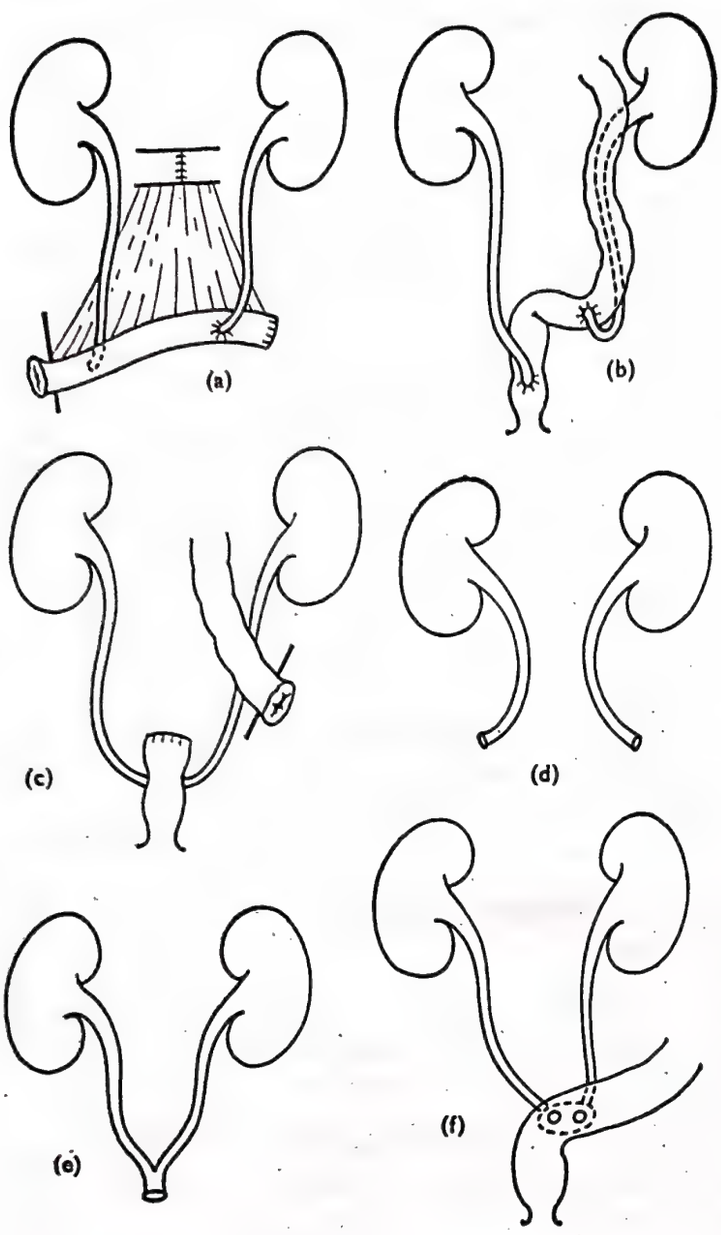

FIG. 1421.—Diversion of urine. Favoured methods: (a) Ileal conduit, (b) Uretero-sigmoidostomy, (c) Rectal bladder with terminal colostomy, (d) Bilateral cutaneous ureterostomies, (e) Joined ureters—cutaneous opening, (f) Trigono-colostomy.

catheter which the patient or nurse changes daily is acceptable.

(*b*) **Cutaneous Stomas:** *Suprapubic Vesicostomy or Urethrostomy.* — Collection from a formal suprapubic vesicostomy (cystostomy), or from the urethra displaced on to the abdominal wall (e.g. for cases of multiple sclerosis in a woman), may be unsatisfactory because the local incisions result in creases which make it difficult to apply a water-tight collecting appliance.

Cutaneous ureterostomies are very liable to stricture formation. In addition two openings (fig. 1421 (d)) and appliances add to the patient's burden. Mobilisation of the ureters and the making of a central abdominal stoma (fig. 1421 (e)) can be successful, but such a degree of mobilisation is attended by the high risk of sloughing of the distal ureters due to impairment of blood-supply.

Ileal or Colonic Conduit.—At present the most generally useful form of diversion is to implant each ureter with as little mobilisation as possible into an isolated segment of gut (ileum or colon), which conducts the urine onwards to a cutaneous stoma (fig. 1421 (a)). Urine is then collected in an ileostomy bag. This form of diversion limits infection and avoids the problems of reabsorption of urine as contact-time with the mucosa is minimal. In some cases in which the pelvis has been subjected to radiation the lower ureters may be unhealthy. A high division with insertion of the ureters into an ileal loop above the roof of the mesentery may be wiser (fig. 1422), (Wallace).

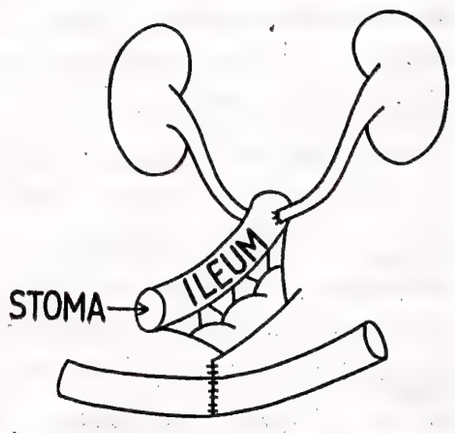

FIG. 1422. (*After D. Wallace, F.R.C.S.*)

Siting of Stoma.—The site for the stoma must be chosen before operation. The ileostomy ring and bag are applied to the abdominal wall, and by trial and error the point at which the belt can support the ring and bag at all times and in all positions is found. Having checked this by sticking on a bag full of water and asking the patient to perform the type of movements which his work will entail, the site of the future stoma is marked indelibly on the skin.

(*c*) **Colon and Rectum.**—The advantage of diverting urine into the colon is that no collecting apparatus is necessary (fig. 1421 (b) and (f)). Clearly, however, the rectal sphincter must be competent. Before any uretero-sigmoidostomy is undertaken, the patient must prove that he can control at least 200 ml. of fluid in the rectum. The disadvantage of the operation is that the renal tract is exposed continuously to infection from the fæces. This can be avoided by establishing a terminal left iliac colostomy, and closing the upper rectum to make a rectal bladder (fig. 1421 (c)). It prevents the urine refluxing retrogradely round the colon to the cæcum, diminishes reabsorption (see below), and protects renal function.

Stricture Formation

Uretero-sigmoidostomy was first used by Chaput (1894). Subsequent modifications included those made by Coffey and Grey Turner. In these methods the ureters were cut obliquely and pulled into the gut by a stitch—the ends were not stitched to the gut wall. Stenosis was not uncommon. Nesbit, Cordonnier, and Leadbetter all recognised that these strictures could be prevented by anastomosing mucosa to mucosa (fig. 1423).

Reflux of Urine and Reabsorption of Urinary Solutes

Reflux of Urine.—Pressure within the colon can interfere with drainage, and so force air, fæces, and organisms up to the renal pelvis. Daniel has demonstrated that a high intra-colonic pressure (over 24 cm water) results in all these complications being more likely. For many years it had been noted that the left kidney was much more likely to cease functioning after uretero-sigmoidostomy than the right kidney. As the left ureter is implanted into the sigmoid and the right often in the upper rectum, the former is more likely to be subjected to higher intra-colonic pressures. A sigmoid myotomy performed from the upper rectum to the splenic flexure may help to overcome this problem.

Reabsorption of Urinary solutes depends upon two factors, (1) reflux of urine round the colon and even into the terminal ileum (fig. 1421 (b) and (f)), (2) because the colon is acting as a reservoir, the urine is in contact with gut wall for a longer period. Biochemical disturbances are rare if a rectal bladder is made (see above).

The biochemical changes associated with transplantation into the colon are due to a combination of reabsorption of chlorides and urea, and progressively diminishing tubular function as a result of chronic pyelo-nephritis. Diarrhœa with loss of potassium-containing mucus may exacerbate the loss of potassium.

The typical changes are a hyperchloræmic acidosis with potassium depletion, and they occur in every patient with a uretero-sigmoid diversion. When severe, the patient develops loss of appetite, weakness, thirst, and diarrhœa. He becomes listless, and respirations are rapid, deep, and unremittent. Coma may ensue. Mild acidosis, unrecognised over a long period, produces osteomalacia from calcium reabsorption. Bone pain and even pathological fractures occur.

Renal impairment from pyelonephritis and reabsorption from the mucosa are infrequent complications if the diversion is into an ileal or colonic conduit.

Treatment.—(*a*) *Prevention.*—Patients should be instructed to empty the rectum two-hourly by day, and in cases where acidosis is present, a rectal tube should be inserted at night to drain the urine continuously. The patient should avoid added salt in

the diet, and he should take a mixture of potassium citrate and sodium bicarbonate t.d.s. (two grams of each either as crystals or tablets). Regular biochemical analyses, including calcium, are required. The patient should be told to report if he loses his appetite or develops weakness.

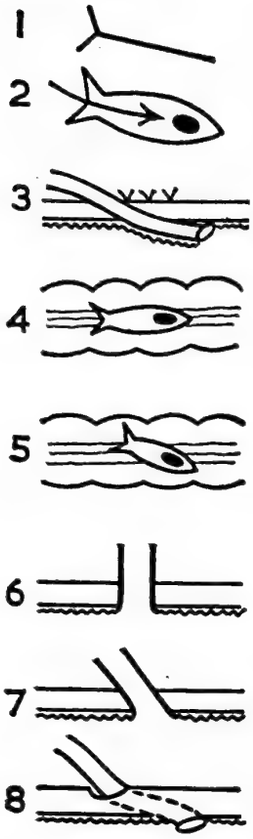

FIG. 1423.—Methods of uretero-colic anastomosis. 1. Incision in the sero-muscular layer, which, on dissection, exposes an area of submucosa and mucosa which looks rather like a fish. 2. The ureter is laid along the 'fish' and inserted through the opening into the lumen made in the 'fish's head'. 3. Lateral view of completed anastomosis. 4. Coffey type. 5. Grey Turner type. 6. Nesbit, 7. Cordonnier, and 8. Leadbetter types entail a careful mucosa to mucosa anastomosis. The last named includes a submucosal tunnel, and is probably the best anastomosis for preventing stricture formation and reflux.

(*b*) *In established hyperchloræmic acidosis*, the patient should be given suitable doses of sodium bicarbonate (8·4% = 1 mEq/ml = molar) intravenously to correct the pH (p. 94), with suitable amounts of potassium, also intravenously, if necessary. Furadantin, ampicillin, or the appropriate antibiotic should be given to correct the inevitable pyelonephritis which will be present. Later, conversion to an ileal conduit should be considered.

Operative Details

Uretero-colic Anastomosis.—The preparation of the colon is the same as that described on p. 992. The abdomen is opened by a right lower paramedian incision. The patient is then placed in the Trendelenburg position and the right ureter is sought as it crosses above the bifurcation of the common iliac artery. An incision is made through the peritoneum overlying the medial side of the ureter, thus avoiding damage to the ureteric vessels which always approach the duct from the outer side (Daniel), and the ureter is identified and dissected from its bed towards its entry into the bladder. The ureter is then divided and its distal stump ligated. The proximal end is trimmed obliquely and split upwards for one centimetre. An incision 3 cm. long is made in the anterior wall of the colon and the peritoneal and muscular coats are divided, but not the mucous membrane (fig. 1423(3)). An incision is made into the extreme lower end of the exposed mucous membrane and the full thickness of the ureteric wall is joined by interrupted 4/0 chromic catgut sutures to the mucosal opening. The incision in the outer coats of the bowel is approximated over the ureter (Leadbetter anastomosis). Suturing the peritoneal incision around the ureteric implant extraperitonealises the site, and a drain is left down to the area. The left ureter is implanted into the colon above in a similar manner. A full-sized Foley's catheter (fig. 1381) is inserted through the anus no farther than the rectal ampulla, the balloon then being inflated. This permits all urine to be measured until the third day, when the catheter is removed. There must be a full fluid intake. If oliguria or anuria supervene, treatment is as described on p. 1139.

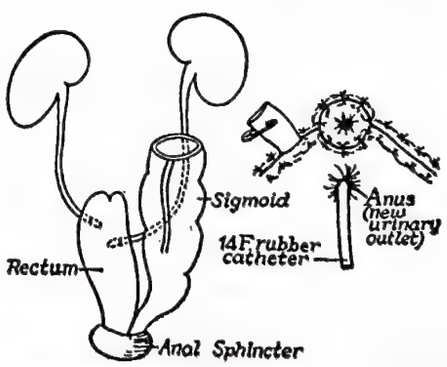

FIG. 1424.—Lowsley's operation.

Uretero-ileostomy (Ileal Loop Conduit).—A coil of ileum, approximately 15–25 cm long, and one foot from the ileo-cæcal valve, with its blood supply intact, is isolated. The left ureter is brought through the pelvic mesocolon, and after the ureter has been cut obliquely, end-to-side anastomosis is performed between the ureter and the intestine. The right ureter is also cut obliquely, and it is joined to an elliptical opening made in the side of the coil. In each case the anastomosis may be effected by the method of Nesbit (fig. 1423(6). The coil of intestine is tacked

lightly to the peritoneum of the anterior abdominal wall at the level of the pelvic brim. The distal end of the coil is brought out through a stab incision in the right lower abdomen, and, because of the anchoring of the intestine to the peritoneum, the opening is made a little lower than is the case when ileostomy is performed for ulcerative colitis. The method of anchoring the ileostomy opening to the abdominal wall, and the after-care of the orifice so formed, in no way differs from that described on p. 977.

Lowsley's Operation.—The rectosigmoid junction is divided completely and its lower end closed. The ureters or the trigone are implanted into the excluded lower segment, so that the rectum functions as a bladder. The sigmoid colon is mobilised sufficiently for it to be drawn through the perineum immediately anterior to the anus. Thus both the original anal canal and the new anal canal are encompassed by the external sphincter ani muscle (fig. 1424).

Oswald S. Lowsley, 1884–1955. Director of Urology, James Buchanan Brady Foundation, New York Hospital.

CHAPTER 56

THE PROSTATE AND SEMINAL VESICLES

Embryology.—The prostate arises from the primitive urethra as a series of solid buds; in a matter of weeks these become canalised. The surrounding mesenchyme becomes the muscular and connective tissue of the gland. The buds are arranged into five groups—anterior, middle, posterior, and two lateral. These are the forerunners of the lobes of the prostate.

Skene's tubules opening on either side of the female urethral orifice are the homologues of the prostate.

Surgical Anatomy.—The prostatic glands (fig. 1425) lie in the fibromuscular stroma and their ducts open into the posterolateral grooves on either side of the verumontanum. The epithelium is columnar. Commencing peripherally, and passing centrally, beneath the anatomical capsule lie the long branched **prostatic glands proper.** This region is named the carcinomatous zone. Beneath this envelope, and separated from it by an indefinite capsule, lies another mass of secreting elements, also branched. These are the **submucosal glands**—and the zone that they occupy is known as the adenomatous zone. Still nearer the urethra are the unbranched **urethral glands** whose mouths open directly into the urethra.

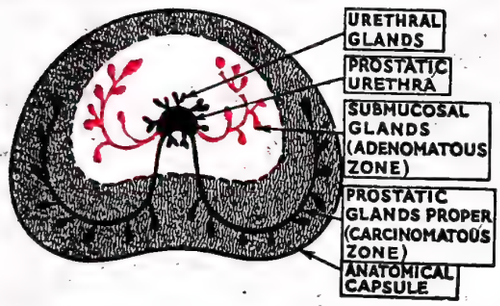

FIG. 1425.—Distribution of the normal glands of the prostate, transverse section. (*After J. C. B. Grant.*)

Into the prostatic urethra, therefore, open the prostatic ducts proper, the ducts of the submucosal and mucosal glands, as well as the common ejaculatory ducts and the prostatic utricle. No wonder that chronic infection of the prostatic urethra is difficult to eradicate!

Certain relationships and divisions of the prostate as seen in sagittal section are set out in fig. 1426. The middle lobe is that part of the prostate included between the common ejaculatory ducts and the prostatic urethra: it contains more secretory glandular element (subcervical glands, as opposed to muscle and fibrous tissue) than the lateral lobes.

An enlarged prostate is invested with three capsules: (1) The compressed outer zone = *the false capsule*; (2) The anatomical capsule = *the true capsule*; and external to this (3) *The prostatic sheath of pelvic fascia.* Between the anatomical capsule and the prostatic sheath lies the prostatic venous plexus (fig. 1427). The prostatic sheath is contiguous with the strong fascia of Denonvilliers that separates the prostate and its coverings from the rectum.

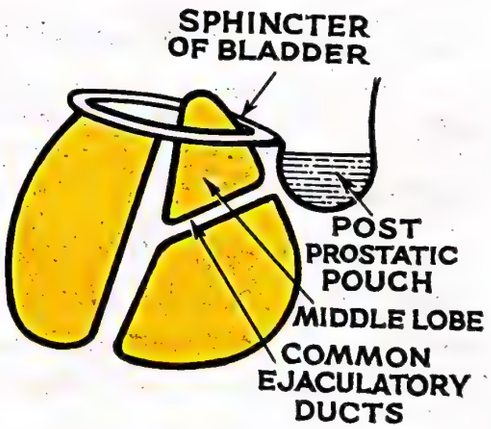

FIG. 1426.—The surgical subdivisions and relationships of the prostate.

Physiology.—That the prostate is purely a genital organ is evinced by the fact that in such animals as manifest a seasonal sexual life, the organ is rudimentary except during the rutting season. That normal adult prostatic epithelium undergoes atrophy after castration was known to John Hunter.

Hormonal Influences.—The prostate is governed by two testicular hormones, one male (androgenic) and the other female (œstrogenic). Normally the preponderant

Alexander Johnston Chalmers Skene, 1838–1900. Professor of Gynæcology, Long Island College Hospital, New York, U.S.A.
Charles Pierre Denonvilliers, 1808–1872. Professor of Anatomy, and later of Surgery, Paris.
John Hunter, 1728–1793. Surgeon, St. George's Hospital, London.

testicular hormone is androgen, which is supplemented by androgens secreted by the adrenal glands (fig. 1428).

Œstrogens cause retrogressive changes in the testes and prostate gland. For example, most capons are produced by implanting œstrogen pellets into the neck of the bird rather than by castration.

Elaboration and Secretion of Acid Phosphatases.—Enzymes that split organic phosphates and are most active about pH5, are present in many human tissues, but their concentration in the adult prostate is several hundred times greater than in any other organ or tissue. This high level is not achieved until after puberty. While the function of this enzyme is speculative, it is highly suggestive that the acidity which is most favourable for its action corresponds to that of the vagina at the time of ovulation. Most of the acid phosphatase secreted by the prostate drains along the prostatic ducts into the urethra, so that the blood level of this enzyme remains low. When the cells producing this enzyme cannot discharge their products externally, the serum acid phosphatase rises.

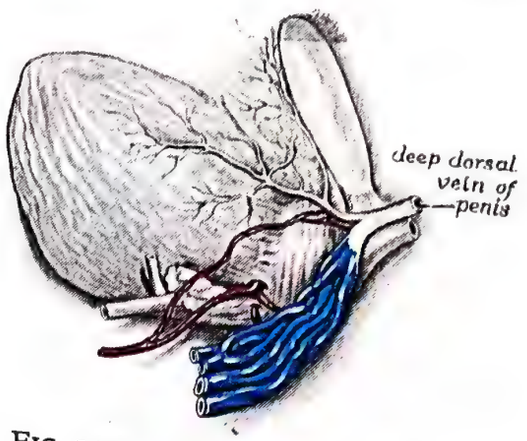

FIG. 1427.—The prostatic venous plexus.

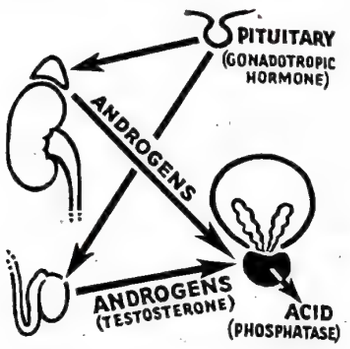

FIG. 1428. — Preponderant hormonal control of the prostate. *(After L. N. Pyrah, F.R.C.S., Leeds.)*

Acid phosphatase estimations are made on plasma or serum, free from hæmolysis. The blood sample must be taken in the morning before breakfast, and on no account after a heavy meal, since lipoid-rich serum gives inaccurate estimations. Digital rectal examination has now been shown not to affect the acid phosphatase level in the blood. The normal range of findings is 0–5 King-Armstrong units per 100 ml. of serum.

The serum acid phosphatase is usually raised in carcinoma of the prostate *with metastases*, but is seldom above normal if the growth is confined to the gland, and almost never in benign prostatic hyperplasia. On the other hand, slightly increased values are not uncommon (1) in acute prostatitis, (2) Paget's disease of bone, (3) hepatic cirrhosis.

BENIGN ENLARGEMENT OF THE PROSTATE

"*When the hair becomes grey and scanty, when specks of earthy matter begin to be deposited in the tunics of the artery, and when a white zone is formed at the margin of the cornea, at this same period the prostate gland usually—I might perhaps say invariably—becomes increased in size.*" (SIR BENJAMIN BRODIE.)

Benign enlargement of the prostate usually occurs in men[1] over fifty years of age; most often between sixty and seventy. In Indians prostatic enlargement is less frequent, and occurs more often in a younger age-group; in Negroes it is rare. The reason for these discrepancies is unknown.

Theories of causation of benign enlargement of the prostate:

The Hormonic Theory.—As age advances the male hormone diminishes while the quantity of the œstrogenic hormone is not decreased equally. According to this

[1] It is interesting to note that the ageing dog is prone to prostatic hyperplasia but, unlike his master, does not often develop retention of urine. Due, however, to the bulging upwards of the enlarged prostate the dog's rectum is compressed. This engenders a feeling of continuous fullness in the rectum, and induces painful straining; symptoms are relieved by stilbœstrol. The prostates of eunuchs are small and completely under-developed, and benign enlargement of the prostate is unknown.

Earl J. King, 1901–1962. Professor of Chemical Pathology, University of London (Postgraduate Medical School), and Arthur Riley Armstrong, Contemporary. Director of Laboratories, Hamilton Health Association, Ontario, formerly co-workers at the Department of Medical Research; Banting Institute, University of Toronto.
Sir James Paget, 1814–1899. Surgeon, St. Bartholomew's Hospital, London.
Sir Benjamin Collins Brodie, 1783–1862. Surgeon, St. George's Hospital, London.

theory the prostate enlarges because of predominance of the œstrogenic hormone. Prostatic enlargement can be regarded as involutionary hyperplasia akin to fibro-adenosis of the breast, due to a disturbance of the ratio and quantity of the circulating androgens and œstrogens.

The Neoplastic Theory postulates that the enlargement is a benign neoplasm. As the prostate is composed essentially of fibrous tissue, muscle tissue, and glandular tissue, the neoplasm is a *fibro-myo-adenoma*.

Pathology.—Hyperplasia affects the glandular elements and connective tissue, but in variable degrees. In this respect the changes are very similar to those occurring in the breast in 'chronic mastitis', where adenosis, epitheliosis, and stromal proliferation are seen in differing proportions. Benign adenomatous hyperplasia affects the submucous group of glands, forming a nodular enlargement—the typical 'lateral' lobes—which compresses the external group of glands into a false capsule (fig. 1425).

As the prostate enlarges extravesically, it tends to displace the seminal vesicles, so that instead of lying on the base of the bladder, these structures become a direct posterior relation of the upper limit of the prostate. When the hyperplasia affects the subcervical glands a 'middle' lobe develops which projects up into the bladder within the internal sphincter (fig. 1426). Sometimes both lateral lobes also project into the bladder, so that when viewed from within, the sides and back of the internal urinary meatus are surrounded by an intravesical prostatic collar.

SECONDARY EFFECTS OF PROSTATIC ENLARGEMENT

Urethra.—That portion of the urethra lying above the verumontanum becomes elongated, sometimes to as much as twice its normal length. The canal is compressed laterally, so that it tends to become an antero-posterior slit. The normal posterior curve may be so exaggerated that it requires a coudé, bicoudé, or even a fully curved metal catheter to negotiate it. When one lateral lobe is enlarged predominantly, lateral distortion of the prostatic urethra occurs.

FIG. 1429.—Trabeculation of the bladder from prostatic obstruction. (*The late Professor K. A. L. Aschoff, Freiburg.*)

Bladder.—The musculature of the bladder hypertrophies to overcome the obstruction. When viewed from within, bands of muscle fibres can be seen—*trabeculation* (fig. 1429). Between these hypertrophied bundles there are shallow depressions, i.e. *sacculations*. Sometimes one of the saecules (rarely two or more) continues to enlarge, and forms a *diverticulum*.

When the middle lobe projects upwards into the bladder it acts as a dam to the last ounce or more of urine, which remains in the post-prostatic pouch. Calculi are prone to form in this stagnant pool of urine.

The enlarged prostate may compress the prostatic venous plexus; the resulting congested veins (vesical 'piles') at the base of the bladder are apt to cause hæmaturia.

Unless the obstruction is relieved, a time is reached when bladder hypertrophy gives place to atony, the tired muscle making no attempt to overcome the obstruction.

Ureters and Kidneys.—Increasing intravesical pressure, or in some cases direct pressure of the intravesical portion of the prostate on the ureteric orifices, causes gradual dilatation of the ureters, followed by some degree of bilateral hydronephrosis. When bladder hypertrophy wanes, the sphincter mechanism around the ureteric orifices ceases to function, permitting reflux of urine from the bladder into the dilated ureters, with increasing damage to the renal parenchyma. As a result of ascending infection, or more rarely from the blood-stream, acute or chronic pyelonephritis supervenes.

Sexual Organs.—In the early stages of prostatic enlargement there is increased libido. Later, impotence is the rule.

Clinical features are variable and depend upon the lobes affected. *Frequency* is the earliest symptom. At first it is nocturnal, the patient being obliged to get up to micturate twice or more during the night, usually commencing at 2 or 3 a.m. Frequent micturition at this stage is probably due to vesical introversion of the sensitive prostatic mucous membrane by the intravesical enlargement of the prostate. The frequency becomes progressive, and is then present both by night and by day. When the vesical sphincter becomes stretched, a little urine escapes into the normally empty prostatic urethra, causing an intense reflex desire to void, and *urgency* is added to the frequency. Later, as residual urine increases, frequency becomes more and more in evidence, and there is terminal dribbling. Finally, in neglected cases, frequency is further encouraged by cystitis, and polyuria due to renal insufficiency.

Difficulty in Micturition.—The patient notices that he must wait patiently for urination to start; it is useless to strain (cf. urethral stricture and fibrous prostate—pp. 1269 and 1244).

The stream is variable, often weak, tending to stop and start, and dribble towards the end of micturition.

Pain occurs with cystitis or acute retention of urine. When hydronephrosis commences there may be a dull pain in the loins. A feeling of weight in the perineum, or a fullness in the rectum, are occasional complaints.

Acute retention of urine is sometimes the first symptom to compel the patient to seek relief because of the intense pain it produces. The postponement of micturition is a common precipitating cause (e.g. a non-corridor train), as also is indulgence in alcoholic liquors, particularly when he goes out of doors on a cold night, as congestion of internal organs then tends to occur. Confinement to bed on account of some intercurrent illness or operation is another cause of acute retention of urine (p. 1198).

Retention with Overflow.—The patient complains that urine constantly dribbles away. It is exceptional for him to have noticed the swelling caused by the distended bladder and he experiences no pain (fig. 1430).

FIG. 1430.—Retention with overflow. The patient's only complaint was that he 'wet his trousers'. Note the distended bladder.

Hæmaturia.—A drop of blood at the beginning or end of micturition is not unusual. Occasionally alarming hæmaturia occurs from a ruptured prostatic vein (p. 1237), or from an erosion on the enlarged prostate itself. Incrimination of an enlarged prostate as the source of hæmaturia before excluding other causes has resulted in the term 'decoy' prostate.

Renal Insufficiency.—The patient presents himself with signs of renal failure (p. 1139).

Examination.—The patient lies on a couch and the abdomen is examined. In patients with a long history, varying degrees of chronic retention of urine will be found on palpation, percussion, and sometimes on inspection. The renal areas are palpated for tenderness and possible enlargement of the kidneys. The state of the tongue is noted; a dry brown tongue and a urine of low specific gravity indicate a considerable degree of renal insufficiency. The external urinary meatus is examined to exclude stenosis, and the epididymes are palpated for signs of inflammation.

Rectal examination is carried out and, in the absence of a full bladder, bimanually in the dorsal position. In benign enlargement of the lateral lobes, increase in their size is evident. They are smooth, convex, and typically elastic, but the fibrous element may give the prostate a firm consistency. The rectal mucosa can be made to move over the prostate. On bimanual palpation an intravesical lobe can sometimes be felt. By exerting pressure on the apex of the prostate by the finger in the rectum, it will be found that a gland which is the seat of benign enlargement possesses a definite degree of mobility. Residual urine may be felt as a fluctuating swelling above the prostate. It should be noted that if there is a considerable amount of residual urine present, it pushes the prostate downwards, making it appear larger than it is.

When possible, the act of micturition should be watched. Loss of projectile power is significant. The urine is passed into two glasses; mere inspection of it is often helpful. It is later examined chemically, and a mid-stream specimen may be sent for bacteriological examination.

The nervous system is examined to eliminate a neurogenic lesion. Tabes and disseminated sclerosis may give symptoms similar to those of prostatic obstruction.

The Mictiograph.—A graphic recording of a patient's stream rate and volume of urine can be obtained and is most helpful in determining the degree of outflow obstruction.

Examination of the Blood.—A blood urea estimation, a blood count, and a Wassermann reaction are all important, the first two being essential.

Excretory pyelography is omitted only if the patient shows clinical signs of renal failure, or if the blood urea estimation is high. It affords a great deal of information without resorting to instrumentation and it is an excellent test of renal function. The preliminary radiograph may show a renal calculus, or a stone in the bladder, or in the diverticulum.

The pyelogram will exclude or confirm the presence of hydroureters and hydronephroses; a vesical diverticulum may be shown and if a film is taken after micturition, residual urine will be revealed. Sometimes an intravesical enlargement of the prostate is outlined by the medium. Nevertheless, complete reliance must not be placed on radiological evidence of residual urine as the patient may have difficulty in passing urine in the radiological department, especially if a female radiographer is nearby!

Cysto-urethroscopy.—Cysto-urethroscopy is an essential preliminary to prostatectomy, especially when the operation is not transvesical, to exclude the presence of a growth, a diverticulum, or non-opaque stones. It may also be necessary in order to make a diagnosis when the gland is small, and sometimes to distinguish between a urethral stricture and a bladder-neck obstruction.

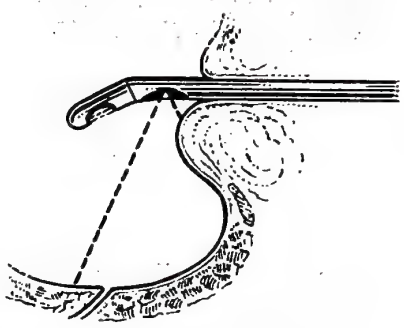

FIG. 1431.—Marion's sign.

The patient must empty his bladder just prior to the examination, so that the amount of residual urine present in the bladder can be measured. After irrigation, if necessary, the bladder is distended and examined. Trabeculation and sacculation are the significant findings. The presence of cystitis will have been anticipated by the examination of the urine. Normally the posterior edge of the internal urinary meatus and a ureteric orifice cannot both be seen in the same cystoscopic field. In cases of moderate enlargement of the middle lobe this becomes possible (Marion's sign, fig. 1431). Should the intravesical projection be considerable, the ureteric orifices and the inter-ureteric bar are hidden completely beneath the prostatic shelf.

The Management of Retention

Acute retention initially is very painful. Chronic retention is painless. It is safe to decompress an acute retention rapidly. It may not be safe to decompress a chronic retention rapidly. If the kidneys are hydronephrotic, reactionary hyperæmia may lead to bleeding from the kidney, impaired blood flow to the tubules, and an acute tubular necrosis. In chronic retention an urgent blood urea estimation is essential, and if above 100 mg. per cent. slow decompression should be the rule. Below this level it is better to avoid instrumentation until the cystoscopy immediately prior to prostatectomy.

Catheterisation.—Where there is a possibility that the catheter may be left indwelling, wash and shave the pubic, perineal, and scrotal regions. Anæsthetise the urethra with 1 per cent. Xylocaine combined with 0·5 per cent.

August von Wassermann, 1866–1925. Director of the Kaiser Wilhelm Institute for Experimental Therapeutics, Berlin.
Jean Baptiste Camille Georges Marion, 1869–1960. Professor of Urology, Faculty of Medicine, Paris.

chlorhexidine in a methyl-cellulose base. Allow three minutes for the anæsthetic and the antiseptic effects to take place. With strict aseptic precautions pass a size 8, 10, or 12 F. plastic catheter by a non-touch technique (Gibbon-type if it is to be left indwelling, p. 1202). Collect a specimen of urine for culture.

Slow decompression can be obtained by joining such a catheter to a bottle and arranging the end of the inlet into the bottle at such a height, 18 to 20 cm, above the pubis so that urine flows over only when the patient coughs or moves, thus raising his intra-abdominal pressure. The bottle can be lowered 2·5 cm every four hours. Alternatively a 'gate' clip can be applied to the drainage tube to permit a rapid drip into the bottle. The clip is released every hour or so. If the urine flow increases, the clip is re-applied, and if no urine flows it is removed, for the bladder is now empty and must not be allowed to refill because this encourages the growth of organisms in the bladder.

In cases of acute retention, especially where there is a history of overholding the urine, as on a long journey or after drinking alcohol, the bladder should be emptied and the catheter removed. Micturition may then be re-established. Failure to do so confirms the need for prostatectomy.

Suprapubic Puncture.—If there is a long history of prostatism, and early prostatectomy is decided upon, relief of pain can be achieved by suprapubic needle puncture, running in a length of polythene tube with multiple side holes and connecting this to a sterile drainage bottle or bag.

All catheters should be connected by straight connections to sterile tubes and drainage bottles, which should contain 120 ml. of 40 per cent. formalin solution. Air vents should be protected by formalin tablets (fig. 1383).

Indications for Operation

(1) *Prostatism.*—Increasing difficulty in micturition, with considerable frequency day and night, delay in starting, and a poor stream—such are the usual symptoms for which prostatectomy is advised. It must be stressed that *frequency alone* is never an indication for prostatectomy, and also that the natural progression of benign prostatic enlargement is variable and rarely gets worse after ten years. A patient with symptoms for nine years is unlikely to get much more severe symptoms, while a similar degree of symptoms reached in three years is a greater indication for surgery. This fact may be helpful when considering the correct advice to give to elderly patients possibly suffering from other disease.

(2) *Acute retention which is unrelieved* by passing a catheter, emptying the bladder, and immediately removing the catheter.[1]

(3) *Chronic Retention.*—A residual urine of 200 ml. or more. A raised blood urea, hydroureter, or hydronephrosis demonstrated on urography, and uraemic manifestations.

---

[1] Wilson Hey recommended immediate prostatectomy as the treatment of choice in such patients who are usually fit, thus avoiding the dangers of infection by instrumentation and the increased liability to venous thrombosis if catheter drainage and bed-rest are instituted.

Wilson Harold Hey, 1882–1956. Surgeon, Royal Infirmary, Manchester, England.

(4) *Complications.*—Stone, infection, and diverticulum formation, which are often present in varying combinations.

(5) *Hæmorrhage.*—Occasionally venous bleeding from a ruptured vein overlying the prostate will not stop with catheter drainage, so prostatectomy must be performed as an emergency measure.

Operative Treatment

Until the commencement of the present century the accepted treatment of prostatic obstruction was a catheter-life. The patient passed the instrument himself, often lubricating it with saliva. The more affluent sufferers carried their catheters in their top hats. Nearly 20 per cent. of all sufferers died within three months. Some of the remainder acquired partial immunity to recurring bouts of infection.

Nowadays a permanent catheter, either urethral or suprapubic, is a rarity. Prostatectomy, or more correctly the removal of the adenomatous hyperplasia, by one of the four routes, is practicable in the great majority of cases.

The prostate can be approached (1) through the bladder (transvesical), (2) retropubically, (3) from the perineum, or (4) perurethrally (fig. 1432).

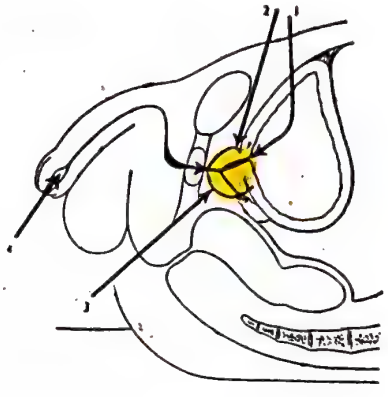

FIG. 1432.—The surgical approaches to the prostate.

Preliminary Vasectomy.—In all the operations about to be described, bilateral vasectomy (dividing the vasa deferentia) is advisable. It prevents infection from the prostatic bed spreading to the epididymes. This minor procedure can be undertaken as a preliminary step, or at the conclusion of prostatectomy. *Technique.*—Through a small incision over each superficial abdominal ring the vas deferens is isolated from the spermatic cord and a small piece resected, the ends being ligated with catgut.

Transvesical Prostatectomy.—The bladder is opened, the prostate enucleated by putting a finger into the urethra, pushing forwards towards the pubes to separate the lateral lobes, and then working the finger between the adenoma and the false capsule. In **Freyer's operation** (1901) the bladder was left open widely and drained by a suprapubic tube with a 16-mm lumen, in order to allow free drainage of blood and urine. **Harris** (1934) advocated control of the prostatic arteries by lateral stitches inserted with his boomerang needle (fig. 1433 and 1434), and closure of the raw

FIG. 1433.—A boomerang needle.

FIG. 1434.—Harris's ligature carrier.

areas by stitching the mucosa of the posterior lip of the internal meatus to the urethral mucosa, and narrowing the cavity with stitches in front of the urethral catheter which was left in to drain the bladder. The bladder wall was left completely closed and the wound drained. **Wilson Hey** (1944) also advocated a transvesical prostatectomy, stressing the importance of careful asepsis in this as in any other surgery. The

Sir Peter Johnston Freyer, 1852–1921. Surgeon, St. Peter's Hospital for Stone, London.
Samuel Harry Harris, 1881–1937. Urologist, Lewisham Hospital, Sydney, Australia.

catheter for drainage was passed retrogradely to avoid carrying urethral organisms up into the raw prostatic cavity. Mass ligatures of tissue for hæmostasis was replaced by careful diathermy of bleeding points with insulated hæmostats (fig. 1435). Careful closure of the bladder enabled the urethral catheter to be removed on the fourth day.

Retropubic Prostatectomy (Millin, 1945).—Using a low, curved transverse suprapubic incision, which includes the rectus sheath, the recti are retracted to expose the bladder with its typical appearance of pale brown muscle bundles with a loose covering of fatty tissue and veins. With the patient in the Trendelenburg position the surgeon separates the bladder and the prostate from the posterior aspect of the pubis. In the space thus obtained the anterior capsule of the prostate is incised with diathermy below the bladder neck, care being taken to obtain complete control of bleeding from divided prostatic veins.

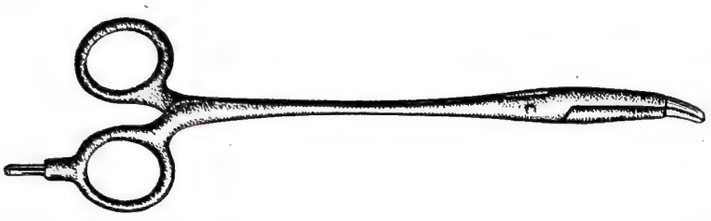

FIG. 1435.—Insulated hæmostat (Riches' pattern).

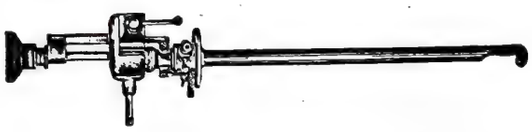

FIG. 1436.—McCarthy's endoscopic prostatic resector.

FIG. 1437.—Punch prostatectomy. The fenestrum engaging the tissue of the middle lobe.

The prostatic adenoma is exposed and enucleated with a finger. A wedge is taken out of the posterior lip of the bladder neck to prevent secondary stricture in this region. The exposure of the inside of the prostatic cavity is good, and control of hæmorrhage is achieved with diathermy and stitching before closure of the capsule over a Porges catheter (inserted per urethram) draining the bladder.

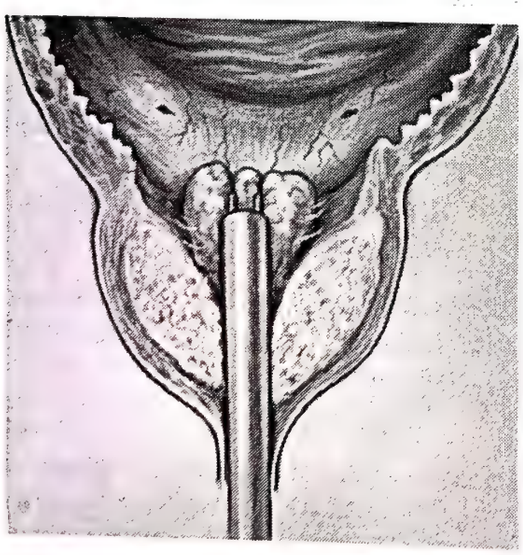

FIG. 1438.—Transurethral resection showing the loop commencing to remove a strip from the middle lobe of the prostate. *(After R. M. Nesbit.)*

Perineal Prostatectomy (Young).—A A-shaped incision in the perineum in front of the anus. The rectum is retracted backwards to expose the posterior aspect of the prostate above the triangular ligament. This is incised and the adenoma enucleated. This operation is not popular in Britain because of the incidence of incontinence.

Perurethral prostate resection, (P.U.R. or T.U.R.) is indicated when obstruction is due to a fibrous prostate, a median bar, or a carcinoma, and occasionally when a middle lobe is associated with slight lateral lobe enlargement. It can be achieved with a McCarthy resectoscope or a cold punch (figs. 1436–1438).

Strips of tissue are cut from the lip of the bladder neck down to the verumontanum. Damage to the external sphincter will not occur if this is the lowest point of the resection. With the McCarthy resectoscope cutting is accomplished by a high-frequency diathermy current applied to the loop. In the case of the Thompson punch, a tubular knife moves across a fenestrum at the distal end of the sheath of a direct-vision cysto-urethroscope. Magnification is less than with the resectoscope, but as less necrotic tissue is left behind, secondary hæmorrhage is less frequent.

After Treatment

(1) 120 ml. of sterile normal saline is left in the bladder for one hour to dilute initial bleeding before continuous drainage is established.

(2) After one hour the catheter is joined via a sterile (non-tapered) connection to a sterile tube and a bottle containing 120 ml. of formalin (fig. 1383).

(3) Bladder wash-outs with full aseptic technique are only given if drainage is unsatisfactory or bleeding excessive.

(4) A high urinary output to ' wash out ' the bladder is essential.

(5) If the urine is infected, a suitable drug or antibiotic should be given pre-operatively to control bacteræmia and to reduce the danger of secondary hæmorrhage.

(6) Early ambulation has diminished the incidence of venous thrombosis and pulmonary embolism.

Complications.—*Hæmorrhage* may continue; transfusion is necessary if the blood pressure falls. *Clot retention* can occur if bleeding is severe and it is not observed that drainage is poor. Suction applied with a Riches's bladder syringe and irrigation with sterile normal saline will clear this. (No fluid must be put into the distended bladder until some has been sucked out. The use of a Bigelow's evacuator in such instances is dangerous and may lead to rupture of the bladder.)

Infection.—The routine employment of sulphonamide or appropriate antibiotic therapy before operation and during the post-operative treatment has considerably reduced complications consequent upon infection of the prostatic bed.

Epididymitis.—Division of the vasa deferentia at prostatectomy almost eliminates post-operative epididymitis, but a localised inflammation of the spermatic cord or a small abscess at the site of the division sometimes occurs.

Acute Pyelonephritis.—Ascending pyelonephritis can often be combated by antibiotics, but bilateral infection occurring in kidneys, already the seat of some degree of hydronephrosis, is always serious.

Renal Failure.—This is extremely rare. If gross renal impairment is present operation should be deferred until continuous bladder drainage has produced maximal renal recovery. Very occasionally renal dialysis before operation is justified.

Extraperitoneal perforation of the bladder is an occasional accident during transurethral prostatectomy. When the patient is under low spinal anæsthesia, immediately the perforation occurs he complains of severe suprapubic pain, often radiating towards the epigastrium. Such symptoms appearing after the patient has regained consciousness from a general anæsthetic are more difficult to interpret. When perforation of the bladder is suspected, immediate suprapubic cystostomy and drainage of the prevesical space should be carried out. If this operation is delayed more than twelve hours, the prognosis becomes grave, except in a few instances when extravasation occurs slowly with the formation of an abscess in one or other inguinal region.

Incontinence of urine occurs in retropubic prostatectomy when the membranous urethra is drawn up and divided. Damage to the external sphincter can occur in transurethral resections.

Later Complications

Osteitis pubis is rare. It is possibly due to pricking of the periosteum during operation, or to infection in the prevesical space. The symptoms do not appear

Sir Eric William Riches, Contemporary. Consulting Surgeon, Middlesex Hospital, London.
Henry Jacob Bigelow, 1818–1890. Professor of Surgery, Harvard University, Boston, Massachusetts, U.S.A.

until two or more weeks after the operation. There is pain and tenderness over the pubes, with inability to walk more than a few steps owing to painful spasms of the adductor muscles. An X-ray shows irregular rarefaction of the ischio-pubic rami (fig. 1439) and widening of the symphysis.

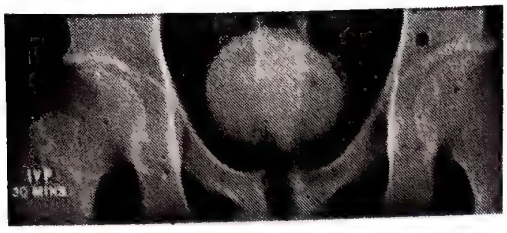

FIG. 1439.—Radiograph showing osteitis pubis following retropubic prostatectomy. (*N. M. Matheson, F.R.C.S., Ashford, Middlesex.*)

This exceedingly painful state continues for many weeks. Spontaneous cure with recalcification of the rarefied bone occurs after several months. Earlier recovery can be achieved by incising the posterior aspect of the symphyses and curetting out the necrotic cartilage and bone. Penicillin and streptomycin are placed in the area and the wound is closed with a small corrugated drain which is removed after forty-eight hours.

Post-operative stricture of the prostatic bed is a troublesome complication. Dilatation must be carried out regularly. More common now are strictures of the anterior urethra following the passage of a wide-bore resectoscope or punch.

CONTRACTURE OF THE BLADDER NECK

Ætiology.—The condition occurs in children of both sexes and in women as well as men. It may be due to a congenital muscular hypertrophy, or fibrosis of the tissues at the bladder neck and is then an aftermath of chronic prostatitis in men, or urethro-trigonitis in women. The former cause may give rise to symptoms at any age, usually in young children or adult life, the latter after the age of forty-five.

Clinical Syndromes:

(*a*) *Due to Muscle Hypertrophy.*—Marion described a series of cases in which muscular hypertrophy of the internal sphincter in a young person had resulted in the development of a vesical diverticulum *or* hydronephrosis (Marion's Disease, or *prostatism sans prostate*) (fig. 1440). Milder degrees of obstruction can occur without the development of these secondary effects (p. 1236). These patients have difficulty in micturition or may present with recurrent urinary infections.

A severe degree of obstruction produces symptoms at birth or in early childhood. A distended bladder may be visible or easily felt. Many cases develop urinary infection. Ureteric reflux of urine associated with high intravesical pressure during micturition leads to loin pain and severe pyelonephritis with gross scarring and contraction of the renal cortex.

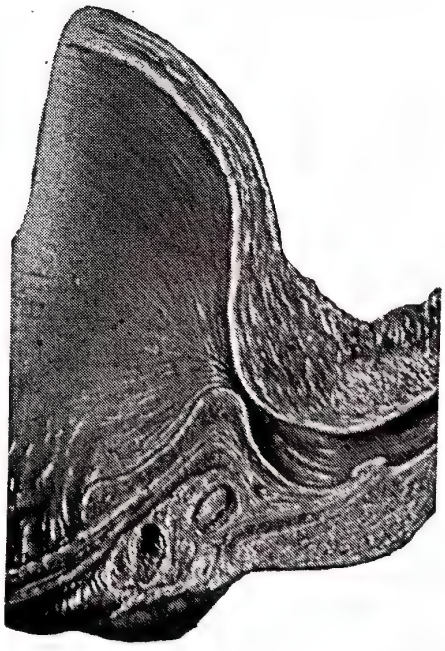

FIG. 1440.—Contracture of the bladder neck causing 'prostatic' obstruction. (*After H. H. Young.*)

(*b*) *Due to Fibrosis.*—The symptoms are similar to those of prostatic enlargement, but straining helps to expel the urine, and as a consequence an inguinal hernia may develop. There is no prostatic enlargement. Secondary effects of the

obstruction are in all respects similar to those seen in prostatic enlargement. Contracture of the bladder neck is the most common cause of a diverticulum of the bladder.

Treatment:

Dilatation.—Minor degrees of the condition sometimes respond satisfactorily to intermittent dilatation by bougies and treatment of the chronic prostatitis, if it is still active. Otherwise operation is always needed.

Transurethral resection is practised widely for this condition. The immediate results are excellent, but early relapses so often follow, especially in women, that opinion is veering to open operation.

Open Operation.—The principle of open operative treatment, like that of Johanson's operation for urethral stricture (p. 1269), is to establish in the strictured portion of the canal one part of the circumference that is non-fibrotic and pliant.

Sphincteroplasty is conducted through a retropubic incision.

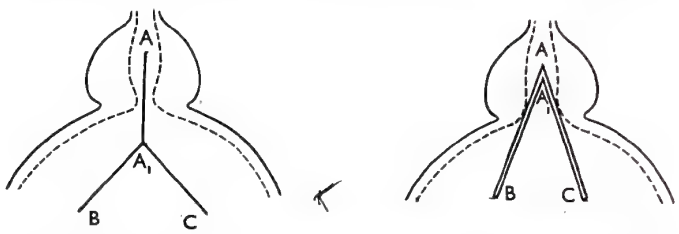

FIG. 1441.—Bonnin's operation for contracture of the bladder neck in the male.

Bonnin's operation is suitable for adult male patients. A V-shaped flap in the bladder (muscle and mucosa) is introduced into the anterior aspect of the vesical outlet, and the steps of the operation are shown in fig. 1441. When severe vesical atony is present, which is usual in cases of some standing, it is desirable to resect a large portion of the bladder. This is accomplished by mobilising the antero-superior aspect of the bladder before incising it. To have the viscus well distended is most important.

Congenital Valves of the Prostatic Urethra (p. 1257).

PROSTATIC CALCULI

Prostatic calculi are of two varieties—endogenous, which are common, and exogenous, which are comparatively rare.

An *exogenous* prostatic calculus is a urinary (commonly ureteric) calculus that becomes arrested in the prostatic urethra. This is considered on p. 1276.

FIG. 1442. — Radiograph showing endogenous prostatic calculi.

Endogenous prostatic calculi are usually composed of calcium phosphate combined with about 20 per cent. of organic material.

Clinical Features.—Quite often prostatic calculi are symptomless, being discovered on radiography of the pelvis, during prostatectomy, or associated with carcinoma of the prostate or chronic prostatitis. The symptoms vary in severity and are at first those of chronic prostatitis, or of prostatic obstruction. On rectal examination it is difficult to differentiate from carcinoma. On X-ray these stones often form a horse-shoe (fig. 1442) or a circle.

Treatment of Prostatic Calculi:

Conservative Measures.—When the calculi are small and the symptoms are mild, the treatment of chronic prostatis by a course of sulphonamide often keeps the patient free from symptoms for months at a time.

Noel James Bonnin, Contemporary. Surgeon, Queen Elizabeth Hospital, Adelaide, Australia.

Transurethral resection of the fibrous prostate will release small calculi as the strips of prostatic tissue are excised, and many more are removed by the irrigation inseparable from transurethral resection. Others are passed per urethram at a later date.

Retropubic Prostato-lithotomy.—After incising the capsule of the prostate, the incision is deepened until the prostatic urethra is opened. Using a sharp curette, all the calculi and as much as possible of the infected prostatic tissue is removed. The bladder neck is then exposed, and a generous wedge of the posterior lip is resected with curved scissors. The operation is concluded in a manner similar to that of retropubic prostatectomy. Total prostatectomy may be necessary in cases where there are frequent acute exacerbations of a chronic prostatitis.

Corpora amylaceæ

Corpora amylaceæ are found in the prostates of elderly men and apes, but not in the prostates of animals lower in the phylogenetic scale than anthropoids. Corpora amylaceæ occur also in the homologue of the prostate—the tubules of the bladder neck of women (Skene's tubules). These bodies consist of amorphous debris and desquamated epithelium. Often an intact epithelial wall of a prostatic duct forms their outer coat. They are always deeply pigmented, and are variously described as like poppy seeds, black pepper, or coal dust. Neither the composition nor the origin of the pigment is known. Probably corpora amylaceæ are the forerunners of endogenous prostatic calculi.

CARCINOMA OF THE PROSTATE

Carcinoma of the prostate is the commonest malignant condition in men over the age of sixty-five years. About 20 per cent. of cases of prostatic obstruction prove to be due to carcinoma, to which must be added a substantial number in whom the first and main symptoms are due to metastases. The incidence of carcinoma of the prostate has been increasing, due to an ageing population as well as to improved methods of diagnosis. Carcinoma of the prostate usually originates in the external group of glands (fig. 1425), so 'prostatectomy' for benign enlargement of the gland confers little protection from the subsequent development of carcinoma.

Latent Carcinoma of the Prostate.—Serial sections of prostates obtained at routine necropsy has revealed carcinoma in that organ in no less than 15 per cent. of men over fifty years of age. True, many of these neoplasms are tiny and (if life had continued) might have remained latent for years. In men over ninety years of age, over three-quarters of the prostates are involved (Franks). It seems, therefore, that a seedling carcinoma is often present in the prostate of an elderly man, awaiting favourable conditions to become active.

Histological Appearance.—Usually the carcinoma is spheroidal celled, with a varying degree of tubule formation, in which case the tumour is a slowly growing one. The anaplastic type is more malignant and manifests itself more aggressively than an adenocarcinoma.

Local Spread.—A growth *commencing in the posterior zone of the gland* is prevented (at least temporarily) from extending backwards by the strong fascia of Denonvilliers. Consequently it tends to grow upwards to involve the seminal vesicles. Further upward extension obstructs the lower end of one or both ureters, the latter terminating in anuria. Carcinoma *commencing in a lateral lobe* involves the prostatic urethra early: in advanced cases the base of the bladder is invaded. The rectum is involved occasionally by

Leonard Maurice Franks, Contemporary. Research Pathologist, Imperial Cancer Research Fund, Royal College of Surgeons of England, London.

infiltration, and stricture of the rectal wall occurs. The mucosa does not ulcerate unless traumatised, e.g. by transrectal biopsy.

Spread by the blood-stream occurs particularly to bones; indeed, the prostate is the most common site of origin for skeletal metastases, being followed in turn by the breasts, the kidneys, the bronchial tree, and the thyroid gland. The bones involved most frequently by metastases of carcinoma of the prostate are shown in fig. 1443. The pelvic bones and the lower lumbar vertebræ are particularly common sites. The frequent proximity of skeletal metastases to the primary growth has been attributed to reversed flow from the vesical venous plexus to the emissary veins of the pelvic bones during coughing, sneezing, etc.

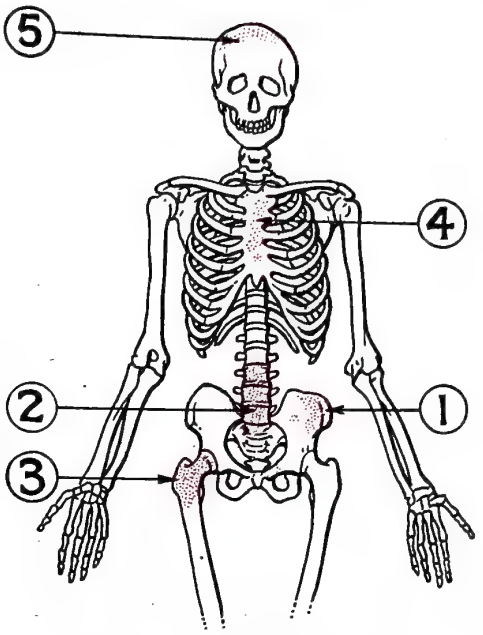

FIG. 1443.—Sites of location, in order of frequency, of metastases in bones from carcinoma of the prostate. (*After Swift Joly.*)

Lymphatic Spread.—(*a*) Via lymphatic vessels passing along the sides of the rectum to the lymph nodes along the internal iliac vein and in the hollow of the sacrum. (*b*) Via lymphatics which pass over the seminal vesicles and follow the vas deferens for a short distance to drain into the external iliac lymph nodes. From both these situations the retroperitoneal lymph nodes, later the mediastinal nodes, and occasionally the supraclavicular lymph nodes, become implicated.

Clinical Features.—Carcinoma of the prostate occurs in the older man but at an earlier age than benign hypertrophy. More than half the patients present with acute or chronic retention of urine.

Type 1. The Pathological.—The symptoms and signs are identical with those of benign enlargement. At histological examination 2 to 5 per cent. of prostates removed in the belief that they were benign prove to contain one or more areas of carcinoma.

Type 2. The Clinically Doubtful.—The symptoms and signs are similar to those of benign enlargement or fibrous prostate, but as a rule the history is comparatively short (weeks, not months). A hard nodule or increased fixation of the gland favours the diagnosis of carcinoma.

Type 3. The Clinically Certain.—The patient complains of pain in the perineum or suprapubic region, in addition to symptoms of prostatic obstruction. On rectal examination (see below) the findings leave no doubt as to the diagnosis.

Type 4. The Occult.—Urinary symptoms are absent or slight. Pain in the back, or sciatica, is the main symptom. Bilateral sciatica in an elderly man is most often due to metastases in the spine from carcinoma of the

prostate. Œdema of one or both legs, paraplegia, or a spontaneous fracture are occasionally due to metastases from a carcinoma of the prostate. Anæmia may be the presenting symptom.

On account of destruction of bone marrow, bone metastases from carcinoma of the prostate can give rise to a hæmorrhagic diathesis, and the patient suffers hæmorrhage, often severe, not necessarily from the urinary tract.

Rectal Examination.—Bimanual examination under anæsthesia, together with cystoscopy and needle biopsy are essential in order to assess the local stage of the growth. Irregular induration, characteristically stony hard in part or in the whole of the gland—with obliteration of the median sulcus suggests carcinoma. Extension beyond the capsule up into the bladder base and vesicles is diagnostic, as is deformity and projection outwards of the capsule.

T.N.M. Classification

Tumour:

T1 Local nodule — T2 Diffuse or deforming capsule — T3 Outside capsule or extension into vesicle — T4 Fixed to other tissue

Nodes: No = No evidence of involvement of regional nodes.
N1 = Involvement of one regional node.
N2 = Involvement of several regional nodes.
N3 = Fixed mass of regional nodes.
N4 = Involvement of common iliac or para-aortic nodes.

Metastases: Mo = No evidence of distant metastases.
M1 = Distant metastases.

Radiological examination to exclude or confirm the presence of prostatic calculi or pelvic and lumbar skeletal metastases is always necessary. Whereas osseous metastases from carcinomas of other organs are usually osteolytic, producing a rarefied 'moth-eaten' appearance, those in the lower lumbar vertebræ and pelvic bones from a carcinoma of the prostate are typically osteoblastic, resulting in increased density of the bone (fig. 1444), and must be distinguished from Paget's disease of bone (p. 285).

FIG. 1444.—Osseous metastases of the pelvic bones in carcinoma of the prostate. (*L. N. Pyrah, F.R.C.S., Leeds.*)

Other methods of detecting metastases:—It is an interesting fact that many apparently early cases can be shown to have distant metastases by employing:

1. *Bone Scanning* with radioactive bromine or selenium. The deposits are shown as 'hot spots'.
2. *Scalene node biopsy.*—A lymph node is removed from in front of the left scalenus anterior muscle in the neck.

3. *Bone marrow aspiration*—(sternum or ilium) reveals metastatic carcinoma cells in a surprisingly high percentage of those cases where radiological examination revealed no evidence of secondary deposits. This investigation should be carried out in every case before radical prostatectomy is even considered.

4. *Lymphangiography*.—By employing the technique described on page 173. X-rays will show whether there are deposits in the pelvic lymph nodes and any lymphatic obstruction.

Serum Acid Phosphatase. (See page 1235).—In about 40% of patients with carcinoma of the prostate the acid phosphatase is raised above normal (1 to 3 King-Armstrong units). A reading between 3 and 5 units is suspicious of carcinoma of the prostate, and above 5 units practically diagnostic. Very high levels up to 100 or more K.A. units can be found at times in patients showing extensive bone marrow involvement.

Confirmation of the Diagnosis.—Should be obtained by examination of histological material from the prostate. A true biopsy of prostatic tissue can be obtained with a Trucut or a Turkel needle passed through the perineum into any suspicious area (fig. 1445). Open perineal biopsy is still favoured in America.

Cysto-urethroscopy.—When there is a history of hæmaturia, this examination is essential. There is often a grating sensation as the prostatic urethra is traversed. With the instrument in place, deep induration in the prostate is more readily appreciated by a finger in the rectum, and fixation of the gland becomes more evident. Puckering of the apex of the trigone, submucous nodules in the base of the bladder, or ulceration of an intravesical projection are late manifestations. In earlier cases there are no pathognomonic visible signs.

Transuretheral Biopsy.—Transurethral resection of the prostate has the advantage of removing the obstruction and providing large pieces of tissue, but it may not reach the posterior zone of the prostate, which is commonly the seat of early carcinoma, and it must be remembered that benign enlargement frequently co-exists.

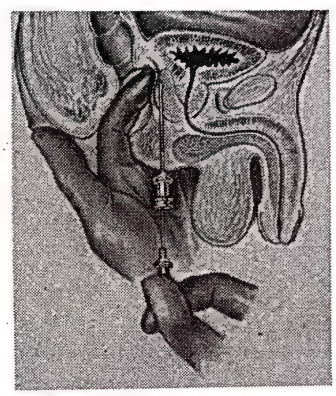

FIG. 1445.—Obtaining a specimen of prostatic tissue by means of Turkel's needle.

Treatment of Carcinoma of the Prostate

In spite of every endeavour, the diagnosis of carcinoma of the prostate usually is made late in the course of the disease, as the following statistics of the condition at the time of diagnosis testify:

Neoplasm confined within the anatomical capsule of the prostate	5 per cent.
Local spread	55 per cent.
Metastases present	40 per cent.

FIG. 1446.—Gynæcomasia following stilbœstrol therapy in a man 80 years of age with carcinoma of the prostate. It can to a large extent be prevented by preliminary radiation (6–800 rads) to each breast.

Radical cure by surgery plays a very small part in the management of the condition. However, a great deal can be done to alleviate the symptoms. Huggins first showed the beneficial effects of castration or stilbœstrol. **Stilbœstrol** causes improvement in 85% or more cases. It is of no value in transitional cell carcinomas arising from prostatic epithelium. Histological changes in many of the malignant cells may be apparent within forty-eight hours of

Eric Francis Turkel, Contemporary. Urological Surgeon, Pomona Valley Community Hospital, Pomona, California, U.S.A.

Charles Brenton Huggins, Contemporary. Professor of Surgery, Chicago, Illinois, U.S.A.

commencing treatment. The cells became distended with glycogen, the nucleus becomes pyknotic, and moves to the edge of the cell, being extruded when the cell breaks up.

Symptomatic changes occur in many cases within two weeks—there is less dysuria, a better stream, less frequency, and aches and pains may disappear. The prostate becomes smaller and softer, and these changes may be detected rectally in three to four weeks. Bone deposits may remain static and occasionally disappear.

The dosage of Stilbœstrol.—Probably only 3 to 5 mg a day are needed to reduce the serum testosterone from a normal of 400–1,200 ng/100 ml (14–42 nmol/l) to a satisfactory level of maintenance of 50 ng/100 ml (1·7 nmol/l). Larger doses produce a more rapid response.

Side-effects of Stilbœstrol.—There is increasing evidence that œstrogens produce an increased incidence of vascular accidents, particularly venous thrombosis and embolism. Caution should be employed in patients with a high serum cholesterol or previous history of coronary or other vascular disease. Gynæcomasia and pigmentation of the nipples is marked with large doses and impotence is invariable. Nausea and gastric upsets are occasionally present, and these are unrelated to dosage. Œdema of the ankles from salt retention may occur. Excessive nasal secretion is complained of by some patients and disturbance of vision by others. Adrenal stimulation elevating the level of androgen secretion may occur.

In all such cases subcapsular orchiectomy (fig. 1447), and cessation of œstrogen therapy can be tried, especially valuable in most of the side-effects previously described. Alternatively **T.A.C.E.** (tripara-anisil-chlorethylene), which is said to stimulate the breast and adrenal less, may be tried. Dose—12 to 24 mg per day.

(A) (B)

FIG. 1447.—(A) Metastases of prostatic carcinoma in the scalp. (B) Thirteen months after orchiectomy. *(Professor C. Huggins, Chicago.)*

Honvan (phosphorylated diethylstilbœstrol) is given i.v. or orally. It is claimed that the acid phosphatase of the prostatic carcinoma cells splits the phosphate element off the preparation, thus releasing the œstrogenic hormone locally and favouring its direct action on the carcinoma cells, and the carcinoma cells only. At first 100 mg are injected (it must be injected very slowly) three times a day for ten days. The dose is then increased to 200 mg, and eventually (enfeebled patients excepted) to as much as 500 to 1,000 mg, until the twentieth day. The dosage is then gradually decreased, until one 200-mg injection is given weekly, and finally monthly. The intravenous

injections, like all intravenous injections, require skilled administration. Orally, the dose of Honvan usually employed is 100 mg daily.

Radiotherapy.—Supervoltage treatment to the prostate (with a linear accelerator or cobalt source) is showing improved results, and, in the face of mounting evidence of vascular complications and malaise associated with stilbœstrol, is increasing in favour. It is most useful for localised disease and, perhaps, in anaplastic tumours. If dissemination is present, subcapsular orchidectomy should be performed.

Treatment of Retention in Carcinoma of the Prostate

Acute retention due to a carcinoma of the prostate should be treated with an indwelling Gibbon catheter (p. 1202) and 25 mg. stilbœstrol four times daily for two weeks. Usually micturition will then be resumed. If after three weeks the patient cannot pass urine normally, then the obstruction should be relieved. This is usually done by a per-urethral resection, but if the gland is also the seat of adenomas, a retropubic or transvesical removal of most of the tissue may be considered. Post-operative radiotherapy should be given after open surgery in definite cases of diffuse carcinomatous change in the gland.

Chronic Retention.—Such cases should not be catheterised, especially if the urine is sterile when first seen. Infection once established is impossible to eradicate in the presence of a growth. The residual urine may decrease gradually with treatment. Perurethral resection may be necessary if this does not occur.

Radical Surgery for Carcinoma of the Prostate.—Total prostatectomy is performed either by a retropubic approach (Millin) or through the perineum (Young). After the prostate is removed the membranous urethra is anastomosed to the base of the bladder (fig. 1448). The advantage of the perineal over the retropubic approach is the ability to perform a biopsy as a preliminary part of the operation.

FIG. 1448.—Approximating the base of the bladder to the membranous urethra. (*After T. Millin, F.R.C.S., London.*)

Other Measures and Prognosis

Treatment of Pain and Enlarged Lymph Nodes.—Severe pain from bone secondaries, but more usually from perineural lymphatic infiltration, can be difficult to control, as is œdema of a leg from enlarged lymph nodes. Deep X-ray therapy combined with intra-arterial nitrogen mustard given into the pelvic vessels via a retrograde catheter up the femoral artery (two doses of 10 to 15 mg at weekly intervals) is most useful.

Adrenalectomy is of little value. Pituitary ablation has occasionally been found helpful.

Prognosis.—Patients who fail to respond to stilbœstrol usually die within one year. On stilbœstrol five-year survival amounts to 25 to 30 per cent. Occasional survivals up to ten years are recorded, but ultimately nearly all patients die of the disease.

PROSTATITIS

In both acute and chronic prostatitis the seminal vesicles are usually infected, and when, as is often the case, the prostatic urethra is involved also, there is present a triad of pathological conditions, to wit: posterior

urethritis, prostatitis, and seminal vesiculitis. Symptoms due to infection of any one of these structures may predominate.

Acute Prostatitis

Ætiology.—Acute prostatitis is common.—The usual organism responsible is *Esch. coli*, but *Staphylococcus aureus* and *albus*, *Streptococcus fæcalis*, and the *gonococcus* may be responsible. As a rule the infection is hæmatogenous from a distant focus, notably furunculosis, infected tonsils, carious teeth, or diverticulitis. In a minority of cases the infection ascends from the urethra or descends from the bladder or kidneys.

Clinical Features.—Infection in most cases seems to be blood-borne, as general manifestations overshadow the local: the patient feels ill, shivers, may have a rigor, has 'aches' all over, especially the back, and may easily be diagnosed as having influenza. The temperature may be up to 39° C. Pain on micturition is usual, but not invariable. The urine always contains threads in the first glass, and it is this initial specimen of urine which should be cultured. Perineal heaviness, rectal irritation and pain on defæcation can occur, and sitting may be uncomfortable. A urethral discharge is rare. Frequency occurs when the infection spreads up to the bladder. Rectal examination reveals a tender prostate, one lobe may be swollen more than the other, and the seminal vesicles may be involved. A frankly fluctuant abscess is uncommon.

Treatment.—Must be rigorous and prolonged or the infection will not be eradicated and recurrent attacks will ensue. Unless treated early, spread of the infection to the epididymes and testes is common. While awaiting the results of culture of the initial and a midstream specimen of urine, the patient is put to bed, given copious fluids, and started on a broad spectrum drug such as tetracycline. As soon as the culture result is available the most suitable drug can be chosen and continued for ten days. It should be followed by a month's course of a sulphonamide such as sulphamethizole (Urolucosil) 100 mg. 4 times daily to prevent recurrence. Bed-rest for ten to fourteen days, avoidance of alcohol and intercourse for six weeks is essential.

Prostatic Abscess.—In addition to the foregoing symptoms and signs, the advent of a prostatic abscess is heralded by the temperature rising steeply, rigors being not unusual. However, antibiotics disguise these leading features. Severe, unremitting perineal and rectal pain with occasional tenesmus often cause the condition to be confused with an ano-rectal abscess. Nevertheless, if a rectal examination is performed, the prostate will be felt to be enlarged, hot, extremely tender, and perhaps softened in one place. Retention of urine is likely to occur.

Treatment.—The abscess should be drained without delay. It is true that if a catheter is passed to relieve acute retention of urine, sometimes the abscess is ruptured into the prostatic urethra. However, in most cases such drainage is insufficient, and is followed by intractable chronic prostatitis or a residual abscess.

(*a*) The abscess can be drained by perurethral resection—unroofing the whole cavity.

(*b*) The perineal route is preferable when there is marked peri-prostatic spread.

Chronic Prostatitis

Ætiology.—This is a sequel of inadequately treated acute prostatitis. While pus is present in the prostatic secretion, often the responsible organism

is difficult to find. Smears show bacteria in about 40 per cent. and cultures are positive in 70 per cent. of cases. The predominant organisms are E. coli, staphylococci, streptococci, and diphtheroids, in that order. Recently trichomonas has been found to be a cause of chronic prostatitis and may be common to both husband and wife.

Pathology.—The lumina of the ducts become blocked with epithelial debris and pus. This causes a soft enlargement of the organ. Later fibrosis occurs, and the prostate becomes smaller and harder.

Clinical features are extremely varied.

1. *Causing Chronic Posterior Urethritis.*—Prostatitis should not be diagnosed unless, after irrigating the urethra and massaging the prostate, the resultant specimen shows fifteen or more pus cells per high power field.

2. *Causing Epididymitis.*—Acute or subacute non-tuberculous epididymitis rarely occurs unless prostatitis is present.

3. *Pain:* (*a*) *Local* pain is a dull ache in the perineum or rectum. It is increased by sitting on a hard chair. (*b*) *Referred* Pain.—Particularly common is low back pain, sometimes extending down the legs (fig. 1449); such pain is usually attributed to lumbago, and many sufferers from prostatitis receive orthopædic treatment and physiotherapy without benefit.

4. *'Silent' Prostatitis.*—Arthritis, myositis, neuritis, and sometimes iritis and conjunctivitis are on occasions explained only when pus has been obtained from the prostate (see diagnosis).

5. *Recurring attacks of mild pyrexia*, lasting about three days and accompanied by malaise.

6. *Sexual Dysfunction.*—Premature ejaculations, prostatorrhœa, and impotence are sometimes due to prostatitis.

Many patients with sexual dysfunction due to chronic prostatitis become hypochondriacal.

FIG. 1449.—Sites of pain in chronic prostatitis.

Diagnosis: (*a*) *A three-glass urine test* is valuable. If the first glass shows urine containing prostatic threads, prostatitis is present.

(*b*) *Rectal examination* of the prostate may or may not confirm the diagnosis. If the organ is soft and boggy, it is obviously abnormal, as also it is if the prostate is smaller and harder than it should be. In mild chronic cases no change can be detected, and reliance must be placed on pathological examinations of the prostatic fluid.

(*c*) *Examination of the prostatic fluid* obtained by prostatic massage. Normal prostatic fluid is slightly opalescent and viscid. A stained specimen shows many pus cells and sometimes bacteria. Non-stained films, in addition to revealing normal epithelial cells, may show trichomonads, if present.

(*d*) *Urethroscopy* reveals inflammation of the prostatic urethra, and pus

may be seen exuding from the prostatic ducts. The verumontanum is likely to be enlarged and œdematous.

Treatment.—*Antibiotic therapy* must be administered in accordance with bacteriological sensitivity tests. The blunderbuss administration of antibiotics in this condition is to be deprecated. Probably 0·5 g t.d.s. of a suitable sulphonamide, e.g. Sulphatriad, for six weeks will effect as much as an expensive course of antibiotics. Where trichomonas is the responsible agent, a rapid response is obtained from administration of Flagyl (metronidazole) 200 mg by mouth three times daily, after meals, for seven days to both partners.

TUBERCULOSIS OF THE PROSTATE AND SEMINAL VESICLES

Tuberculosis of the prostate and seminal vesicles is associated with renal tuberculosis in at least 60 per cent. of cases. In 30 per cent. of cases there is a history of pulmonary tuberculosis within five years of the onset of genital tuberculosis.

Tuberculosis of one or both seminal vesicles is more common than tuberculosis of the prostate, and is often discovered when examining a patient with chronic tuberculous epididymitis, there being no symptoms referable to the internal genitalia. On rectal examination the affected vesicle is found to be nodular and tender. In process of time tuberculous seminal vesiculitis may lead to congestion and œdema of the base of the bladder, and later to basal cystitis.

When the Prostate is Involved.—Rectal examination reveals characteristically one or more well-defined nodules, most often near the upper or lower border of one or both lateral lobes. Less frequently a larger solitary mass is felt occupying a more central position. Nodules in the prostate lack the stony hardness of carcinoma.

A patient with tuberculous prostatitis usually presents with one or more of the following symptoms:

A urethral discharge is occasionally the first symptom. Then the diagnosis has to be made from gonorrhœa and abacterial urethritis entirely on bacteriological findings, for the prostate at this early stage is likely to feel normal.

Painful, sometimes blood-stained, ejaculations occur in 20 per cent. of cases.

A mild ache in the perineum is not uncommon.

Infertility.—In patients with tuberculous prostatitis and/or bilateral seminal vesiculitis, fertility is very much reduced; it is safe to say that 80 per cent. of them are sterile. In this connection, owing to the considerable interest in male fertility at the present time, a number of very early cases of tuberculous prostato-vesiculitis are being discovered by culture of the semen.

Urinary Symptoms.—In later cases, when the posterior urethra becomes involved from extension of tubercles from the prostate or by the discharge of a prostatic abscess, there is painful, frequent micturition and sometimes terminal hæmaturia.

Abscess Formation.—If a cold abscess forms in the prostate, it is felt as a slightly tender, soft swelling. Like other prostatic abscesses, it usually ruptures into the urethra, more rarely through the perineum or into the rectum. Occasionally an abscess of the prostate or seminal vesicle bursts into the bladder, and at cystoscopy a ragged, deep ulcer is seen alongside the trigone.

Special Forms of Investigation:

Even in cases without urinary symptoms a complete urological examination is necessary.

Radiography sometimes displays areas of calcification in the prostate and/or the seminal vesicles. Large scattered areas of calcification in the prostate suggest tuberculosis rather than endogenous prostatic calculi.

Bacteriological examination of the seminal fluid yields positive cultures for tubercle bacilli in most cases of tuberculous prostatitis.

Posterior urethrography often reveals one or more dilated prostatic ducts. Typically they are multiple and gaping. Dilated prostatic ducts are not specific for tuberculosis (they can occur in other forms of chronic prostatitis), but dilated ducts plus the finding of tubercle bacilli in the ejaculate establishes an absolute diagnosis.

Transmission of genital tuberculosis to the female partner is exceptional, but it does occasionally occur in the form of tuberculous cervicitis.

Treatment.—The general treatment given is as for renal tuberculosis (p. 1184). On no account must a tuberculous prostate or seminal vesicle be subjected to massage. Urethral instrumentation should be avoided, or reduced to a minimum only to confirm the diagnosis.

If a prostatic abscess forms, it is better to evacuate it by the perineal route than to permit it to rupture spontaneously.

Considerable involvement of the prostate, which goes on to suppuration, is a comparatively unfavourable form of genito-urinary tuberculosis. On the other hand, tuberculous seminal vesiculitis and non-suppurative tuberculosis of the prostate usually heal after an associated lesion of the kidney or epididymis has been eradicated, but stricture of the prostatic urethra may occur.

AFFECTIONS OF THE SEMINAL VESICLES

Acute seminal vesiculitis always occurs in association with prostatitis. Prior to the antibiotic treatment of gonorrhœa, gonococcal vesiculitis was common. When a seminal vesicle is distended it can be palpated per rectum as an acutely tender swelling above and lateral to the prostate. The treatment is discussed on p. 1267.

Abscess of a Seminal Vesicle.—In addition to the usual signs of acute prostatitis, pain is frequently referred to the suprapubic region. If on rectal examination the seminal vesicle is found to be greatly enlarged and tender, the abscess should be drained through an incision in the perineum, viz.⟶ The incision is deepened until the swelling is palpated, and a hæmostat is then thrust into the abscess cavity.

Chronic seminal vesiculitis is less frequently recognised than it should be, because the associated chronic prostatitis overshadows the symptoms of pain on coitus, hæmospermia, aching in the sacral region, recurrent epididymitis, and, at times, associated disturbances of micturition and defæcation. The treatment is the same as for chronic prostatitis, except that in rebellious cases vasotomy and irrigation of the vesicle with normal saline is often rapidly curative.

Tuberculous Seminal Vesiculitis.—The clinical features and treatment are discussed on p. 1254 and above.

Diverticulum of the seminal vesicle occurs occasionally. In such cases the kidney of that side is often absent, and the diverticulum represents an abortive ureteric bud. It is a cause of persistent infection of the urethra.

A cyst of the seminal vesicle is uncommon. It should be removed by dissection through an incision similar to that for perineal prostatectomy.

FIG. 1450.—Palpating an enlarged gland of Cowper.

AFFECTIONS OF COWPER'S GLANDS

Cowperitis.—The diagnosis of Cowperitis is often wanting for lack of a simple examination. On passing the forefinger into the rectum and placing the thumb first on one side and then on the other of the median raphé of the perineum, Cowper's glands can be palpated (fig. 1450). In acute cases the least pressure causes excruciating pain. In this way the condition is differentiated from an ischio-rectal or periurethral abscess. **Treatment.**—In acute

William Cowper, 1666–1709. Surgeon and Anatomist, London.

cases antibiotic therapy, and rest in bed, often brings about resolution. Should suppuration occur, incision and drainage is necessary.

Fistula formation is the result of an abscess of the gland terminating in spontaneous rupture; it is necessary to excise the fistula and the remnants of the gland.

A cyst of Cowper's gland either bulges into the urethra and causes disturbances of micturition, or gives rise to a unilateral swelling in the anterior part of the perineum. The cyst should be excised.

CHAPTER 57

THE URETHRA AND PENIS

THE MALE URETHRA

Embryology.—From the internal urinary meatus to the sinus pocularis (uterus masculinus) the urethra is developed from the urogenital sinus. This portion corresponds to the entire female urethra. Beyond the sinus pocularis the male urethra, as far as the glans, is formed by fusion of the edges of the medial labial folds, which also form the corpus spongiosum. The part traversing the glans is formed by canalisation of a down growth of a solid pencil of ectoderm.

CONGENITAL ABNORMALITIES OF THE URETHRA

Meatal Stenosis.—The external urinary meatus, normally the narrowest part of the male urethra, is occasionally the seat of congenital stenosis which is associated with phimosis (p. 1280). In the circumcised, meatal stenosis may also be acquired or increased by fibrosis following meatal ulceration. All degrees of narrowing are encountered. When the opening is reduced to a pin-hole, back-pressure affects the whole urinary system. Pin-hole meatus is occasionally a cause of enuresis, and at any age it may result in chronic retention of urine (fig. 1451).

FIG. 1451.—Pin-hole meatus causing chronic retention of urine (distended bladder outlined) in a man of fifty-one. Cured by meatotomy.

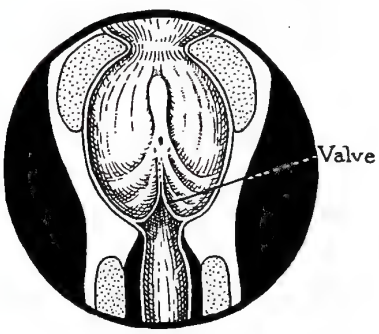

FIG. 1452.—Congenital valves of the posterior urethra. (*After D. Innes Williams.*)

Treatment.—Meatal stenosis, sufficient to (*a*) give rise to symptoms, (*b*) prevent free drainage of the discharge in cases of urethritis, or (*c*) obstruct the passage of full-sized urethral instruments or a cystoscope, should be treated by meatotomy. Lesser degrees of narrowing respond to dilatation with Hegar's dilators.

Meatotomy.—The narrowed section must be split back into normal urethra, and the mucosa stitched to the skin edge. Alternatively, a skin flap can be turned in from the underside of the skin behind the glans.

Congenital stricture of the urethra is very rare; some cases are due to reduplication of the urethra. Usually the symptoms are delayed until adolescence. Treatment by dilatation is effective.

Congenital valves of the posterior urethra are often symmetrical and occur usually just below (fig. 1452), but occasionally above, the verumontanum. They allow the ingress of a catheter but obstruct the outflow of urine. In a few instances

Alfred Hegar, 1830–1914. Professor of Obstetrics and Gynæcology, Freiburg, Germany.

the valves are incomplete and the patient may reach adolescent or adult life without symptoms; however, in such cases the prostatic urethra is greatly dilated and sacculation or diverticula of the bladder are present.

The valves are difficult to see at cysto-urethroscopy, because the irrigating fluid sweeps them into the open position. The most reliable method of confirming the diagnosis is voiding cysto-urethrography, by which is meant that radiographs are taken during attempts to micturate after the bladder has been filled with contrast medium. Alternatively, pressure above the pubes while the radiograph is taken achieves the same objective. In this way the dilated urethra above the valves is outlined, as well as the bladder.

Treatment.—Suprapubic drainage of the bladder is a life-saving measure; several weeks should intervene before attempting to remove the valves. At the second operation the retropubic space is displayed. A vertical incision is made into the bladder just above the prostate and continued downwards into the dilated prostatic urethra. Bleeding-points are coagulated with a diathermy needle and the valves are picked up with toothed dissecting forceps and excised with scissors. The incision into the bladder and urethra is closed with fine catgut sutures, and the bladder is drained by a suprapubic catheter for ten to fourteen days. Infection is controlled by antibiotic therapy. In older children and adults the valves can be excised transurethrally with a resectoscope.

Because of their importance in the differential diagnosis of congenital valves of the urethra, the following causes of chronic retention in childhood are included here:

Obstruction to the neck of the bladder (*syn.* **Marion's disease**) is analogous to hypertrophic pyloric stenosis of infants, and gives rise to symptoms identical with those of congenital valves. The diagnosis can often be appreciated cystoscopically as a hypertrophied interureteric bar. Voiding cysto-urethrography demonstrates that the posterior urethra does not fill, and clarifies the differential diagnosis between the two conditions. Treatment consists in opening the bladder and performing a Y—V plasty (p. 1245).

Neurogenic bladder must be excluded in both the above lesions. Spina bifida, and the accompanying lesions of the central nervous system, is the usual cause of retention of urine of neurological origin in childhood. As with obstruction due to congenital valves, cysto-urethrography shows the dilated prostatic urethra. In neurogenic obstruction, the ease with which the bladder can be emptied by manual pressure above the pubis serves as a ready means of distinguishing chronic retention of urine due to this cause from other varieties.

HYPOSPADIAS

Hypospadias is the commonest congenital malformation of the urethra, and it occurs once in every 350 males. The external meatus is situated at some point on the *under*-surface of the penis or in the perineum.

There are five degrees of the deformity, classified as follows:

1. **Glandular Hypospadias.**—There is an ectopic opening on the under-surface of the glans, separated from a blind depression at the normal site of the external urinary meatus. Sometimes a channel connects the ectopic to the normal meatus.

2. **Coronal Hypospadias.**—The meatus is situated at the junction of the under-surface of the glans with the body of the penis.

3. **Penile Hypospadias.**—the meatus opens at some part of the under-surface of the penis (fig. 1453).

4. **Peno-scrotal Hypospadias.**—The urethra opens at the junction of the penis with the scrotum.

5. **Perineal Hypospadias.**—The scrotum is split and the urethra opens between its two halves. This variety is sometimes associated with bilateral maldescended testes, in which event the sex of the child may be difficult to determine.

Jean-Baptiste Camille-Georges Marion, 1869–1960. Emeritus Professor of Urology, Faculty of Medicine, Paris.

Glandular hypospadias is the most frequent variety, and is due to a failure of canalisation of the glans (see embryology). The other varieties are looked upon as an absence of the urethra and corpus spongiosum distal to the ectopic orifice, the absent structures being represented by a fibrous cord. In all except the first variety the penis is curved in a downward direction (chordee). The farther away the opening is from the normal position, the more pronounced is the bowing. In all cases the inferior aspect of the prepuce is poorly developed (' hooded prepuce ').

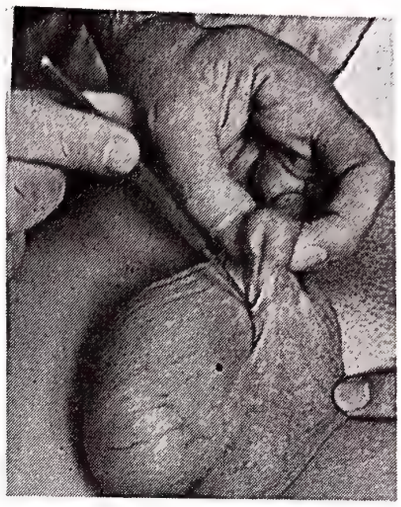

FIG. 1453.—Penile hypospadias. The patient passes urine through the orifice demonstrated by the probe.

Treatment.—In glandular hypospadias no treatment is required, unless the opening is too small, in which case meatotomy is performed. In other varieties a plastic operation, of which there is a great variety, should be carried out. On this account circumcision during infancy should not be performed in these cases as the redundant skin will prove useful later.

Stage 1.—*Straightening the penis* is undertaken preferably between one and a half and two years of age. A transverse incision is made on the ventral surface 1·25 cm distal to the misplaced external urinary meatus, and the skin on either side of the urethra is undermined, exposing the fibrotic corpus spongiosum, which is detached from before backwards by severing its fibrous attachment to the corpora cavernosa. This accomplished, the urethral orifice recedes towards the perineum; thus a coronal hypospadias becomes a penile, peno-scrotal, or perineal, and the penis is no longer tethered. The original transverse incision is further lengthened by carrying it into the under-surface of the prepuce on either side. The incision is then closed vertically, tension being relieved by making a longitudinal incision in the middle line through the skin of the dorsum of the penis and prepuce.

Stage 2.—*Denis Browne's method of constructing a urethra* is undertaken, preferably between five and seven years of age. Diversion of all urine from the seat of operation can be accomplished only by *perineal urethrostomy*. A small catheter is passed into the bladder on an introducer. The introducer is withdrawn slightly, and rotated so that its beak can be felt in the perineum. Strictly in the middle line a small incision is made, and the catheter is seen within the urethra. The wall of the catheter is grasped in a hæmostat while the assistant withdraws the introducer. The butt end of the catheter is then drawn along the urethra and made to emerge in the perineum. Two cotton sutures are tied around the catheter and utilised to anchor it to the edges of the perineal wound.

Fashioning a New Urethra.—An incision is made as outlined in fig. 1454 (A). The flaps are undermined, special attention being paid to freeing the skin in the direction of the perineum, so that when the flaps are united they lie well forward of the old urethral opening. When the undermining involves the scrotum, stab wounds should be made on either side to allow the ready escape of blood and serum. Next, with sharp scissors, a triangular area of glans is bared of skin on either side of the proposed new meatus (fig. 1454 (B)). An incision is made through the skin along the whole length of the dorsum of the penis. This is to relieve tension, and the wound is allowed to epithelialise. The flaps are sutured, but not too tightly. Browne employed glass beads and small sections of soft aluminium tubing, which are crushed, and hold the sutures in place (fig. 1454 (C)). No dressing is employed—only a spray of Nobecutane. Tetracycline is given for two weeks. The sutures are removed in a week, and the catheter is withdrawn on the tenth day. The perineal wound usually closes three to five days later.

Sir Denis John Wolko Browne, 1892–1967. Surgeon, Hospital for Sick Children, Great Ormond Street, London.

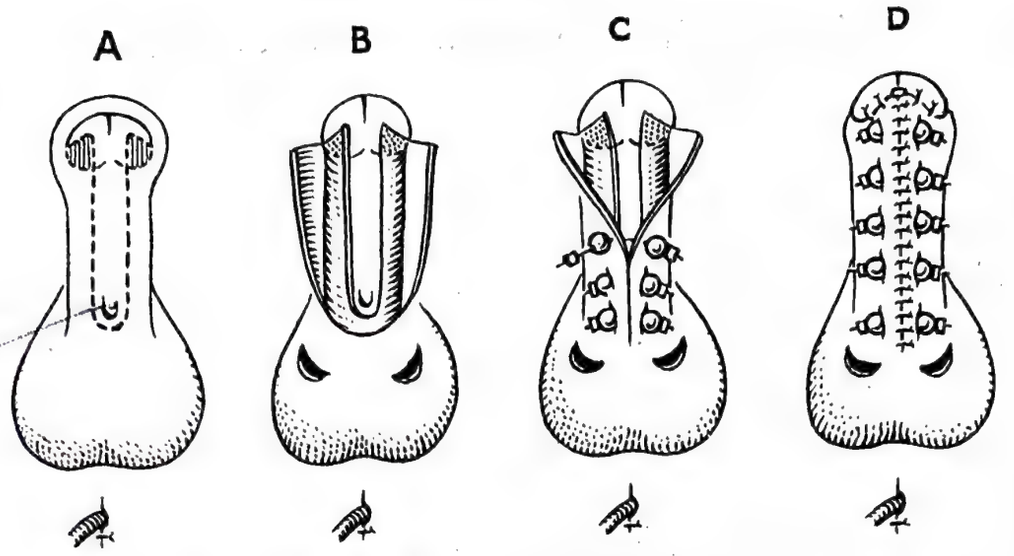

FIG. 1454.—Denis Browne's operation for hypospadias. The buried strip of skin forms the new urethra.

EPISPADIAS

Unlike hypospadias, epispadias is very rare, occurring in one in 30,000 males and one in 400,000 females. The defect may be glandular (fig. 1455), penile, or total, the latter usually associated with ectopia vesicæ. In the first two varieties the urethral orifice is situated on the dorsum, and in the second variety the penis curves upwards as well.

FIG. 1455.—Glandular Epispadias.

Treatment.—The operative treatment is similar in principle to that of hypospadias, and is somewhat less difficult to perform.

INJURIES OF THE URETHRA

Rupture of the urethra is divided into two distinct classes—rupture of the bulbous urethra, and rupture of the membranous urethra (*syn.* intrapelvic rupture) (fig. 1456). Each is again subdivided into complete and incomplete which relates to the circumference of the urethral wall, and total and partial which relates to the thickness of the wall.

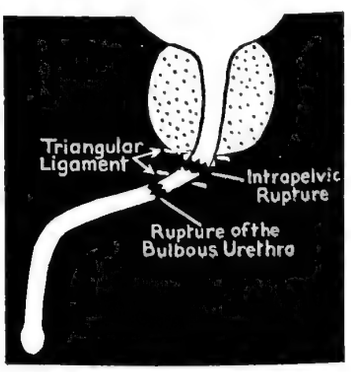

FIG. 1456.—Showing the two varieties of rupture of the urethra.

Rupture of the Bulbous Urethra

Rupture of the bulbous urethra is the more common accident. Almost without exception there is a history of a fall astride a projecting object. In the days of sailing-ships, the common cause was falling astride a spar from aloft. To-day a loose manhole cover (fig. 1457) and cycling accidents account for a number of cases.

Clinical Features.—The triad of signs of a ruptured bulbous urethra is urethral hæmorrhage, a perineal hæmatoma, and retention of urine.

Preliminary Treatment and Investigation.—If the condition is suspected, in order to diminish the possibility of extravasation, *the patient should be told not to try to pass urine.* No attempt should be made to catheterise him until he is fit to be taken to an operation theatre, where asepsis can be

assured and operation can be undertaken in necessary cases. A suitable dose of morphine is given, a course of chemotherapy started. When circumstances are extenuating and the bladder is full, it should be emptied by suprapubic puncture (p. 1199) until the patient can be treated as above. If the patient has passed urine when first seen and there is no extravasation, then the rupture is partial and catheterisation should be avoided.

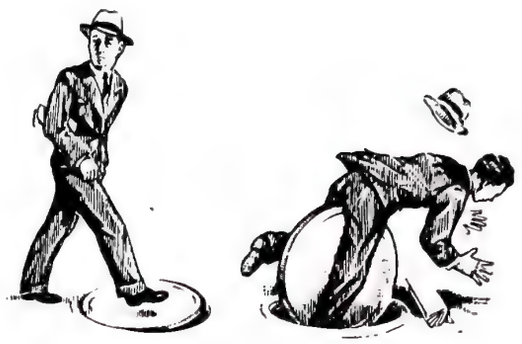

FIG. 1457.—The type of accident which results in rupture of the bulb of the urethra. (*After V. J. O'Conor.*)

Treatment

1. Under strict aseptic precautions an attempt is made to pass a plastic coudé catheter (14–16 F). The roof of the urethra is the most likely part to be intact, so the beak of the catheter should be directed towards this.

2. If the catheter passes it should be left in position for forty-eight hours. A perineal hæmatoma must be drained, and the mid-line wound packed.

3. If the catheter fails to pass, the site of the obstruction is explored, with the patient in the lithotomy position, through a mid-line perineal incision. Should it be impossible to define the proximal end of the ruptured urethra, a suprapubic cystotomy is performed and a fully curved sound passed down from the internal meatus. The exposed ends of the urethra are trimmed and the ventral aspect split longitudinally for 1·5 cm. The circumference is then sutured as a flat ribbon, with fine catgut, the knots being left on the outside of the wall (fig. 1458). The bladder, if opened, is drained by a suprapubic catheter. If the repair has been accomplished without cystostomy the catheter can be passed into the bladder from the urethrostomy (fig. 1458 (B)). A small balloon Gibbon-type catheter (12 F) is very satisfactory. The perineal wound is packed, not stitched.

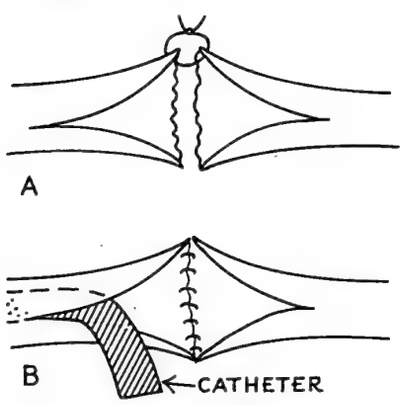

FIG. 1458.—Repair of ruptured bulbous urethra.

After-treatment.—A course of chemotherapy (e.g. Urolucosil 100 mg. six hourly) is continued until healing is complete. The urine must be recultured after a week. The perineal wound is irrigated daily with a weak Eusol (hypochlorite) solution. The catheter is removed after eight to ten days. A perineal leak will persist for a few days. Sounds must be passed two weeks after healing to calibrate the urethra, and a urethrogram, performed two months later, will reveal the result.

Complications:

Subcutaneous extravasion of urine occurs in total rupture if the patient attempts to pass urine (p. 1264).

Stricture.—This common complication is due, for the most part, to infection (p. 1269).

Rupture of the Membranous Urethra
Extraperitoneal rupture of the Bladder

Intrapelvic rupture of the urethra occurs in the membranous portion near the apex of the prostate (fig. 1456). Like extraperitoneal rupture of the bladder it may be due to penetrating wounds, but in civil life is more usually the result of fracture of the pelvis or dislocation of the symphysis pubis.

Norman Otway Knight Gibbon, Contemporary. Surgeon, Sefton Hospital, Liverpool, England.

Only about 10–15% of cases of fractured pelvis sustain either or both injuries.

Complete rupture with floating prostate	1–2%
Incomplete intrapelvic rupture of urethra	4–6%
Extraperitoneal rupture of bladder	4–6%
Combined urethra and bladder damage	1–2%

Clinical Features.—Signs of a fractured pelvis are present, with shock. Blood, and later, urine produce a swelling in the perivesical and peri-prostatic tissues and an assessment of mobility of the prostate may be difficult. In *urethral injuries* some blood leaks from the urethral meatus, and the bladder will distend before extravasation occurs (fig. 1459). In *extraperitoneal rupture* of the bladder, the organ will not be palpable (fig. 1378). However,

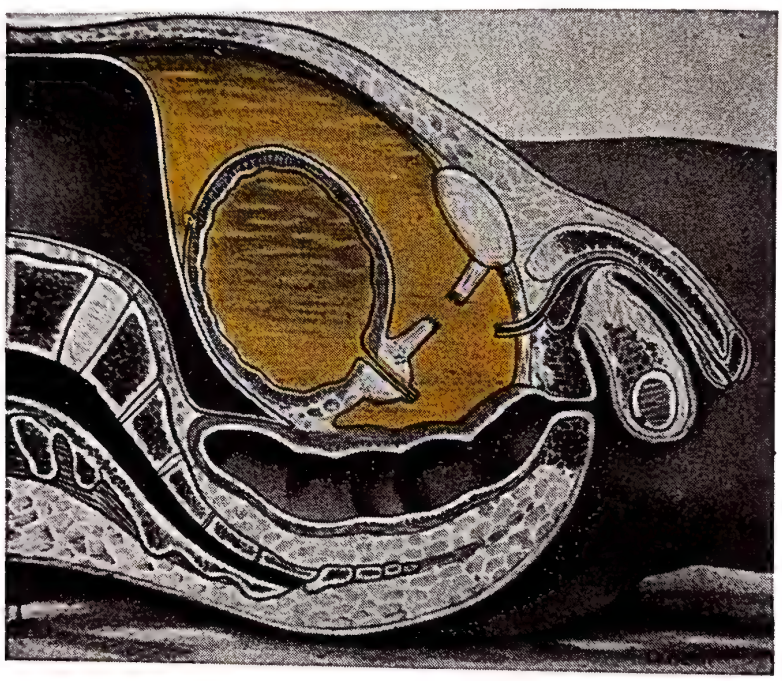

FIG. 1459.—Intrapelvic rupture of the urethra. Note the displacement of the bladder backwards, due to the tearing of the pubo-prostatic ligaments.

dullness and some tenderness extend upwards from the pubis, and an ill defined swelling is appreciable in all but the very obese.

Investigation.—A plain X-ray to demonstrate the fractures is essential, likewise a blood count, blood-grouping and cross-matching for blood transfusion because massive loss from pelvic veins can occur. Urethrography and attempts at cystography or catheterisation are damaging and may destroy any residual intact urethral wall. They must not be permitted. It is less dangerous to wait to see if the patient will pass urine (Mitchell).

Treatment.—Blood loss and shock are treated. As soon as the diagnosis is reasonably certain a suprapubic catheter should be inserted (under general anæsthesia if the patient is fit). On opening the suprapubic tissues, any fluid should be aspirated, but no attempt should be made to displace a hæmatoma, or explore the area behind the pubis.

The bladder is opened and by inserting two fingers it is possible to ascertain that the *prostate is not floating* so high that total rupture is certain. At

John Phillimore Mitchell, Contemporary. Consultant Urologist, United Bristol Hospitals.

the same time a depressed fracture of the symphysis can be pushed forward. Provided the prostate is not grossly displaced, the bladder is closed round a large (28F) Malécot catheter. The wound is closed loosely round the catheter to allow drainage from the perivesical space. An antibiotic should be given to diminish the risk of infection in the hæmatoma.

The urethra is subsequently explored three weeks after the injury by careful visualisation via a panendoscope. In many cases this can be manipulated past blood clot and into the bladder. Occasionally a guiding sound passed from the bladder downwards may assist the manoeuvre. If this can be achieved then the suprapubic tube may be clipped off after a further three days and a trial of micturition made. In those cases where the block cannot be negotiated re-exploration and urethroplasty will be necessary.

If the prostate is floating, and there is no doubt that the rupture is complete and total, then the older classical method, railroading a catheter across the gap, and drawing the prostate down on to the triangular ligament, should be adopted.

Railroad technique.—A metal bougie is passed from the bladder through the internal meatus with the retropubic space. A second metal bougie is passed from the external urinary meatus. The two bougies are manipulated until their tips touch (fig. 1460). By slowly withdrawing the first bougie and steadily advancing the second, while keeping their tips in contact, it is possible to guide the second bougie into the bladder past the seat of the rupture. The first bougie is withdrawn and a

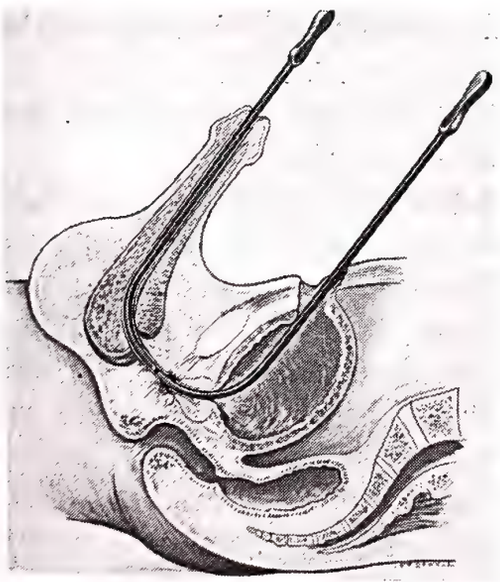

FIG. 1460.—Intrapelvic rupture of the urethra. Showing the tips of the metal bougies in contact.

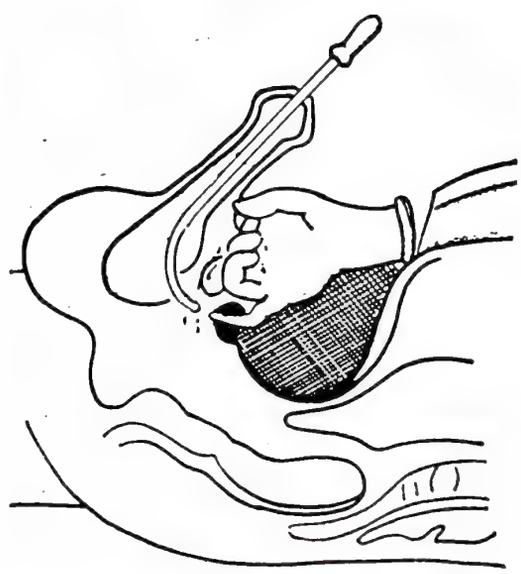

FIG. 1461.—Shahade and Shah procedure (see text).

piece of plain rubber tubing of such a size as to fit tightly is threaded on to the beak of the second bougie, which is withdrawn, carrying with it the rubber tubing. Outside the external urinary meatus the bougie is disengaged from the rubber tubing, and to the latter is fastened, by means of a stitch, the tip of a Foley's catheter. By pulling on the vesical end of the rubber tubing the tip of the Foley's catheter is drawn into the mouth of the suprapubic wound, where it is disconnected from the rubber tube.

At this stage it is advisable to tie a long piece of silk firmly to the tip of the Foley's catheter, and to wind the excess around a wooden spatula. (Thus, should the balloon burst, the Foley's catheter can be replaced by the rail-road method just described).

Achille-Étienne Malécot, 1852–?. He invented his catheter while Interne des Hôpitaux de Paris, France.
Frederic Eugene Baisal Foley, 1891–1966. Urologist, Miller and Ancker Hospitals, St. Paul, U.S.A.

FIG. 1462.—Malécot catheter.

This completed, the balloon (30 ml.) of the catheter is moderately distended with water and the side tube is ligated (fig. 1463).

The *Shahade and Shah procedure* (fig. 1461) employs the little finger instead of the second metal bougie as it makes the operation easier.

Concluding the Operation. — The catheter is drawn down so that the balloon rests upon the bladder neck. The bladder is closed around a Malécot catheter (fig. 1462), and the prevesical space is drained with corrugated rubber.

After-treatment:

Urological. — (1) By the mediation of a length of silk, attached to the bell end of the catheter and transfixing both walls of the catheter, extension is applied to the catheter via a pulley and a weight; thus the severed ends of the urethra are brought into contact (fig. 1463). The weight applied is 900 g for the first three days and 450 g for the next ten days. Bed-cages are arranged so as to prevent the bedclothes touching the taut silk cords.

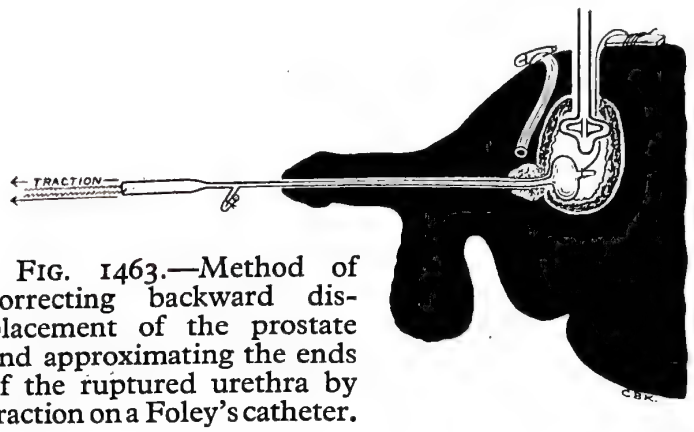

FIG. 1463.—Method of correcting backward displacement of the prostate and approximating the ends of the ruptured urethra by traction on a Foley's catheter.

(2) Suprapubic drainage of the bladder is maintained for fourteen to twenty-one days.

(3) The urine is kept alkaline and antibiotic treatment is given until the patient has a sterile urine and completely healed wounds.

(4) On or about the twelfth day the Foley's catheter is removed, and during the process the silk attached to its tip is unwound from the spatula; thus the silk lies along the whole length of the urethra, one end being tied to the spatula and the other emerging from the external urinary meatus. The suprapubic tube can be clipped off at about the fourteenth day, and if the patient passes urine easily is can be removed. The silk thread should be retained for the passage of bougies by the rail-road method at the end of another week, and then it should be removed, unless the insertion of another catheter becomes necessary.

Orthopædic.—For management of the fractured pelvis, see p. 394.

EXTRAVASATION OF URINE

Superficial extravasation occurs in neglected cases of complete rupture of the bulbous urethra, i.e. when operation is not undertaken within twelve to twenty-four hours, and in ruptured periurethral abscess.

The extravasated urine cannot pass (1) behind the mid-perineal point, because of the attachment of the perineal (Colles's) fascia to the triangular ligament; (2) into the thighs, for the deep layer of the superficial fascia of the abdominal wall (Scarpa's fascia) blends with the pubic portion of the fascia lata just distal to the inguinal ligament; (3) into the inguinal canals, because of the intercolumnar fibres and fascia of the external oblique (external spermatic fascia).

M. G. Shahade, Contemporary. Formerly Professor of Surgery, Govt. Medical College, Surat, Gujarat, India.
V. C. Shah, Contemporary. Surgeon, Rajkotwthin, Gujarat, India.
Antonio Scarpa, 1747–1832. Professor of Anatomy, Pavia, Italy.

It therefore must pass (1) into the scrotum; (2) beneath the superficial fascia of the penis; (3) up the abdominal wall beneath the deep layer of the superficial fascia (fig. 1464).

Treatment.—Urgent operation is a necessity.

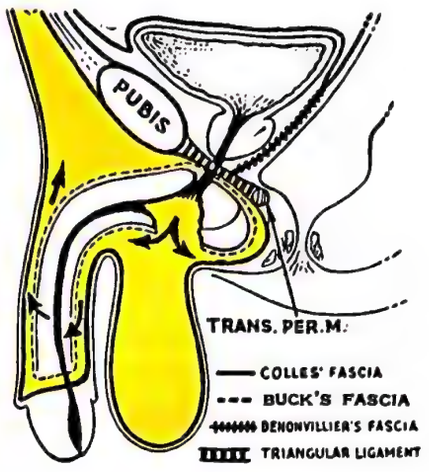

FIG. 1464.—The fascial planes concerned in superficial extravasation of urine. Trans. Per. M. = Transverse Perineal muscle.

Multiple incisions are made in the infiltrated tissues of sufficient depth to penetrate the limiting fascia. By the time extravasation has occurred it is unlikely that the urethra can be repaired in the way described already (p. 1262), for the sutures would cut out of the œdematous inflamed tissues. It is therefore often advisable to adopt the sutureless operation of Rutherfurd. Suprapubic cystostomy is performed and a metal bougie is passed through the internal urinary meatus. The patient having been placed in the lithotomy position, another metal bougie is passed from the external urinary meatus to the perineum, and perineal section is carried out. A Foley's catheter is introduced from the external urinary meatus into the bladder in the same way as that described for intrapelvic rupture of the urethra, and the bladder is closed around a de Pezzer catheter. The perineal wound is left widely open. The urethral catheter is removed after three or four days. In other respects the after-treatment is similar to that for complete rupture of the bulbous urethra.

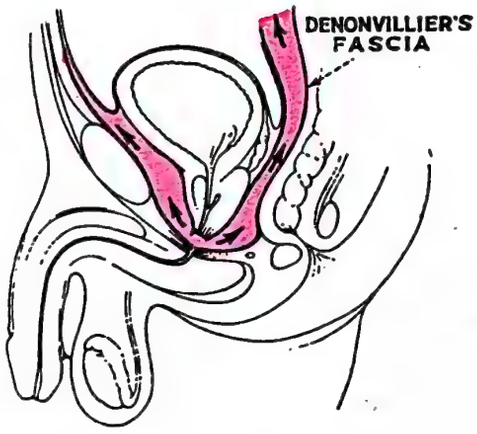

FIG. 1465.—Area occupied by extravasated blood and urine in the case of intrapelvic rupture of the urethra.

Deep extravasation (fig. 1465) occurs in the case of extraperitoneal rupture of the bladder, intrapelvic rupture of the urethra, and after suprapubic puncture, when the bladder has been allowed to refill. It can also result from rupture or perforation of a ureter, or unnoticed damage to the bladder or prostatic capsule during per-urethral resections. In these conditions urine extravasates in the layers of the pelvic fascia and in the retro-peritoneal tissues.

Treatment.—When extravasation is proceeding from the bladder, it is necessary to drain the prevesical space (cave of Retzius) and to perform suprapubic cystostomy. The treatment of the various conditions which give rise to deep extravasation of urine is considered in the appropriate sections.

INFLAMMATIONS

Ulceration of the Urethral Meatus

Ulceration of the meatus in young male children is a common clinical entity. It is never found in the uncircumcised. It is common after circumcision, though an interval of three to eighteen months may elapse between the operation and the onset of symptoms. Lack of protection given by the prepuce is the initial cause. Friction of the clothing and ammoniacal urine are important secondary ætiological factors. The ulcer causes a scab to form which closes the meatus, and the child can only urinate by bursting this scab. This process is usually accompanied by pain and

Henry Rutherfurd, 1861–1929. Surgeon, Royal Infirmary, Glasgow, Scotland.
Oscar Michel Benvenuto de Pezzer, 1853–1917. Assistant in the Urological Department, Necker Hospital, Paris.
Andreas Adolf Retzius, 1796–1860. Professor of Anatomy and Physiology, Carolina Institute, Stockholm.

screaming, and a few drops of blood may be passed. Ulceration and scab formation alternate, and if neglected, cicatrical contracture of the meatus may result eventually in an acquired pin-hole meatus.

Treatment.—A simple regimen of washing the napkins in boric acid crystals after boiling and applying 5% boracic ointment (or Drapolene) locally is usually curative. These measures neutralise the alkaline urine. A few cases require meatotomy (p. 1257).

Urethritis

Gonorrhœa

This venereal disease is caused by *Neisseria gonorrhœæ*—a Gram-negative kidney-shaped coccus occurring in pairs. In pus from early infections the cocci are easily found on Gram staining; large numbers may be seen inside the pus cells. In chronic cases, especially in females, the gonococci become scanty and secondary invaders multiply, so that microscopic diagnosis becomes difficult or impossible. Bacteriological diagnosis should therefore be confirmed by culture. Unfortunately, the culture technique is difficult, but if it is not done the diagnosis will be missed in many cases, especially in women.

The complement-fixation test is of value for confirming the diagnosis in chronic and systemic infections, e.g. arthritis, but is usually negative in patients treated by antibiotics early in the infection.

Acute Stage.—The disease manifests itself two to ten days after sexual intercourse with an infected partner. The early symptoms are itching and redness of the external urethral meatus, the lips of which are sticky. A viscid discharge appears, which soon becomes thick and yellowish. Anterior urethritis develops within a day or two, with the characteristic symptom of scalding pain on micturition. Acute retention is a very rare complication. Malaise and slight elevation of temperature are present during the acute stage, and the inguinal lymph nodes are sometimes tender. After ten to fourteen days acute symptoms abate, but the discharge persists.

Local complications.—*Anterior Urethritis.*—Folliculitis following infection of glands of Littré is a common complication. Balanitis is sometimes troublesome, and chordee (p. 1285) may result from inflammation of the corpus spongiosum or corpora cavernosa. Cowperitis occasionally occurs.

Posterior Urethritis.—This complication is liable to occur at any time, either from extension of the infection or ill-advised treatment, such as the passage of instruments. It is recognised by the frequency or urgency of micturition, with slight hæmaturia at the end of the act, aching in the perineum, painful erections and turbidity of a second specimen of urine after the first flow has washed out the anterior urethra.

Acute prostatitis (p. 1252).

Epididymitis usually causes pain in the groin or lower abdomen due to inflammation of the vas deferens and may cause sterility.

Basal cystitis is common and causes frequency and pain at the end of micturition.

Chronic prostatitis (p. 1252), with which is associated chronic vesiculitis, is a common cause of persistence of infection.

Strictures may occur (p. 1269).

Alexis Littré, 1658–1726. Surgeon and Anatomist, Paris.
William Cowper, 1666–1709. Surgeon and Anatomist, London.

'Gonorrhœal' warts occasionally occur on the glans or prepuce, and are due to an associated virus infection.

Metastatic Complications.—Infection of joints and fibrositis may occur in neglected cases. Endocarditis occurs as a rare complication, and is associated with pyæmic abscesses. Iridocyclitis sometimes occurs in chronic cases, and necessitates repeated instillation of atropine. Most cases respond favourably to cortisone.

Chronic or Latent Stage.—The discharge is often very inconsistent and may occur only after such events as undue exercise or alcoholic excess. Typically, a 'morning dewdrop' or 'gleet' appears, which is thick and whitish in colour. Massage of the prostate and vesicles and examination of any expressed fluid will probably reveal latent infection. Partial emptying of the bladder followed by prostatic massage and completion of the act is a valuable test for posterior urethritis and prostatitis. Any threads which appear should be examined bacteriologically.

Urethroscopic examination may reveal folliculitis, erosions, abscesses and other abnormalities, and also allows the application of local treatment.

Treatment.—Procaine penicillin is commonly given immediately the diagnosis is assured, and one injection of 600,000 units is usually curative. However, penicillin-resistant strains are increasing in number, and at one clinic, in spite of 600,000 units for five days, 20 per cent. of patients had positive smears or relapsed shortly after treatment. For patients who relapse or fail to be cured, an alternative drug should be used after the sensitivities of the strain of gonococcus have been ascertained. The patient is warned of the risks of conjunctivitis and transmission of infection, and he is kept under observation for 3 months, the blood being tested for syphilis, as penicillin may mask a syphilitic infection or prolong the incubation period.

Non-gonococcal urethritis has become a world problem; it is now nearly as common as gonorrhœa in the male. The incubation period is somewhat longer than that of gonorrhœa. The cause of this infection has yet to be discovered. An organism of the pleuro-pneumonia group has been incriminated, but at the present time this is considered not to be the cause, but an early symbiotic intruder. In most instances the infection is the result of coitus with a woman suffering from leucorrhœa and a cervical erosion, and whenever possible the female partner should be examined and treated, otherwise reinfection is probable. While in many cases organisms in the discharge are absent, in others, especially those of long standing, a profuse and varied flora is found. Undoubtedly most of these organisms are the result of secondary infection.

The symptoms are identical with those of gonorrhœa, and the diagnosis can only be established by failing to find the gonococcus after intensive investigation on several occasions.

Treatment.—Non-gonococcal urethritis is a self-limiting disease, which makes the results of treatment difficult to assess. Prebble has found that urethral irrigations with oxycyanide of mercury in a strength of 1 in 8,000 and the temperature of the irrigating fluid 40·5° C given once daily for three to seven days is successful in 85 per cent. of cases. In some quarters treatment by local irrigation is decried as old-fashioned, whereas treatment

Ernest Earlam Prebble, Contemporary. Formerly Venereologist, Liverpool Royal Infirmary, Liverpool, England.

exclusively by antibiotics (which are very costly but are less troublesome to administer) are in favour generally. Good results have been obtained by oxytetracycline and also spiramycin, given orally four times a day for five days (Willcox). Furacin urethral suppositories quickly render the patient asymptomatic, but on withholding the treatment early relapse is the rule. In most instances refractory cases are due to misdiagnosis, the most common being overlooking the presence of a urethral polypus or especially a trichomonas infection.

Urethritis due to *Trichomonas Vaginalis*.—Although infection due to *Trichomonas vaginalis* is regarded as a disease of women, there is increasing evidence of its occurrence in men as well; indeed, the carrier of the disease is often a male in whom the parasite causes no symptoms. In men, the small number of parasites present in the discharge, and the difficulty in finding them, accounts for the fact that infection with *Trichomonas vaginalis* is not widely recognised, and such infection is considered to be due to non-gonococcal urethritis. The type of discharge is in no way diagnostic: it is slight to moderate in amount, greyish in colour, and of a thin or mucoid nature. It is only by examining at once a specimen of the discharge as a 'hanging drop' preparation that this protozoon (fig. 1466) can be identified. *T. vaginalis* urethritis in the male often proves a most difficult infection to eradicate, the treatment being handicapped by the high rate of reinfection, which emphasises the necessity for treating the female partner as well as the male. The most promising results have followed treatment with metronidazole, 200 mg. by mouth t.d.s. for ten to fourteen days.

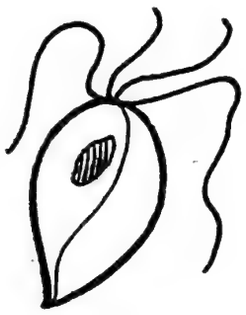

FIG. 1466.—*Trichomonas vaginalis.*

REITER'S DISEASE

The condition is venereal in origin and commences as a subacute urethritis four to six weeks after contact. The discharge is usually devoid of organisms, being clear and viscid. A few days later conjunctivitis occurs, at first unilateral, and then bilateral. Usually in ten days to two weeks arthritis supervenes (acute hydrarthrosis of at least one joint is present in every case). Another concurrent manifestation that often accompanies the onset of arthritis is keratoderma blennorrhagicum, consisting of nodules, vesicles, and pustules, frequently found on the soles of the feet (fig. 1467). Pleuro-pneumonia-like organisms have been isolated from the various lesions of this condition in approximately 30% of cases.

FIG. 1467.—Reiter's disease—keratoderma blennorrhagicum of the heel.

Differential Diagnosis.—In untreated gonorrhœa, arthritis and ophthalmic infection were not rare in the past. The absence of the gonococcus is of the highest importance in coming to the conclusion that the symptoms are due to Reiter's disease. In Reiter's disease the urethritis, as well as the arthritis, is milder and the incubation period is much longer than in gonorrhœa. Furthermore, never are the ocular manifestations of Reiter's disease so destructive as those of gonorrhœa.

Richard Robert Willcox, Contemporary. Venereologist, St. Mary's Hospital, London.
Hans Reiter, 1861–1969. President of the Health Service and Honorary Professor of Hygiene, Berlin. Described Reiter's Disease in 1916. The syndrome had been noted previously by Sir Benjamin Brodie.

Prognosis.—The urethritis and conjunctivitis frequently subside in a few weeks, but more often than not the arthritis persists for many months.

Treatment.—While the ophthalmic complications must be treated thoroughly following the usual lines (eye-baths and shades). Various antibiotics and fever therapy induced by graduated doses of triple typhoid vaccine (TAB) have been tried, the last being given for the arthritis. There is increasing interest in work which may implicate trachoma infection and its treatment in certain cases of non-specific urethritis.

URETHRAL STRICTURE

Congenital.

Traumatic — Bulbous. / Membranous.

Inflammatory — Post-gonorrhœal / Post-urethral chancre. / Tuberculous.

Instrumental — Indwelling catheter. / Following the passage of a large calibre endoscope, notably a resectoscope.

Post-operative — Prostatectomy. / Amputation of the penis.

Post-gonorrhœal stricture, which has become very much less common since the introduction of the antibiotic treatment of gonorrhœa, is situated most frequently (*a*) in the bulb (70 per cent.); (*b*) at the peno-scrotal junction; (*c*) in the distal part of the spongy urethra, in that order. The membranous and prostatic parts of the urethra are exempt.

Multiple strictures are relatively common. When there are two strictures, the deeper is the narrower; when there are three strictures, the deepest is the narrowest. If a stricture in the penile urethra has a very narrow orifice, there is seldom another stricture behind it.

Pathology.—Following inadequately treated gonorrhœa, infection persists in the periurethral glands, and spreads to the periglandular tissues, which become infiltrated with round cells and fibroblasts. Gradually the infiltrated periurethral tissues contract with the formation of scar tissue, localised thrombophlebitis of the corpus spongiosum playing a part in the more dense varieties. Whereas in the bulbous urethra the fibrosis is most in evidence in the roof, in the penile urethra it predominates in the floor. Most strictures develop during the first year after gonorrhœal infection, but they may not give rise to difficulty in micturition for ten to fifteen years.

Clinical Features.—In a stricture of large calibre the only symptoms are the occasional passage of flakes (desquamated epithelium) in the urine and a varying amount of urethral discharge (gleet), most in evidence in the early morning (the morning 'dew-drop'). Often these symptoms are neglected until the diminished calibre of the urethra causes considerable difficulty in micturition. In contradistinction to obstruction due to an enlarged prostate, the patient finds he must strain to empty the bladder. Another distinguishing feature is the patient's age. He is often considerably younger than the prostatic sufferer, or the symptoms date back to some time prior to the fiftieth year. The stream becomes progressively narrower, micturition is prolonged, and after it has seemingly ended dribbling occurs. This is due to urine trickling from the dilated urethra above the stricture. Increasing

frequency of micturition, at first during the day and then both by day and by night, is another common complaint, due either to incomplete emptying of the bladder at each act of micturition, or to cystitis, or to both. In long-standing cases it is often possible to palpate the stricture from without as an induration in the urethral floor. The evil effects of urethral obstruction upon the bladder, ureters, and kidneys are similar to those of prostatic obstruction (p. 1236). Untreated, sooner or later retention of urine supervenes. Sometimes acute retention sets in while the stricture is still of moderate calibre; it is then due to superadded œdema of the urethral mucous membrane in the neighbourhood of the stricture, brought about by voluntary retention, alcoholic excess, or recrudescence of local infection. In other cases narrowness of the stricture results in increasing inability to expel residual urine, and acute-on-chronic retention, or retention-with-overflow, supervenes.

Urethroscopy renders the diagnosis of urethral stricture very precise.

The stricture can be seen as a white scar of fibrous tissue, and its position in the urethra, the size of its contained lumen, and its dilatability can be judged (fig. 1468).

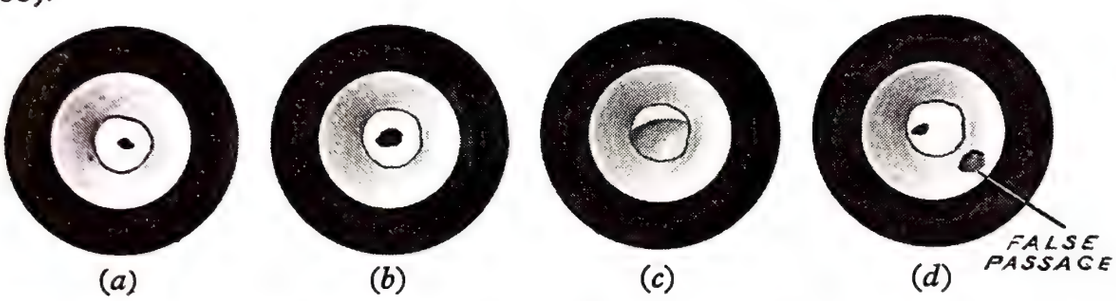

FIG. 1468.—Urethroscopic appearances. (*a*) Fine-bore stricture. (*b*) Moderate-bore stricture. (*c*) Crescentic stricture of the roof. (*d*) Stricture with false passage.

Often a stricture encircles the whole urethra, and the lumen is more or less centrally placed, but from time to time a variety of urethroscopic appearances is noted in individual cases; for instance, the stricture may take the form of a crescent.

False passages may be seen. They are recent penetrations of the urethra in front of the stricture due to unskilful attempts to pass a bougie. False passages are particularly liable to bleed, and it is essential to abandon æro-urethroscopy if urethral hæmorrhage occurs, for fatal air embolism has resulted from air being pumped into the cavernous tissue through a urethral wound.

FIG. 1469.—Urethrogram showing a stricture of the membranous urethra following fracture of the pelvis.

Urethrography (p. 1137) supplies information concerning the length of a stricture, of dilatation or diverticulum formation above the stricture, or failure of the medium to pass a stricture (figs. 1469 and 1470).

Instrumental Treatment.

Intermittent Dilatation.—In the majority of instances, provided the patient attends regularly, dilatation at suitable intervals is a satisfactory form of treatment. Before each dilatation the patient should pass urine, the glans

penis and urinary meatus are cleansed and the urethra is filled with a mild antiseptic solution, and local anæsthetic in a methyl cellulose base (Lidothesin). Dilatation must be carried out gently with bougies of increasing size.

On no account should the stricture be forcibly or over-dilated, both of which result in trauma that induces inflammatory œdema and subsequent formation of more fibrous tissue.

FIG. 1470.—Gonnorrhœal stricture of the bulbous urethra. Note that some contrast has entered the penile veins (p. 1137).

Strictures of very small calibre should be dilated twice a week at first. With this exception it is sufficient for the patient to attend for treatment at regular intervals, and an erstwhile reminder to the patient was that he must return for treatment 'once a week for a month, once a month for a year, and every year on his birthday'. A few strictures are cured by full dilatation, but in the majority the patients must be kept under supervision for the remainder of their lives.

Gum-elastic bougies (*syn.* French bougies) (fig. 1471) should be the standard instruments in the early stages of treatment of all but the very finest strictures. It is

FIG. 1471.—Gum-elastic bougie.

usual to commence with a No. 10 French, and if this cannot be passed, progressively smaller, or even filiform bougies are employed.

Filiform bougies are gum-elastic bougies varying in size from 1 to 3 French. If one fails to pass, it is often valuable to insert several as far as the stricture. By manipulating each back and forth, frequently one of them can be induced to negotiate the stricture (fig. 1472). If this method fails, it is sometimes possible to pass a filiform bougie through the stricture under the vision afforded by a urethroscope. If any bleeding has been occasioned by the attempt to pass bougies, urethroscopy should be postponed for several days. Very few urethral strictures are impassable, but it often requires patience to insinuate even the finest urethral guide: only when even a filiform bougie cannot be passed on three successive occasions is a stricture held to be impassable.

FIG. 1472.—'Faggot' method of introducing a bougie through a stricture.

Filiform Bougies with Followers.—Filiform bougies furnished with threaded hollow mounts at their proximal ends are to be preferred, because screw-ended gum-elastic bougies of a larger size can be attached and guided by the filiform through the stricture. In this way many strictures of very small calibre can be dilated sufficiently to render subsequent dilatations less tedious.

FIG. 1473.—Filiform bougie with follower.

By means of gum-elastic bougies a stricture is dilated up to the size of 14 French. Thereafter metal bougies are to be preferred.

FIG. 1474.—Lister's metal bougie.

Lister's metal bougies (*syn.* English bougies) (fig. 1474) are in-

Lord Lister, 1827–1912. Professor of Surgery successively at Glasgow, Edinburgh, and King's College Hospital, London. (*See footnote p. 1.*)

dicated after the second or third attendance of the patient, when it has been proved that the stricture is responding to dilatation by the French bougies. Metal bougies of a smaller size than 7/9 English should not be used, for fear of making a false passage.

Continuous dilatation necessitates some days of in-patient treatment, but it is of immense benefit in cases where little or very slow progress is made by intermittent dilatation. In a number of instances continuous dilatation obviates the necessity for operative treatment. After dilatation with gum-elastic bougies a catheter of corresponding size is tied into the urethra. On its removal two or three days later it will be found possible to pass much larger bougies.

Operative Treatment

1. External urethrotomy (Wheelhouse's operation) is the operation of choice when a patient presents with acute retention and the stricture proves impassable.

With the patient in the lithotomy position the Wheelhouse staff (fig. 1475) is passed down to the face of the stricture, and the urethra distal to the stricture opened by cutting down on to the groove in the staff. Stay sutures hold the edges open to display the face of the stricture. The mid-line incision is then carried backwards

FIG. 1475.—The Wheelhouse staff.

until the dilated proximal dilated urethra is opened. Urine will usually leak out under some pressure. A catheter is now passed from the external meatus across the opened urethra into the bladder, and the wound packed lightly. *Alternatively* the operation can be concluded formally as the first stage of a urethroplasty (see below) by stitching skin edge to mucosal edge.

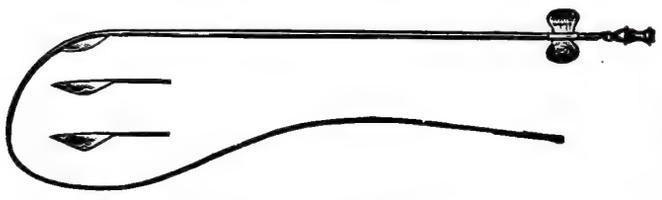

FIG. 1476.—Thomson-Walker's urethrotome.

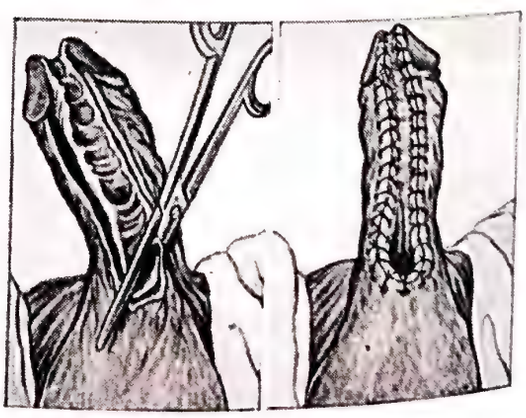
2. Internal urethrotomy is now a rare procedure. It may only be used if the stricture is passable. A triangular cutting knife (fig. 1476) runs in a grooved staff, which is guided through the stricture by a fine gum-elastic bougie. The stricture is divided by one sharp thrust of the knife on either side of the urethra. Intermittent dilatation by bougies should be commenced fourteen days later.

3. Urethroplasty.—Nowadays surgical cure by means of a two-stage urethroplasty is applicable to all strictures of the bulbar and penile portions, and is the treatment of choice.

Johanson's Urethroplasty.—The urethra is exposed by a mid-line incision in the skin overlying the stricture. A Wheelhouse staff as described above is used to open the normal urethra for 2 cm. distal to the stricture. The urethra is then cut clearly in the midline, through the stricture and 2 cm. into proximal normal urethra. The cut edges of skin and urethra are stitched to each other, leaving a defect in the urethra through which urine will be passed while the stricture contracts (fig. 1477). When the contraction is complete (3–4 months) the urethra can be reconstructed by employing the principle of the Denis Browne repair of hypospadias (p. 1259), or constructing a urethra from the



A B

FIG. 1477.—Johanson's urethroplasty. In this case much of the urethra was strictured from the meatus.

Claudius Galen Wheelhouse, 1826–1909. Surgeon, General Infirmary, Leeds, England.
Sir John William Thomson-Walker, 1870–1937. Surgeon, St. Peter's Hospital for Stone, London.
Bengt Johanson, Contemporary. Associate Professor of Plastic Surgery, Gothenburg, Sweden.

adjacent skin (fig. 1478). The skin outside the incision is mobilised to close in front of the reconstructed urethra, but a dorsal relieving incision may be necessary.

Where the stricture is in the bulb the first stage is similar. The urethral floor is divided up to and into normal urethra. In many cases this entails splitting the urethra through the external sphincter up into the wide prostatic urethra. In order to stitch skin between the edges, either a perineal skin flap has to be constructed at the time of skin incision (Blandy), or a scrotal funnel (Turner-Warwick) displaced backwards to be sutured to the open edges of the urethral defect (fig. 1479). Second stage closure is simple, a complete tube being reconstructed. A small catheter should be left in the urethra after these operations for 5 days.

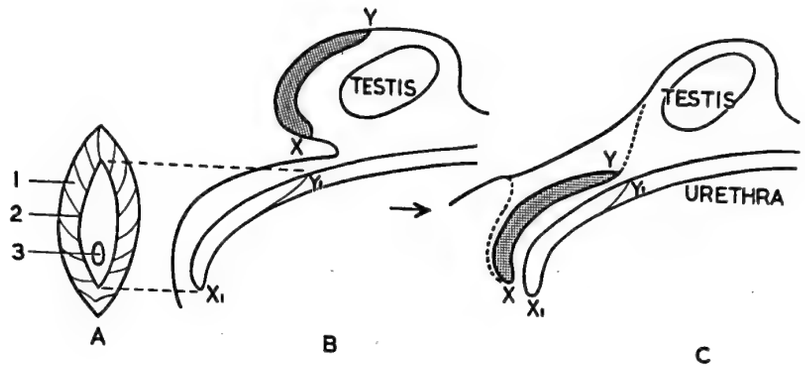


FIG. 1478.—Urethroplasty for the posterior part of the bulb using a funnel of scrotal skin.

Other Causes of Urethral Stricture

Congenital stricture has been considered on p. 1257.

Traumatic stricture follows unskilful or delayed treatment of rupture of the urethra. If dilatation is unsatisfactory, a urethroplasty should be done.

The so-called stricture following neglected or untreated rupture of the membranous urethra is often not a stricture at all, but a complete loss of continuity of the urethra (fig. 1459). If, as frequently occurs, it proves impossible to keep a passage dilated by the usual methods, the only alternative to transplantation of the ureters is Badenoch's pull-through operation. After the bladder has been opened suprapubically, with the patient in the lithotomy position, a metal sound is passed up the urethra and when arrested by the stricture its tip is cut down upon in the perineum. The distal urethra is then freed as a tube for 4 to 6 cm. A large metal sound is passed suprapubically down the urethra and cut down upon from the perineum until it can be forced through the area of fibrosis. A rubber catheter is attached to it by the butt end and pulled back through the suprapubic opening. The freed distal urethra is threaded over the lower end of the catheter and its end stitched to the catheter

John Peter Blandy, Contemporary. Professor of Urology, London Hospital Medical College.
Richard Trevor Turner-Warwick, Contemporary. Urologist, The Middlesex Hospital, London.
Alec William Badenoch, Contemporary. Consulting Surgeon, St. Bartholomew's Hospital, London.

some 10 cm. from its tip with interrupted chromic catgut stitches. Traction on the catheter then guides the distal urethra into the prostatic urethra where it is held by attaching an artery forceps to the catheter as it emerges on to the abdominal wall (fig. 1480). Finally, the perineum is closed and suprapubic cystostomy temporarily established.

FIG. 1480.—Badenoch's pull-through operation completed.

Post-instrumental stricture can occur in any part of the urethra from trauma due to the passage of too large an endoscope, or from urethritis from an indwelling catheter. To avoid the former, some surgeons advise performing perineal urethrostomy in order to pass a resectoscope in patients with a narrow urethra.

Post-operative Stricture.—A stricture develops in about 4 per cent. of cases after prostatectomy, irrespective of the method employed. The stricture is usually situated in the proximal end of the prostatic urethra. In many cases the stricture can be dilated by regular intermittent dilatation. When the stricture takes the form of a shelf at the junction of the bladder with the prostatic bed, the bladder must be opened and the shelf excised.

Post-operative stricture can also follow partial or complete amputation of the penis. Methods of avoiding this complication are described in the section dealing with these operations (p. 1288). Regular dilatation is satisfactory.

Complications of Urethral Stricture

1. Retention of urine (p. 1198).
2. Urethral diverticulum.
3. Periurethral abscess.
4. Urethral fistula.
5. All the attendant evils of 'back pressure', culminating in bilateral hydronephrosis, combined with a susceptibility to urinary infection and an increased liability to urinary calculus.
6. Hernia, hæmorrhoids, or rectal prolapse may be induced by the straining.

Diverticulum of the male urethra (*syn.* urethral pouch)

1. Congenital.
2. Due to increased intraurethral pressure behind a stricture.
3. Due to the long-standing presence of a urethral calculus.
4. Indwelling catheters in paraplegics.

In many cases the pouch can be seen and those which are not obvious at first become so when the patient interrupts the stream of urine.

Treatment is excision of the diverticulum and removal of the cause if possible.

PERIURETHRAL ABSCESS

There are two main varieties of acute abscess:

Penile periurethral abscess arises as an infection of one of the glands of Littré, and is usually a complication of acute gonococcal urethritis. A tender induration can be felt on the under-surface of the penis (fig. 1481). Left to nature, frequently the abscess bursts externally, and a urinary fistula is liable to result.

Treatment.—The passage of a bougie often causes the abscess to burst into the urethra. When this is unsuccessful, a ureteric meatotome is passed

FIG. 1481.—Common situations of a periurethral abscess. (*After F. Papin.*)

through a urethroscope and the abscess is opened by diathermy. When an abscess lies behind a stricture of the urethra it must be drained externally.

Bulbar periurethral abscess runs a variable course. Its most acute form, formerly termed periurethral abscess with extravasation of urine, is better termed periurethral phlegmon, because in 50% of cases there is no stricture of the urethra present. Of the remainder, the majority have a passable stricture, while in the minority the stricture is impermeable. Consequently, in the majority of cases there is no reason why urine should extravasate. The condition is due to a spreading cellulitis caused by streptococci and anaërobic organisms invading the same cellular plane as that of superficial extravasation of urine (p. 1264).

Clinical Features.—There is pain in the perineum, a high temperature, repeated rigors, and a rapid pulse-rate. In early cases the tenderness and swelling are limited to the perineum. Later, often in a matter of hours, the scrotum and then the penis becomes œdematous, and the infection spreads beneath the superficial fascia of the abdominal wall.

Treatment.—Antibiotics have greatly improved the prognosis.

Operation.—The perineal abscess should be opened. In addition, if spreading cellulitis is present, incisions deep enough to divide the superficial fascia are made into the infiltrated scrotum, penis, and abdominal wall, wherever considered necessary. When there is partial or complete retention of urine and if the infection is limited to the scrotum and the penis, after changing gloves and instruments, suprapubic cystostomy should be performed. If the superficial layer of the abdominal wall is implicated, it is best to drain the bladder by performing perineal urethrostomy. It should be noted that the abscess usually communicates with the urethra by a minute opening which cannot be found.

After-treatment.—After instilling hydrogen peroxide into them, the various incisions are irrigated with weak potassium permanganate solution. Later sitz baths[1] of the same solution are given. When the infection has been overcome, the stricture of the urethra, if present, is treated by one of the methods described already.

Chronic periurethral abscess is nearly always situated in the perineum (fig. 1482) and is associated with much periurethritis. It is almost invariably the result of a long-standing stricture of the bulbous urethra. The abscess should be opened, together with the various pockets that are often present. Later the associated stricture must receive adequate treatment. The condition is liable to be complicated by a urethral fistula which occurs either spontaneously or as a result of incision of the abscess.

FIG. 1482.—Chronic periurethral abscess.

URETHRAL FISTULA (p. 1213)

The most frequent cause of an acquired external urethral fistula is bursting or incision of a periurethral abscess. When the opening is situated in the penile urethra or at the peno-scrotal junction, the amount of urine that escapes at each act of micturition is

[1] Sitz bath = in which the patient sits in a bath-tub, bathing only the hips and the buttocks.

often small. A fistula following a periurethral abscess of the bulbous urethra can be either single or multiple. In the latter case the fistulæ originate behind a tight stricture and the patient passes most or all of his urine through the various fistulæ (watering-can perineum). A fistula can also follow external urethrotomy when there is a stricture situated more distally.

Treatment.—A small fistula often closes spontaneously after repeated dilatation of the urethra. Searing the track with the diathermy needle often encourages closure. Occasionally urethroplasty (p. 1272) is indicated.

URETHRAL CALCULUS

Calculi occur less frequently in the urethra than in any other part of the urinary tract. A urethral calculus can arise primarily in the urethra behind a stricture or in an infected urethral diverticulum. The latter are composed of phosphates. Less rarely a calculus which has migrated from the ureter becomes arrested in the prostatic, bulbous, or penile portions of the urethra. Migratory calculi are arrested in the urethra relatively frequently in children under the age of two, the explanation being that the comparatively large vesical neck allows them to pass out of the bladder.

Clinical Features.—In the case of a migratory calculus arrested in the urethra, typically there is a history of an attack of ureteric colic two or three days previously. During micturition the patient experiences sudden pain in the urethra and the stream of urine ceases abruptly. A few drops of blood-stained urine follow, and then there is retention of urine. A stone can be palpated readily through the floor of the urethra. When the stone has been arrested in the prostatic urethra a rectal examination usually reveals a tender, hard nodule in the middle line of the prostate, generally near its apex. A calculus forming behind a urethral stricture often does so without causing much additional discomfort and it sometimes attains a considerable size before giving rise to retention of urine or painful dysuria. In some cases such a stone can be felt easily; in others, owing to periurethral thickening, its presence is not suspected until it is seen at urethroscopy, or a grating sensation is experienced on passing a gum-elastic bougie or a characteristic click is heard if a metal bougie has been employed. In all but superficially placed calculi giving rise to acute symptoms, radiography is necessary to confirm the presence, and particularly to reveal the size of the calculus (fig. 1483) before commencing treatment.

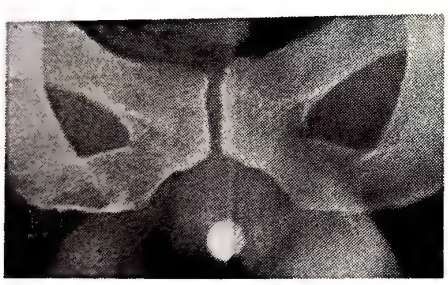

FIG. 1483.—Radiograph showing calculus impacted in the bulbous urethra.

Treatment:

(1) *Prostatic Urethra.*—When the stone is arrested in the prostatic urethra a general anæsthetic is given, and a metal bougie is inserted along the urethra as far as the calculus. In cases of recent impaction the stone can be pushed into the bladder, where it can be crushed by litholapaxy and the fragments evacuated. In cases of long-standing the stone is hour-glass shaped, and impacted firmly, in which event it is best approached through the bladder.

(2) *Membranous* and (3) *Bulbous Urethra.*—Occasionally a small stone can be removed from the deeper parts of the urethra by means of urethral forceps passed through a urethroscope. On no account must aero-urethroscopy be employed (danger of air embolism if bleeding occurs). A stone impacted in the proximal urethra sometimes can be manipulated forward if the urethra is distended with lotion. Another method is to pass a number of filiform bougies beyond the stone, twist them, and endeavour to dislodge the calculus by pulling all the bougies out together. A stone impacted in the fossa navicularis, or manipulated into this position, sometimes can be removed by urethral forceps, or by inserting a probe behind it.

Operative Measures (situations 2 and 3).—Meatotomy is often required to permit the stone to be withdrawn. When a stone cannot be removed by one of the expedients described above, an incision is made through the floor of the urethra on to the stone (external urethrotomy). After the stone has been extracted, in the absence of a stricture and gross infection, the urethra can be closed in layers.

NEOPLASMS OF THE MALE URETHRA

Polypi are usually multiple and occur most frequently in the region of the verumontanum. As seen at urethroscopy, each polypus is a pale, finger-like projection (fig. 1484) with blood-vessels coursing over it. Polypi are never found without chronic infection. Sometimes, if the infection can be cured, the polypi disappear: conversely, if polypi are destroyed, chronic urethritis, which previously resisted treatment, often responds to it. Possibly this condition should be classified as a granuloma.

Papilloma.—From time to time a solitary papilloma occurs, most often within the fossa navicularis and, as it enlarges, it protrudes from the external urinary meatus.

Multiple papillomas associated with penile papillomas (p. 1285) sometimes arise from mucous membrane just within the external urinary meatus.

Papillomatosis of the urethra is most often associated with papillomas of the bladder—the posterior urethra is considerably more often affected than the anterior urethra.

The typical symptom of papilloma of the urethra is slight hæmaturia immediately preceding micturition.

FIG. 1484.—Polypi in a male posterior urethra. They occur also in the posterior urethra of females.

Angioma is rare. The hæmaturia to which it gives rise is often profuse, and may occur independently of micturition.

Treatment of all the foregoing neoplasms is diathermy coagulation through a urethroscope. Exceptionally the neoplasm is so accessible that it can be fulgurated without employing a urethroscope.

Carcinoma is rare. Usually a urethral stricture is antecedent to the carcinoma. Spread to the inguinal lymph nodes often occurs. Blood-borne distant metastases are uncommon unless the cavernous tissue of the penis becomes implicated.

Clinical Features.—As a rule, the first and only symptom is a profuse urethral discharge. Carcinoma of the urethra is therefore one of the many causes of ' urethritis'. Later, the discharge becomes blood-stained and the symptoms of stricture of the urethra supervene. The chronic nature of the condition in a man past forty years of age, the presence of blood in the discharge or in the urine, a tendency to bleed easily during instrumentation, and above all palpable induration, are factors that lead to a suspicion of carcinoma. In the deeper parts of the urethra, sometimes the first manifestation is an indolent periurethral abscess that after incision not only fails to heal, but the periurethal induration increases.

Biopsy then establishes the diagnosis.

Treatment.—When the growth is in the anterior part of the penile urethra partial amputation of the penis can be carried out, and provided the growth has been diagnosed reasonably early, long survival can be expected. Complete amputation with the construction of a perineal meatus is required when the neoplasm is situated more posteriorly.

When the carcinoma is situated further back a still more extensive operation, which includes radical prostatectomy, is the only hope of eradicating the disease.

THE FEMALE URETHRA

Urethritis.—As in the male, acute urethritis can be due to gonorrhœa or to non-gonococcal urethritis. Likewise chronic urethritis may or may not be due to gonorrhœa, and in its severe forms is a urethro-trigonitis. The symptoms are increased frequency, pain on micturition, urgency, terminal hæmaturia, and low back pain. Urethral tenderness is an important sign of infection of Skene's tubules. Pressure on the urethra causes pus to exude from the orifices of the ducts surrounding the urethral opening. Incomplete cure of the infection in these tubules is a source of chronicity in anterior urethritis. In cases of posterior urethritis, urethral polypi are often present and can be seen on urethroscopy.

Alexander Johnston Chalmers Skene, 1838–1900. Professor of Gynæcology, Long Island College Hospital, New York.

Gonorrhœa in the Female

The early symptoms are much less pronounced than in the male. Infection usually commences in the urethra or cervix, and Bartholin's glands are infected in 2% of cases. The symptoms of acute infection include a sensation of heat and discomfort of the vulva and pain on micturition, but in about 30% of cases symptoms are negligible. Should the cervix become infected, a blood-stained discharge is noticed and backache follows.

Complications.—Vaginitis is common in children who are accidentally infected, but adults usually escape. Cervicitis sometimes occurs spontaneously, or is encouraged by unwise instrumentation. Salpingitis, which may be accompanied by oöphoritis or peritonitis, is a dreaded complication which is apt to cause sterility. Proctitis often occurs, and is commoner than in males owing to the greater ease of infection.

Local Complications.—Chronic endometritis occasionally occurs, and results in menorrhagia, metrorrhagia and mild dysmenorrhœa, associated with backache. Salpingitis is often quiescent, but exacerbations are liable to follow sexual excess, debility or labour. Warts are not uncommon and are sometimes large and numerous.

Chronic or Latent Stage.—Chronic gonorrhœa occurs as urethritis, cervicitis, or Bartholinitis, and any discharge from these organs must be meticulously examined. The symptoms accruing from chronic infection are very slight and the patient may merely notice an occasional yellowish discharge.

Ophthalmia Neonatorum.—Infection by the gonococcus at birth is an important cause of blindness. The incubation period is twenty-four to forty-eight hours, and is followed by chemosis, lacrymation and purulent discharge. Corneal ulceration and sloughing may follow in neglected cases. If infection occurs, the eye must be irrigated with penicillin (10,000 units in 1 ml.) at frequent intervals, and intramuscular penicillin is administered. (See also trachoma comment, p. 1269).

Treatment.—In addition to appropriate antibiotic treatment (p. 1267), local treatment is necessary. In cases of non-gonococcal urethritis Furacin urethral suppositories are sometimes beneficial. Intermittent dilatation of the urethra, by promoting drainage of infected foci within the urethra, often helps to eradicate the infection. If polypi are present, the condition is seldom remedied unless they are removed by fulguration. Swabbing the urethra with 10% solution of silver nitrate is also helpful. Excision of the distal 1 cm. of the urethral mucous membrane is the best method of curing chronic infection proved to be due to infection of Skene's tubules.

***T. Vaginalis* Urethritis.**—About 12% of women, one-third of whom are unmarried, suffer from *T. vaginalis* vaginitis. In a large percentage of cases *Trichomonas vaginalis* infection must be regarded as a venereal disease; the way in which the remaining patients become infected is speculative. Lavatory seats are often blamed, and their culpability is almost impossible to disprove for *T. vaginalis* can survive thereon for forty-five minutes (Whittington). On the other hand, the fact that virgins are never infected with this protozoon adds to the scepticism with which this explanation is received. Trichomal vaginitis is complicated by urethritis in many instances. This form of urethritis responds to metronidazole (p. 1268), but the vaginitis must be treated also.

Caspar Bartholin, 1655–1738. Professor of Medicine, Anatomy and Physics, Copenhagen.
Margaret Joan Whittington, Contemporary. Biologist, Whitechapel Venereal Clinic, The London Hospital.

Senile urethritis is an atrophic lesion due to deficiency in endogenous ovarian hormone. Suppositories containing diethylstilbœstrol 0·1 mg. in a topical anæsthetic agent are extremely effective.

Prolapse of the Urethra.—Prolapse of the posterior margin of the urethra occurs in many women past the menopause, and is symptomless unless it is associated with senile urethritis when, on account of straining on micturition, the condition is progressive. Prolapse of the urethral mucous membrane occurs also as a congenital condition. When half or more of the circumference prolapses the local discomfort, especially on walking, is proportionate to the degree of the prolapse. The urinary meatus is examined while the patient strains: when the prolapse is complete the opening of the urethra is central; when it is partial, the opening is eccentric.

Treatment.—The associated urethritis, if present, must be treated first. Often lesser degrees of prolapse can be cured by making one or more linear grooves in the long axis of the mucous membrane of the urethra with a diathermy needle, employing the coagulating current. Subsequent contraction of the scar reduces or obliterates the prolapse. More advanced cases are treated by transfixing the whole thickness of the prolapse as far from its extremity as possible with four catgut sutures placed at equidistant intervals. Redundant urethral mucous membrane is excised distal to the sutures, which prevent retraction of the stump into the canal. The cut edges of the mucous membrane are then united.

Urethral Stricture.—An adult female urethra which fails to admit freely a No. 20 French bougie is the seat of a urethral stricture.

The causes are (*a*) urethritis, not necessarily gonococcal, and (*b*) trauma as the result of difficult labour. Inflammatory stricture is situated at the external meatus; traumatic stricture usually affects the middle or posterior part of the urethra.

Sometimes the stricture will only admit a guide, and in these cases acute retention of urine is particularly prone to occur. Dilatation of the stricture yields satisfactory results. The recognition and treatment of a stricture often clears up an obscure case of pain on micturition.

Urethral diverticulum (*syn.* urethrocele) is more common in women than in men. Arguments favour a congenital origin in one of Gärtner's ducts[1], but some diverticula are acquired by (*a*) rupture of a distended urethral gland or (*b*) injury of the urethra during parturition. A small uninfected pouch may be symptomless. As the diverticulum enlarges, inability to pass all the urine at one time, or dribbling after micturition, occurs. Once infected—and infection is almost inevitable if the diverticulum is not evacuated completely at each micturition—recurrent attacks of cystitis perpetuated by reinfection from the diverticulum continue in spite of antibiotics and chemotherapy. On digital examination a swelling can be felt on the anterior vaginal wall in the line of the urethra, and when it is compressed, urine, usually obviously purulent, is expressed. If the beak of a curved metal bougie is passed gently along the floor of the urethra, from time to time the orifice of the diverticulum is large enough for the beak to enter the sac. In 10% of cases a stone forms in the diverticulum, and hæmaturia may then occur.

Treatment.—The simplest method is to open the diverticulum through an incision in the vaginal wall. After irrigating the interior of the diverticulum, the mucous membrane is curetted, and the cavity is packed lightly with Oxycel. The incision in the diverticulum and vaginal wall is then closed by interrupted catgut sutures. An indwelling catheter remains in place for a week. It is presumed that fibrosis obliterates the sac (Lane). This procedure is so often successful that formal excision is seldom required, and is reserved for diverticula with wide mouths.

Calculus impacted in the female urethra is exceptional. When it occurs it can be removed by grasping it with forceps while a finger on the anterior vaginal wall presses it forward.

Urethral caruncle is common in middle-aged and elderly women. The condition presents as a soft, raspberry-like, pedunculated, granulomatous mass about the size of a pea, attached to the posterior urethral wall near the external urinary meatus. Histologically it is composed of highly vascular connective tissue stroma infiltrated with polymorphonuclear leucocytes and covered by squamous epithelium.

---

[1] The unobliterated distal end of the mesonephric duct.

Hermann Treschow Gärtner, 1785–1827. Surgeon and Anatomist, Copenhagen.
Daniel Francis Victor Lane, Contemporary. Surgeon, Meath Hospital, Dublin.

Clinical Features.—There is increased frequency of micturition, and often great pain during and after micturition. Terminal hæmaturia often occurs, and there may be a blood-stained discharge independent of micturition. The condition can be diagnosed on inspection, although it must be differentiated from prolapse of the mucous membrane. With a probe it can be determined that the protrusion arises from a pedicle attached to the posterior urethral wall. The mass is exquisitely tender and bleeds readily.

Treatment.—The pedicle should be divided flush with the floor of the urethra with a diathermy needle, using a cutting current, after which that portion of the urethra from which the pedicle arose is coagulated with the diathermy current. The chronic urethritis with which the condition is always associated should be treated by Furacin suppositories and intermittent urethral dilatation until the patient is symptom-free.

Papillomas acuminata occur on the external urinary meatus, and spread on to the labia minora. They differ in no respect from, are acquired in the same way as, and the treatment is similar to that of, papillomas acuminata of the penis (p. 1285). In female Africans papillomas acuminata are common, and they increase at an alarming rate during pregnancy. Towards term, so great does the neoplastic mass become that it may obstruct labour and necessitate Cæsarean section (Bowesman).

Carcinoma of the urethra occurs twice as frequently in the female as in the male. Whether or not a caruncle can become malignant is disputed, but a visible bleeding protrusion is the commonest manifestation of a carcinoma of the urethra, and the most common site of the carcinoma in its early stages is the external urinary meatus. A carcinoma commencing within the urethra gives rise to dysuria, hæmaturia, and sometimes retention of urine. Usually induration distinguishes it from an innocent tumour.

Treatment.—Interstitial irradiation by gold grains or radium needles is the method of choice. If this fails to cure the condition, the advanced state of the disease necessitates total urethro-cystectomy.

THE PENIS

PHIMOSIS

While the condition can be acquired as a result of chronic or acute inflammation of the lining of the prepuce, usually it is due to congenital narrowing of the preputial orifice, often associated with an unduly long foreskin. In extreme examples of congenital phimosis, when the patient micturates the prepuce balloons out first, and a thin, weak stream of urine follows. Difficulty of micturition, with residual urine, hydroureters, and hydronephroses are rarely due to phimosis, but more often occur as a result of atresia meati which may lie hidden by the phimosis. The treatment is circumcision.

Circumcision[1]

Indications.—(*a*) *In infants and young boys*, because of a request by the parents (religious and personal); because of recurrent balanitis with inability to retract the prepuce; and, rarely, because of a very long prepuce. Except for the ritual operation most circumcisions are unnecessary: it is normal for the prepuce to be long and adherent to the glans within, for these parts become satisfactorily separated and the prepuce mobile in the first few years of life. Recurrent balanoposthitis and phimosis often follow attempts by the parents forcibly to retract the prepuce. (*b*) *In adults*, because of inability to retract for intercourse, a tight frenum, balanitis, and sometimes prior to radiotherapy for carcinoma a dorsal slit may suffice.

[1] Apparently circumcision did not originate among the Jews: they took the custom from either the Babylonians or the Negroes, probably the latter. It has been practised in West Africa for over 5,000 years.

Charles Bowesman, Contemporary. Formerly Surgical Specialist, Colonial Medical Service, Kumasi, Ghana.

Technique in an Infant.—The parts are washed with soap and water, and painted with a non-irritating antiseptic. If it is not possible to retract the prepuce, the preputial orifice should be stretched with a hæmostat in order that the post-coronal sulcus can be cleansed of contained smegma. A pair of sinus forceps or, better still, bone forceps, is applied obliquely to the prepuce, parallel to the corona, just beyond the tip of the penis (fig. 1485), and the skin distal to the forceps is excised with scissors close to the forceps, which are then removed. The outer layer of the preputial skin retracts, leaving the glans covered by the inner layer, which is divided in the middle line anteriorly by introducing a blade of delicate scissors between it and the glans. Each leaf of the deep layer of skin (formerly called the mucosa) is excised, leaving a narrow collar around the corona. The frænal artery usually requires ligation (fig. 1486), as well as several small vessels on the dorsum. The cut edges of the deep and superficial layers are approximated with fine catgut sutures. A wisp of cottonwool soaked in tinct. benzoin co. makes an excellent waterproof dressing, which becomes detached when the patient is sat in a bath six days later.

FIG. 1485.—Applying sinus forceps preparatory to excising the redundant skin.

FIG. 1486.—The 'four-in-one' frænal stitch.

In adolescents and adults the following method is preferable. The prepuce is retracted until its tense orifice is apparent, or until the tip of the glans comes into view, and on to the edge of the prepuce are placed three hæmostats, one in the middle line ventrally and two on either side of the middle line dorsally. The prepuce is then slit up in the middle line dorsally to within 1·25 cm. of the corona. The undersurface of the prepuce having been completely separated from the glans and the corona, the layers of each flap are excised, keeping 1·25 cm. distal to the corona. The superficial layer is retracted and bleeding-points are secured and ligated. The inner layer of the prepuce having been trimmed to 3 mm. from the corona, the two cut edges

FIG. 1487.—Method of circumcision in an adult described in the text.

are approximated accurately with fine interrupted catgut stitches (fig. 1487). The cut edges in the immediate vicinity of the frænum can be drawn together neatly by a mattress suture. It is best dressed by wrapping a thin layer of wool round and painting this with Tinct. Benz. Co. (Friar's Balsam).

PREPUTIAL CALCULI

Late in life, chronic posthitis (p. 1282) resulting in fibrosis constricts an already inadequate orifice of a preputial sac. When the prepuce has not been retracted nor its interior cleansed for many years, preputial calculi are wont to form. Three types are described: 1. Those resulting from inspissated smegma. 2. Those consisting of a mixture of smegma and urinary salts. 3. Those consisting entirely of urinary salts. The treatment is circumcision.

PARAPHIMOSIS

The tight prepuce has been retracted but cannot be returned, and it is constricting the glans which is engorged and œdematous. The diagnosis is apparent at a glance.

Treatment.—One ml. of normal saline containing 150 turbidity units of hyaluronidase is injected into each lateral aspect of the swollen ring of prepuce. Fifteen minutes later the swelling is much reduced, and in early cases reduction (fig. 1488) can be accomplished with ease. If this is unsuccessful, a general anæsthetic must be given and the constricting band is incised, and the narrow cuff of skin which formed the constricting band excised (fig. 1489). There is now no obstruction tor eduction, and there remains only to remove a broad cuff of normal skin on the proximal side of the gap and unite the cut free edges, thus performing circumcision.

FIG. 1488.—Reducing a paraphimosis.

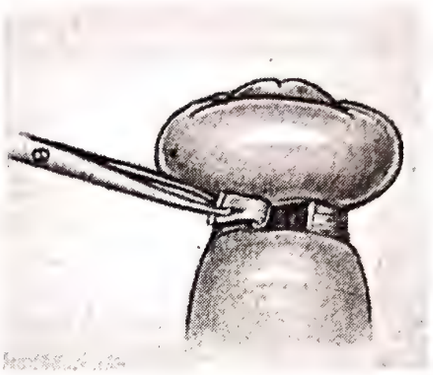

FIG. 1489.—Excising the constricting band.

FIG. 1490.—Covering the denuded shaft of the penis by burying it in a scrotal tunnel.

INJURIES

Avulsion of the Skin of the Penis.—Entanglement of clothing in rotating machinery accounts for the majority of these injuries. Repair can be carried out by burying the shaft of the penis in the scrotum (fig. 1490), with subsequent surgical release at a propitious time.

Fracture of the penis is a very uncommon accident due, most often, to the erect organ being bent forcibly downwards. Following trauma, the erect organ suddenly becomes flaccid. The extravasation of blood, which is considerable, causes great pain and swelling. In early cases incision, clearing out blood-clot, and suture of the ruptured corpus cavernosum has yielded good results.

STRANGULATION OF THE PENIS BY RINGS

Removal is prevented by venous engorgement. Consequently aspiration of the corpora cavernosa may assist in removal of the ring in early cases, otherwise a ring cutter or a hacksaw must be employed. If a tight ring is not removed within six hours, unless the bladder is drained suprapubically, or perineal urethrostomy performed, rupture of the urethra with extravasation may ensue.

INFLAMMATIONS

Balanoposthitis.—An inflammation of the prepuce is known as posthitis; an inflammation of the glans penis is called balanitis. Frequently the opposing surfaces of the prepuce and the glans are implicated in the inflammatory process—hence the term balanoposthitis.

N.B.—It is imperative to bear in mind that cancer, chancre, or sugar in the urine may be the primary factor, and that the condition is nearly always associated with some degree of phimosis (fig. 40). In mild cases the only symptom is itching and some discharge. Acute cases show a red, swollen and tender foreskin with exuding pus. Monilial (candida) infections are quite common.

Treatment.—A dorsal slit of the prepuce is often essential to promote drainage, but it should be delayed twelve hours while a broad-spectrum antibiotic is given. Local cleaning can then be effective. A formal circumcision may be necessary later.

HARD CHANCRE (*syn.* HUNTERIAN CHANCRE)

Hunterian chancre is described on p. 40, and soft chancre on p. 44.

PENILE HERPES

This is an uncommon infection which is due to a virus and occurs on the glans and the prepuce. Rarely is it seen in the vesicular phase because the vesicles rupture early. The resulting erosions are superficial, red, and frequently take the form of multiple circular lesions encroaching upon one another, which is characteristic. Unlike other conditions from which it must be differentiated, penile herpes is painful and tender. The diagnosis can be confirmed by inoculating embryo chicks with some of the exudate. The cervix of the patient's female partner should also be examined.

LYMPHOGRANULOMA INGUINALE (*syn.* LYMPHOGRANULOMA VENEREUM)

Although predominantly a tropical venereal disease, lymphogranuloma inguinale is not rare in temperate climates where there is a mixed population of white and negro races. The condition is encountered in England mainly in seafarers whose ships have come from afar. The infection is caused by a filtrable virus of the psittacosis-lymphogranuloma inguinale group. It is transmitted by sexual intercourse, but accidental infection has occurred (e.g. in surgeons operating on infected patients).

The Primary Lesion.—Because the symptoms are so slight, rarely does the patient present with the primary lesion, but a careful history unfolds the occurrence of a primary sore on the genitals in about 25 per cent. of cases. The sore takes the form of fleeting, painless, herpetic vesicles. Exceptionally it is within the anterior urethra, when it constitutes one of the many causes of non-gonococcal urethritis.

The Secondary Lesion.—Almost invariably the patient presents only when the secondary lesion has appeared, i.e. two to six weeks after exposure to infection. Constitutional symptoms are generally absent, although in white people pyrexia and anæmia are sometimes in evidence. The secondary local lesion is as follows :

In the Male.—A lymph node in one groin or both groins enlarges, usually in the medial part of the groin. The infection spreads to other nodes and palpable enlargement of the iliac lymph nodes is also found in some cases. Soon periadenitis occurs, and a brawny mass presents, increases in size, and the overlying skin (in white races) becomes purple. Untreated, the mass proceeds to liquefy. Unless treated by aspiration, the mass breaks down and discharges thick yellowish-white pus free from organisms. The resulting sinus or sinuses persist for months or years. An occasional aftermath is lymphatic obstruction, resulting in elephantiasis of the scrotum and penis. With this exception, complications are rare in the male, and consist of transient joint effusions. Should the rectum be affected (cf. the female), homosexuality is implied.

In the Female.—If the primary lesion lies in the anterior part of the vulva,

John Hunter, 1728–1793. Surgeon, St. George's Hospital, London. He bequeathed 13,682 specimens, prepared and mounted by his own hands. Many were destroyed by enemy action in 1941, but the remainder now form part of the Hunterian Museum of the Royal College of Surgeons of England.

an inguinal bubo follows, as in the male. When, as is much more usual, the primary lesion is on the vaginal wall or cervix, œdematous thickening of the posterior vaginal wall occurs and it is not long before the para-rectal lymph nodes enlarge and suppurate. As a result of this intense para-rectal inflammation, dense fibrosis of the rectal wall follows with the formation of a stricture of the rectum (p. 1082). Elephantiasis of the vulva sometimes develops in chronic cases (Esthiomene). Ischiorectal abscess and recto-vaginal fistula are not infrequent complications, and perianal polypus can occur.

Confirmatory Tests:

1. **The Frei Test**[1].—The original Frei antigen consisted of bacteriologically sterile pus obtained from an unruptured bubo of a patient suffering from the disease. This is more reliable than the now frequently employed lygranum, which is an extract of the content of yolk sacs of embryo chicks infected with the virus. 0·05 or 0·1 ml. of either of these is injected intradermally. A positive reaction appears within forty-eight hours, and is a red papule of at least 6 mm. in diameter. The control site should be unchanged.
2. **The complement fixation test**[1] is more sensitive than the foregoing, and has the merit of giving a positive result earlier in the course of the disease.
3. **Biopsy** is occasionally necessary to differentiate other diseases of lymph nodes.

Treatment.—The disease responds both to sulphonamides and to several antibiotics. Many patients derive more benefit when two different drugs are exhibited successively than from any single drug.

(*a*) A course of sulphadimidine, 1 g four times a day for ten days, to be followed by

(*b*) A course of oxytetracyline, 250 mg. six-hourly for a similar period, in patients who respond poorly or incompletely to (*a*).

If resolution has not been effected by the end of the dual course, other antibiotics should be tried after a suitable interval.

Fomentation of the bubo should be eschewed, as it favours softening and increases the necessity for aspiration (*not incision*), which should be carried out before the skin becomes involved. If general treatment is commenced reasonably early, aspiration will be required in only about 10 per cent. of cases.

Other complications such as stricture of the rectum must be treated on their merits (p. 1084).

GRANULOMA INGUINALE (*syn.* GRANULOMA VENEREUM)

This disease is a different entity from *lymphogranuloma* inguinale. It affects the genital, inguinal, crural, perineal, and perianal regions but not the lymph nodes, and is due to Donovania granulomatis, a Donovan body that can be seen as a Gram-negative rod found characteristically in the cytoplasm of large mononuclear tissue cells. It occurs in people living in or coming from sub-tropical or tropical areas.

Clinical Features.—The primary lesion is a vesicle surrounded by an area of erythema and induration, and looks a bright, beefy red. The overlying epithelium soon disintegrates and the lesion develops, either as a slightly raised ulcer or a mass of exuberant granulation tissue. Pain and

[1] Unfortunately, these tests, unlike a Wassermann reaction in syphilis, cannot be used as a test for cure.

Wilhelm Siegmund Frei, 1885–1943. Professor of Dermatology, Berlin, who later settled in New York, U.S.A.
Charles Donovan, 1863–1951. Lieutenant-Colonel, Indian Medical Service.

tenderness are singularly absent unless secondary infection occurs. The lesion progresses slowly by peripheral extension, and also by satellites due to auto-inoculation.

Extragenital granuloma inguinale (by which is meant that the lesion is distant from all the commonest sites set out above) occurs in about 6 per cent. of cases, but usually these lesions are due to auto-inoculation. Disseminated disease from a genital primary lesion is particularly liable to occur in pregnant women, who thereby become extremely emaciated, with sores in various parts of the body. In general it can be stated that granuloma venereum of the cervix uteri is a most serious lesion, and not a few women die from the effects of involvement of the pelvic viscera. In none of the manifestations of the disease does complete recovery occur without thorough treatment, but sometimes there is partial healing with the formation of thick or keloid scar tissue. Other complications are rectovaginal fistula, pyelitis, cystitis, and urethral stricture. Scarring may cause lymphatic obstruction and œdema of the genitalia.

Confirmatory Test.—If a needle is drawn through the tissues near the edge of the lesion, sufficient material is obtained for microscopical examination after staining.

Treatment.—The treatment of choice is oxytetracycline (Terramycin) 2 g daily for twenty days. In resistant cases, after an interval, a further course is sometimes required.

CHORDEE[1]

Chordee is a fixed bending or bowing of the penis due to (*a*) hypospadias or (*b*) acutely as a result of general urethritis. Erection is grotesque and very painful. The treatment is stilbœstrol 6 mg. daily.

INDURATIO-PENIS-PLASTICA (*syn.* PEYRONIE'S DISEASE)

Usually the patient is over forty years of age and seldom is there a history of venereal disease. At the onset pain and curving of the penis on erection cause the patient to seek advice, but after a few weeks the pain disappears. On palpation an indurated plaque can be felt on the dorsal surface of one corpus cavernosum. The condition is slowly progressive and sometimes extends across the middle line. Its ætiology is unknown; bygone trauma is a possible explanation.

Treatment has remained an unsolved problem for over 200 years. In some cases there is a tendency to slow resolution over three to five years.

PERSISTENT PRIAPISM

The penis remains erect, and is painful. Most often the erection is due to idiopathic thrombosis occurring in the prostatic venous plexus. Less frequently it is associated with leukæmia or sickle-celled anæmia. Secondary malignant deposits in the corpora cavernosa, or in the pelvis, account for about 7 per cent. of cases. In another completely different category are cases due to spinal injury or disease.

Diagnosis.—A low spinal anæsthetic will cause priapism of neurogenic origin to abate temporarily. A blood-count is essential to exclude leukæmia.

Treatment.—Local applications are useless. Anastomosis of the saphenous vein to one corpus cavernosum can be very effective if done within the first 48 hours. The corpora should be washed out with saline. Otherwise anticoagulant therapy can be given a trial for 14 days.

NEOPLASMS OF THE PENIS

Papillomas Acuminata[2] (*syn.* venereal warts), the commonest benign growths of the penis, occur both in the uncircumcised and the circumcised.

[1] *Cordee* (Fr.) = corded.

[2] *Acuminatus* (Lat.) = sharp pointed.

François de la Peyronie, 1678–1747. Surgeon to Louis XIV and Founder of the Royal Academy of Surgery, Paris.

Most often they are situated in the coronal sulcus (fig. 1491), but in the male they can occur anywhere on the penis, scrotum, perineum, and the anal region. Usually they are moist, and attended by an offensive serous discharge. Often they are transmitted by sexual contact and are possibly due to a virus infection.

FIG. 1491.—Penile warts.

Treatment:

(*a*) **Fulguration** of the growths by diathermy.

(*b*) **By Podophyllin.**—The parts are cleansed thoroughly and then unaffected skin should be protected by smearing with a zinc oxide ointment. A 10 or 20 per cent. solution of podophyllin in tinct. benzoin is applied with a sterile applicator, and the prepuce is held back for three to five minutes until the tincture dries. The patient is instructed to wash the part thoroughly in thirty minutes. Thereafter he must pay particular attention to cleanliness. The papillomas gradually disappear. Often such treatment is followed by considerable local reaction, and is painful. For this reason fulguration is advisable, especially if it is necessary to circumcise the patient.

CARCINOMA OF THE PENIS

Ætiology.—For a reason that is only partially understood, circumcision correctly performed soon after birth confers almost total immunity against carcinoma of the penis. On the other hand (and this is difficult of explanation) circumcision after early infancy does not provide the same degree of protection. Mohammedans, who are circumcised between the ages of four and nine years, exemplify this.

For practical purposes, then, carcinoma of the penis occurs only in men who have not been circumcised in early infancy, and undoubtedly the development of this neoplasm is favoured by chronic balanoposthitis. Furthermore, there are definite pre-carcinomatous states, viz.:

(*a*) **Leukoplakia of the glans** is exactly comparable to the well-known condition of the tongue (p. 547).

(*b*) Long-standing **penile papillomas** (p. 1285).

(*c*) **Paget's Disease of the Penis** (*syn. Erythroplasia of Querat*).—' I have seen a persistent rawness of the glans like a long-standing balanitis followed by cancer of the substance of the penis ' (Sir James Paget). It is possible that penile Paget's disease escapes detection until carcinoma has developed. Treatment is by radium or diathermy excision.

Pathology.—There are two types of squamous carcinoma of the penis—the flat or infiltrating, and the papilliferous. The former may be associated with leukoplakia; the latter commences in a papilloma of long standing. The growth remains purely local

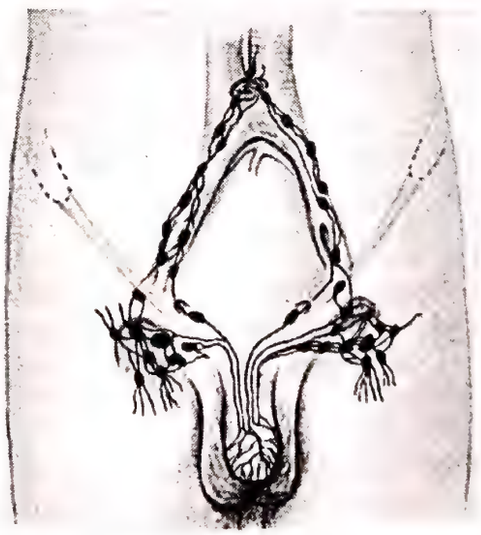

FIG. 1492.—The lymphatic drainage of the penis. The superficial lymphatic vessels drain into the inguinal while the deep lymphatics drain into the iliac lymph nodes. (*After Archie L. Dean.*)

Sir James Paget, 1814–1899. Surgeon, St. Bartholomew's Hospital, London.

for months. The earliest spread is to the inguinal, and then to the iliac lymph nodes. Direct spread to the body of the penis is prevented for many months by the fascial sheath of the corpora cavernosa, but once this barrier becomes broken the growth extends more rapidly and the iliac lymph nodes (fig. 1492) become involved. Distant metastatic deposits are infrequent.

Clinical Features.—It is a mistake to believe that this is a disease confined to the elderly—40 per cent. of the sufferers are under forty years of age. The progress of the disease is slow; the first symptoms are a mild irritation and a purulent discharge from the prepuce. These symptoms are often neglected (fig. 1493), and by the time the patient reports, sometimes more than a year after symptoms have appeared, there is a blood-stained, foul discharge. Pain is singularly absent. The inguinal lymph nodes are enlarged in over 60 per cent. of cases, but in only half of these is the enlargement due to secondary deposits, the remainder being due to sepsis. In most cases the prepuce cannot be retracted, and in order to view the lesion the prepuce must be slit. In all cases a biopsy should be performed.

Untreated, the whole glans becomes a fungating and particularly foul-smelling mass. Later, the inguinal lymph nodes fungate through the skin of the groin, and often death relieves the victim by torrential hæmorrhage following erosion of the femoral or external iliac artery.

FIG. 1493.—Carcinoma of the penis.

Treatment:

Radiotherapy gives good results (60 to 70 per cent. five-year survival) with small well-differentiated tumours. **Surgery** is needed for large anaplastic growths; if there is infiltration of the shaft of the penis; when radiotherapy has failed; in elderly men who do not mind the mutilation as much as the pain to be expected from the extensive reaction to radiotherapy. *Partial amputation* is used for distal growths providing there is at least 2 cm. of the dependant shaft which is not involved. With an advanced, infiltrating, or anaplastic lesion *total amputation* must be performed.

FIG. 1494.—Partial amputation of the penis.

Radiotherapy methods are: implantation with flexible radio-active tantalum wires (total dose 6,000 rad in five to seven days); medium or high-voltage X-rays (5,000 to 6,000 rad given in divided doses over five weeks); by radium mould applicators worn intermittently or continuously (not exceeding 6,000 rad in seven to ten days). If not already performed, a dorsal slit is a prerequisite for treatment and nursing.

Partial Amputation Technique (guillotine amputation).—A tourniquet, in the form of a No. 6 French rubber catheter, is placed around the most proximal portion of the penis, being tied once, and the knot clipped in a hæmostat. An abdominal pack is placed over the glans penis and with a piece of strong silk is tied tightly to the shaft of the penis at the proposed level of section. A guillotine amputation is then performed, and the pack,

with its contents, is dropped into a receptacle. The exposed cross-section of the penile stump is examined for extensions of the growth. If, as is usual, none is present, the dorsal vessels are ligated. The corpus spongiosum is dissected from the corpora cavernosa for 1 cm. A long straight needle carrying a double stout catgut suture is passed from the ventral to the dorsal aspect of the fibrous septum separating the two corpora cavernosa, the needle entering just distal to the attached portion of the corpus spongiosum. The needle having been removed (fig. 1494), each corpus cavernosum is ligated firmly. The free portion of the urethra and its surrounding corpus spongiosum is divided on the dorsal aspect for nearly 1 cm. The tourniquet is now removed. The urethra is carefully attached to the adjacent skin by interrupted stitches that pass through the whole thickness of the corporus spongiosum, thereby avoiding a post-operative stricture. Bleeding-points having been ligated, the remaining portions of the skin edges are approximated vertically over the cut corpora cavernosa. An indwelling catheter is employed until the dressings are dispensed with.

Complete amputation includes the removal of the corpora cavernosa from the pubic bones and division of the corpus spongiosum so as to leave at least 1·3 cm. protruding from the perineum, as a perineal urethrostomy via an incision behind the scrotum. Careful suture of the divided urethra to the skin avoids a subsequent stricture.

The Treatment of Associated Enlarged Inguinal Lymph Nodes.—It is advisable to wait for at least three weeks after the local lesion has been dealt with by one of the methods described. If the enlargement is due to inflammation, the lymph nodes will decrease in size or disappear with antibiotic treatment. When these lymph nodes remain unaltered at the end of this period, block dissection of the more affected side should be undertaken, followed by contralateral block dissection at a later date. The five-year survival rate falls to some 35 per cent. in these cases.

If the enlarged lymph nodes are massive and fixed (inoperable), X-ray therapy causes some temporary regression.

Secondary carcinoma of the penis occurs from time to time, and about a hundred cases have been reported. The primary source of the disease is usually the bladder, rectum, or prostate.

The metastasis arrives in the penis in one of three ways: (*a*) by direct spread; (*b*) by retrograde lymphatic transport; (*c*) by retrograde venous embolism via the dorsal vein of the penis. The condition must be differentiated from Peyronie's disease. As would be expected, secondary carcinoma of the penis occurs only late in the course of the disease; nevertheless, in many instances active treatment is worth while.

CHAPTER 58

THE TESTES AND THE SCROTUM

CONGENITAL ABNORMALITIES

Anterior inversion is said to be present in one in every fifty males. The epididymis lies anteriorly, and the body of the testis and the tunica vaginalis posteriorly. When the organ is diseased this anomaly may cause confusion in diagnosis.

Polar inversion is less frequent. In some cases when there is complete inversion the globus major lies inferiorly (fig. 1495(B)). In other cases it lies horizontally (fig. 1495(C)). Both varieties predispose to torsion (p. 1294). Complete inversion, impossible to detect clinically, is an incidental finding at operation, when it is observed that the hydatid of Morgagni is situated at the lower, instead of the upper, pole.

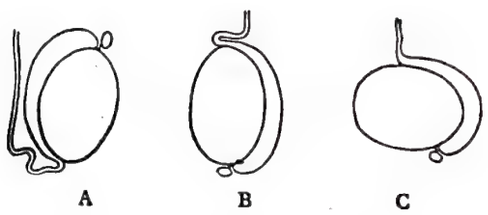

FIG. 1495.—A. Normal. B. Inverted. C. Horizontal inversion.

IMPERFECT DESCENT OF THE TESTIS

Under this heading are included two conditions :

Incomplete Descent.—The testis is arrested in some part of its path to the scrotum.

Ectopic Testis.—The testis is abnormally placed outside this path.

Development of the Testes.—The testes develop from the genital fold, which lies medial to the mesonephros (Wolffian body), and therefore in early fœtal life they lie in the cœlomic cavity behind the peritoneum and below the developing kidneys. The primitive testis is attached to the posterior abdominal wall by a mesentery, the mesorchium, which contains the testicular blood-vessels and nerves, derived from the tenth and twelfth dorsal segments respectively. About the tenth week of intrauterine life some of the transverse tubules of the mesonephros unite with the rete testis to form the vasa efferentia; others remain rudimentary. Most of the Wolffian body disappears, but the Wolffian duct becomes the epididymis and vas deferens. About this time tissue in a fold of peritoneum (plica inguinalis) develops, containing the precursor of the gubernaculum[1]; it is attached to the junction of the vas deferens and epididymis, and can be traced through the abdominal wall to end in the region of the developing phallus. The processus vaginalis appears as a dimple of peritoneum about the tenth week and precedes the testis through the layers of the abdominal wall down into the scrotum. Muscular fibres develop in the mesoderm of the plica inguinalis to form the gubernaculum but there is still no certainty as to the part this structure plays in regulating testicular descent.

Chorionic gonadatrophin from the maternal circulation stimulates the growth of the testis and may play some part in the migration of the organ. Undoubtedly imperfect development of a testis is a significant factor in incomplete descent of the organ.

---

[1] Gubernaculum = a rudder. It was first described by John Hunter, who believed that its function was to guide the testis into the scrotum.

Giovanni Battista Morgagni, 1682–1771. Professor of Anatomy, Padua, Italy. He held the Chair for fifty-six years, and is regarded as the founder of Pathological Anatomy.
Kaspar Friedrich Wolff, 1733–1794. Professor of Anatomy and Physiology, St. Petersburg (now Leningrad), U.S.S.R.
John Hunter, 1728–1793. Surgeon, St. George's Hospital, London.

Morphology.—Most of the misplacements of the testes in man are a counterpart of the varying normal placements of the testes in animals. In the whale and the elephant the testes remain in the undescended abdominal position throughout life. Rodents and hibernating animals, such as the hedgehog, the mole and the bat, maintain open inguinal canals, and the testes are housed in the abdomen, to descend into the scrotum only during the breeding season.

INCOMPLETELY DESCENDED TESTIS

Incidence:

In the Neonatal Period.—At birth, and for a variable number of weeks afterwards, the cremasteric reflex, which is so active in young boys, is absent. Scorer examined 2,000 newborn male infants and found that the incidence of incomplete descent on one or both sides was 4 per cent. in full-term infants and 30 per cent. in premature infants. A follow-up of all cases showed that in more than 50 per cent. the testis or testes reached the scrotum during the first month of life. More often than not incomplete descent of the testis is not detected during infancy.

In later childhood and puberty the incidence is 2 per cent. Frequently the condition still remains unrecognised unless a routine examination is made by the school medical officer. In a few cases the presence of a hernia, pain in the region, or acute torsion, in that order of frequency, directs attention to the abnormality.

In Adult Life.—It is inconceivable that a man can fail to notice the absence of one or both testes in his scrotum, yet there must be many with this abnormality who do not seek advice about it unless symptoms develop. Sometimes the condition is first discovered at the medical examination for entrance to one of the Public Services. In an examination of 10,000 recruits during World War II the incidence was found to be 0·8 per cent. In 10 per cent. of unilateral cases there is a familial history.

Pathology.—Up to the age of six years there are no microscopical differences between an incompletely descended testis and a normal testis. After that time, due, it is believed, to the higher temperature to which it is subjected, the development of the incompletely descended organ becomes progressively retarded.[1] By the time puberty has been reached the incompletely descended testis is flabby and hardly more than half the size of its intrascrotal counterpart. Histologically, the epithelial elements are grossly immature, and by the age of sixteen irreversible destructive changes have occurred in the germinal epithelium.

The *external secretory mechanism* of an incompletely descended testis functions but feebly, and often after a few months or years ceases; thus its power of spermato-genesis is negligible.[2]

The internal secretory activity of an incompletely descended testis is reduced. In bilateral cryptorchism about half the normal amount of androgen is produced: notwithstanding, the secondary sexual attributes of a cryptorchid are seldom noticeably in abeyance.

If an incompletely descended testis is brought down satisfactorily *before puberty* it often develops and functions satisfactorily.

Clinical Features.—The right testis alone is affected in 50% of cases, the left alone in 30%, while double arrested descent occurs in 20%. Other

---

[1] The scrotum is a thermo-regulator to the testes, and keeps them at a temperature at least 1° C lower than that of the inguinal canals.

[2] Sir Astley Cooper taught that patients with bilateral retained testes were usually sterile, whereupon one of his pupils, a cryptorchid, left the room and committed suicide. At the necropsy motile spermatozoa were demonstrated. It is therefore unsafe to deny the possibility of parentage to those with retained testes.

Charles Gordon Scorer, Contemporary. *Surgeon, Hillingdon Hospital, Uxbridge, Middlesex, England.*
Sir Astley Paston Cooper, 1768–1841. *Surgeon, Guy's Hospital, London.*

abnormalities of the urinary tract may be present. Felton found that intravenous pyelograms demonstrated major abnormalities in 13·5% of children with cryptorchism. The testis may be:

1. *Retained within the abdomen* extraperitoneally, usually just above the internal abdominal ring.

2. *In the Inguinal Canal.*—Early in life the testis is a soft structure, and when, as in this instance, it is submerged in the non-resisting floor of the inguinal canal, and shielded by the overlying tendinous aponeurosis of the external oblique, it cannot be felt.

FIG. 1496.—A cryptorchid, aged 12. Note the retracted, underdeveloped scrotum. In cases of retractile testes the scrotum is comparatively well-developed.

When both testes are in the abdomen or the inguinal canals and are consequently impalpable, the condition is known as cryptorchidism (hidden testes) (fig. 1496).

3. *In the Superficial Subinguinal Pouch.*—Very frequently during childhood the testes are mobile, each being withdrawn by the contraction of the cremasters into the superficial subinguinal pouch (fig. 1497), a space lined by loose areolar tissue lying beneath Scarpa's fascia and superficial to the external oblique aponeurosis (Denis Browne), or into the inguinal canal. Reflex retraction occurs from a very slight stimulus such as touching the thigh or the abdomen, or even by exposure of the parts. Not infrequently this testicular mobility continues throughout childhood on both sides, or less frequently on one side. At all times it is liable to be mistaken for incomplete descent unless a special method of examination is undertaken, if necessary on more than one occasion.

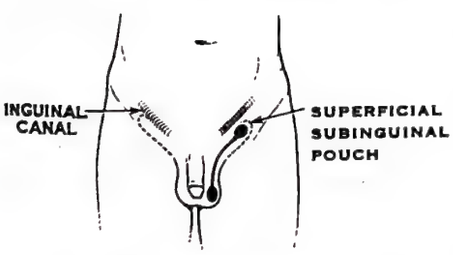

FIG. 1497.—Mechanism of retractile testis. *(After the late Sir Denis Browne, London.)*

Retractile testes should be suspected if the scrotum is normal; in incomplete descent the corresponding side of the scrotum is undeveloped. This inspection completed, the pulps of two fingers are placed over the superficial inguinal pouch, exerting moderate pressure. By drawing the fingers towards the neck of the scrotum a testis of the retractile type can be pushed into the upper part of the scrotum, where it is grasped between the finger and thumb of the other hand. *Only if the testis cannot be made to touch the bottom of the scrotum*[1] *is it imperfectly descended.* When the testis *can* be placed in a normal position temporarily it is not truly an imperfectly descended testis, and it should be known by its fitting title '*retractile testis*'. Such testes require neither endocrine nor operative treatment. In course of time (it may be delayed until puberty), the testis will take up a normal position permanently. Another valuable method of encouraging the testes to drop down into the scrotum is to make the child squat, the thighs being brought up on to the abdomen.

[1] Only by applying the test carefully and correctly in every case will the extravagant claims of some of those who employ endocrine therapy be dissipated.

Lester Mahan Felton, Contemporary. Urologist, Worcester Hahnemann Hospital, Worcester, Mass., U.S.A.
Antonio Scarpa, 1747–1832. Professor of Anatomy, Pavia, Italy.
Sir Denis John Wolko Browne, 1892–1967. Surgeon, Hospital for Sick Children, Great Ormond Street, London.

In infancy 80% of non-apparent testes are retractile. In the remaining 20% true incomplete descent is present.

The Hazards of Incomplete Descent

1. *Sterility* in bilateral cases.
2. *Pain.* An inguinal testis is liable to oft-repeated trauma.
3. *An associated indirect inguinal or interstitial hernia* is present in 70% of cases, and in adolescent and adult patients it is frequently the hernia that causes the symptoms.
4. *Torsion* (p. 1294).
5. *Epididymo-orchitis.*—Right-sided epididymo-orchitis occurring in an incompletely descended organ is extremely difficult, if not impossible, to differentiate from an acute appendicitis. It is, however, very rare because the abnormal testis is less likely to become involved by descending infection.
6. *Atrophy*, even before puberty, sometimes occurs when the testis is situated in the inguinal canal. This is attributed to recurrent trauma.
7. *Increased Liability to Malignant Disease.*—All types of malignant testicular tumour have been recorded as developing in undescended testes, and in those brought down surgically. It is definite that seminoma is more common possibly because the testis is frequently histologically abnormal. Some compute that 1 in 20 abdominal and 1 in 80 inguinal testes become malignant; others say this estimation is far too high. Reliable statistical evidence as to whether orchiopexy diminishes the liability to tumour formation later, is not available. However, at the worst it should improve the prospect of early diagnosis.

Treatment by Orchiopexy.—Most surgeons favour performing the operation between the ages of six and eight years. Many choose the earlier age in order to reduce the incidence of thermal damage to the germinal epithelium. After the age of puberty the percentage of successful operations, which at the optimum age approaches 80%, falls considerably. In cryptorchidism one side should be operated upon at a time, with an interval of six months between the operations.

The operation consists of (1) mobilising the spermatic cord and the testicular vessels; (2) retaining the mobilised testis in the descended position.

1. **Mobilising the Spermatic Cord.**—The inguinal canal is opened. The cord and testis are freed from surrounding structures and a concomitant inguinal hernial sac is dealt with. The dissection of the diaphanous sac from the cord is greatly facilitated by opening the sac and injecting a small amount of normal saline just underneath that part which is adherent. Near the internal inguinal ring all the coverings of the cord are divided; every muscle fibre and fibrous band is severed, leaving only the vas and its blood-vessels and the spermatic blood-vessels. Sometimes this provides sufficient length for the testis to be placed in the scrotum. If not, the spermatic vessels are dissected from the peritoneum to which they are adherent. This abolishes the wide, outward curve of the vessels, thereby gaining up to 2·5 cm. It is most exceptional for the above measures to fail to elongate the pedicle sufficiently for the testis to be placed in the scrotum, and even beyond it: the avoidance of vascular tension is the keystone of plastic surgery. The empty half of the scrotum is stretched thoroughly with the index finger passed into it through the inguinal incision.

2. **Retaining the testis in the scrotum** is effected by one of a number of ingenious methods, of which the following are popular:

(*a*) *Narrowing the neck of the scrotum and fixation of the testis to the bottom of the scrotum*, is all that is needed in many cases. The neck of the scrotum is narrowed with catgut sutures, and the testis is anchored below by an unabsorbable suture passed through the scrotal skin, this suture being removed after one week.

(*b*) *Dartos pouch.*—The testis is retained in the scrotum by placing it in a dartos pouch just under the scrotal skin.

(*c*) *Ombrédanne's operation* is similar, but the testis is passed through a gap in the scrotal septum, which is then narrowed round the cord. This is useful when the length of cord is short as the septum can be drawn across to the external ring. The weight of the opposite testis will supply gentle traction which will gradually draw the undescended one further down (figs. 1498 and 1499).

FIG. 1498.—Method of passing the suture attached to the testis through the septum dartos and the skin of the opposite side of the scrotum.

Failure to bring the testis down.—(1) Sometimes a two-stage procedure is successful: mobilisation as far as possible, and anchorage with an unabsorbable suture, followed six months later by further mobilisation. (2) *Orchiectomy*, if the other testis is normal, and the incompletely descended testis is hopelessly atrophic, or, after puberty.

FIG. 1499.—The disposition of the testes in relation to the septum dartos following bilateral Ombrédanne's operation.

Orchio-cœlioplasty (abdominal replacement of the organ). This measure is justifiable when the contralateral organ has been removed previously and orchiopexy is found to be impossible. It is then the only method of preserving a supply of internal testicular secretion and protecting the organ from injury.

Hormone Treatment.—The only indications for hormone treatment are:

1. Cases of bilateral incomplete descent associated with hypogenitalism and obesity.
2. In lieu of waiting for retractile testes to descend, thereby avoiding jibes that small boys endure from others in the changing rooms of swimming baths, etc. (Scowen).
3. In cases of uncertainty as to whether the case is one of testes retracting into the inguinal canal or one of true incomplete descent.

Of many preparations having a gonadotrophic action, chorionic gonadotrophin extracted from the placenta (Pregnyl) is the one usually employed. It should be given at about eight years of age, and 1,000 international units are given twice a week until the testes descend, the limit of the course being ten weeks, after which it must never be repeated, otherwise secondary male characteristics may develop prematurely.

ECTOPIC TESTIS

An ectopic testis may be found, in order of frequency:

1. Anchored in the superficial inguinal pouch. 2. In the perineum. 3. At the root of the penis. 4. In the femoral triangle.

Unlike the imperfectly descended testis, an ectopic organ often develops well, if not fully. Its main hazard is that it is liable to injury.

Ætiology.—To explain the appearance of the testis in these anomalous positions, Lockwood advanced the ingenious theory of many gubernacular tails. His theory postulates that in ectopic testis the scrotal tail becomes ruptured. As a consequence the testis, adrift from its usual mooring, follows one of the accessory rudders. Lockwood stated that the accessory gubernacula depicted in fig. 1500 could be demonstrated in the fœtus.

FIG. 1500.—The 'gubernacular tails' of Lockwood.

INJURIES OF THE TESTIS

Closed rupture of the testis from blows and the like is an uncommon accident owing to the extreme mobility

Louis Ombrédanne, 1871–1956. Surgeon, Hôpital des Enfants Malades, Paris.
Sir Eric Frank Scowen, Contemporary. Formerly Professor of Medicine, St. Bartholomew's Hospital, London.
Charles Barrett Lockwood, 1856–1914. Surgeon, St. Bartholomew's Hospital, London.

of the organ within the scrotum. Severe contusion and rupture are each associated with a hæmatocele which surrounds the testis, rendering the differential diagnosis impossible without exploration. Operation is advisable in these cases in order to:

1. Evacuate the hæmatoma.
2. Repair the tunica albuginea, if split, excising only that part of the testicular tissue that extrudes. If the testis is severely damaged, orchiectomy should be performed.

Hæmatocele (p. 1301).

Traumatic Displacement of the Testis.—As a result of a blow the testis occasionally becomes displaced and by reason of blood-clot anchored, usually in one of the positions described under ectopic testis. Unless the displacement is reduced early by manipulation, an operation is required to replace the organ in the scrotum.

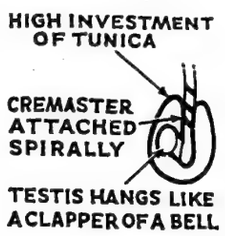
TORSION OF THE TESTIS (*syn.* TORSION OF THE SPERMATIC CORD)

Predisposing Causes.—Torsion of the testis (fig. 1501) is uncommon. It does not occur in a normal fully descended testis: its anchorage prevents rotation. Therefore one of several anomalies must be present.

(*a*) *Inversion of the Testis* (p. 1289).—This appears to be the commonest predisposing cause.

FIG. 1501.—Torsion of the testis. Note the inversion of the organ.

(*b*) *High investment of the tunica vaginalis* causes the testis to hang within the tunica like a clapper in a bell, viz.——→



Very occasionally torsion is extravaginal.

(*c*) *In cases where the body of the testis is separated from the epididymis*, torsion of the body can occur without involving the cord. The twisting is confined to the mesentery that joins the testis to the epididymis, viz.——→

Exciting Causes.—Normally the cremaster contracts *pari passu* with violent contraction of the abdominal musculature. Contractions of the spirally attached cremaster favour rotation around the vertical axis in relevant cases. Straining at stool, lifting a heavy weight, and coitus are all exciting causes, but often the history fails to reveal any one of them. Occasionally torsion develops during sleep.

Clinical Features.—The highest incidence is between ten and twenty-five years of age, and the second most common age period is during infancy. The symptoms vary with the degree of torsion present. Most commonly the patient experiences sudden and agonising pain in the groin and lower abdomen,[1] and vomits. Upon theoretical grounds one might think that the

---

[1] But, in about 23 per cent. of K. H. Smith's patients, the first symptom was a dull ache in the loin or hypogastrium. It is insufficiently appreciated that true testicular pain is situated in the lower abdomen at the level of the internal inguinal ring in accordance with Brown's law.[2]

[2] Brown's law: Pain, produced in an organ which has migrated from its primary position, and which has not acquired an additional nerve supply in its secondary or permanent position, is invariably localised in the primary relative position of that organ.

Kenneth Halsted Smith, Contemporay. Surgeon, Llandudno, General Hospital, Llandudno Caernarvon, Wales.
Francis Robert Brown, Surgeon, 1889–1967. Royal Infirmary, Dundee, Scotland.

diagnosis is simple, but sometimes it is practically impossible to distinguish *torsion of an imperfectly descended testis* from a strangulated inguinal hernia until the parts have been displayed by operation. The fact that the side of the scrotum is empty and œdematous is certainly in favour of the tender lump at the external abdominal ring being the testis with its twisted cord. *Torsion of a completely descended testis* is a less difficult problem. Sometimes the actual twists in the cord can be felt, thus establishing the diagnosis. At other times the condition can be mimicked exactly by a small, tense, strangulated inguinal hernia compressing the cord and causing congestion of the pampiniform plexus, viz.

Torsion of the fully descended testis can also simulate closely acute epididymo-orchitis; after a lapse of six hours or so the skin of the scrotum becomes reddened (fig. 1502) and the temperature is raised slightly—37·2° C. Elevation of the scrotum usually relieves the pain in epididymitis, but increases it in torsion of the spermatic cord. Therefore in a boy (if mumps has been excluded) and in a man (if urethritis has been eliminated), a diagnosis of torsion of the testis should be *insisted* upon, and almost invariably when the testis is exposed the diagnosis will be substantiated.

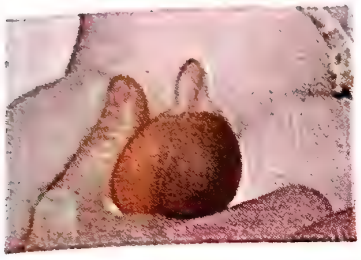


FIG. 1502.—Torsion of the left testis of twenty-four hours duration in a boy aged thirteen. The acutely tender testis and the inflamed scrotum simulate acute epididymo-orchitis.

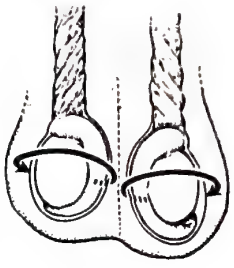

FIG. 1503. — Usually the testis *twists* in a direction away from the septum dartos, but it may twist in either direction.

Treatment.—In the first hour or so an attempt to untwist the testis may immediately relieve the pain and gentle twisting should be tried in one direction first. If this is the correct way, continue until relief is obtained. If one has chosen the wrong direction pain will increase. If untwisting can be achieved it removes the urgency, but operation and fixation should be performed as quickly as possible.

Urgent exploration of the scrotum is indicated if untwisting is not successful in relieving pain. If after undoing the torsion the testis is viable, then it must be fixed to prevent a recurrence (fig. 1504). The opposite testis should also be fixed at the same time, as the anatomical variation responsible is likely to be bilateral. A totally infarcted testis should be removed. Should the patient not be operated upon, but only seen days or weeks later when pain has subsided little is to be gained by exploring the affected side; the testis will slowly become woody hard and shrink to a fibrous nodule. The opposite testis must be fixed at an early date.

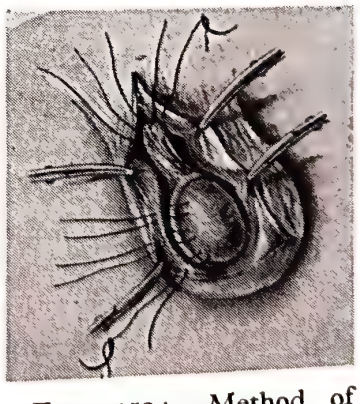

FIG. 1504.—Method of anchoring the testis with non-absorbable sutures to prevent torsion.

FIG. 1505.—Torsion of the appendix of the epididymis (pedunculated hydatid of Morgagni).

Torsion of an Appendage of the Testis.—Vestigial structures related to the testis and epididymis are liable to undergo axial rotation. The most common of these structures to twist is the appendix of the epididymis (the pedunculated hydatid) (fig. 1505). Torsion of an appendage of the testis is essentially a lesion occurring before or at the age of puberty. The condition is often mistaken for acute epididymo-orchitis of unknown origin and frequently, although the symptoms are comparatively mild, they cannot be distinguished with certainty from those of torsion of the testis. Immediate operation with ligation of the pedicle and amputation of the twisted appendage cures the condition.

Idiopathic Scrotal Œdema (4–12 years) (fig. 1506) may occur in childhood and has to be differentiated from torsion of testis or appendix. The scrotum is very swollen but has not the exquisite tenderness of torsion, and pain is slight. The swelling may extend to the perineum or groin (see extravasation p. 1264) and penis. The swelling subsides after 1–2 days. It may be a recurrent phenomenon. It might also be allergic in origin—occasionally an eosinophilia is present.

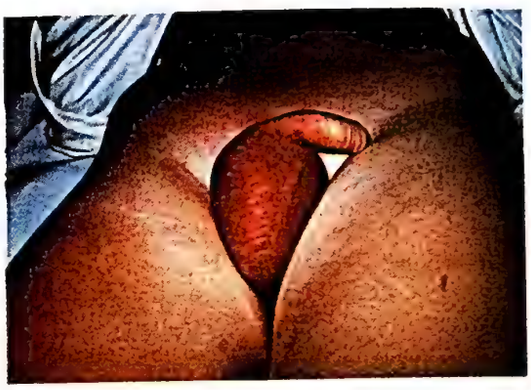

FIG. 1506.—Œdema of the scrotum.

VARICOCELE

Varicocele is a state of varicosity of the cremasteric and occasionally the testicular veins.

Surgical Anatomy.—The veins of the testis and epididymis form an anastomosing plexus—the pampiniform plexus—which is the most bulky constituent of the spermatic cord. As the veins pass upward through the inguinal canal they become reduced in number to between four and eight. Coalescence in the neighbourhood of the internal inguinal ring brings about further reduction in their number, and by the time the posterior abdominal wall is reached, a single, or a duplicated testicular vein pursues its cephalad course behind the peritoneum, to empty into the renal vein on the left, and the inferior vena cava on the right. Only near their terminations are the testicular veins provided with valves, and not infrequently even these valves are absent, in which case valves will be found nearby in the renal veins. The cremasteric veins anastomose with the testicular veins, so providing an alternative (collateral) venous return and draining mainly into the inferior epigastric veins.

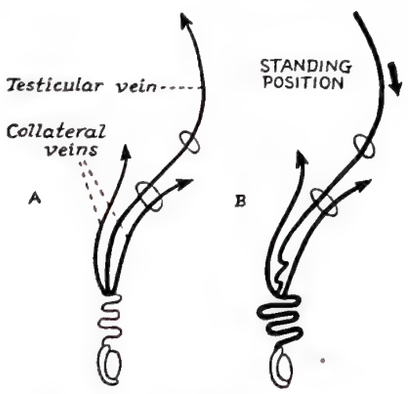

FIG. 1507.—(*a*) Normal drainage of the pampiniform plexus; (*b*) reflux along the testicular vein in varicocele. (*After J. W. Lane.*)

Ætiology.—(1) Most varicoceles are noted in the 'teens' or early adult life. The left side is affected in 95 per cent. of cases. The left testicular vein joins the renal vein and reflux into this vein can be demonstrated by angiograms. Nathan has shown that the left testicular artery arches over the left renal vein in 16 per cent. of cases and may obstruct it (fig. 1508).

(2) Hanley and Harrison, however, maintain that in many cases the dilated vessels are cremasteric veins, and not veins of the pampiniform plexus. The cremasteric veins drain into the inferior epigastric veins mainly,

Hilel Nathan (formerly Notkovich), Contemporary. Professor and Chairman, Department of Anatomy and Anthropology, Tel-Aviv University Medical School, Tel-Aviv, Israel.
Howard Granville Hanley, Contemporary. Surgeon, St. Paul's Hospital, London.
Ronald George Harrison, Contemporary. Derby Professor of Anatomy, Liverpool, England.

but also communicate freely with the veins in the pampiniform plexus.

(3) Obstruction of the left testicular vein by growth of a hypernephroma along the left renal vein is a rare cause (0·4 per cent. Riches) of a recent varicocele arising in middle life.

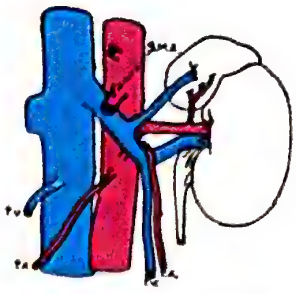

FIG. 1508.—Arching left testicular artery compressing the renal vein of the corresponding side. (*After H. Nathan.*)

Clinical Features.—Varicocele is more frequent and more troublesome in hot climates; in all parts of the world tall, thin, visceroptotic men are frequently affected, whereas short, fat individuals are seldom so. Usually symptoms are entirely absent, but in some cases the patient experiences a dragging pain in the affected side. Pain is due to the fact that the elongated scrotum no longer supports the testis, whose full weight is now borne by the cord. The scrotum, particularly the left side, hangs lower than normal (fig. 1509), and on palpation with the patient standing, the varicose plexus feels like a bag of worms. If, while lightly holding the varicocele between the fingers and thumb, the patient is instructed to bow, tension within the veins becomes appreciably less. An impulse is often felt when the patient coughs. When the patient lies down and the scrotum is elevated, the veins will be emptied by gravity and the opportunity of comparing the size of the left testis with its fellow should be taken. In long-standing cases the left testis is somewhat smaller and softer than the right, due to a minor degree of atrophy. Infertility can be caused by a varicocele.

FIG. 1509.—A large varicocele. A left inguinal hernia is also present.

Varicocele and Spermatogenesis.—The testis is supported in the scrotum by the cremaster and the dartos muscles. The main function of the cremaster is one of defence, for a fright or threat of trauma will cause reflex retraction of the testis towards the external inguinal ring, especially in the young. The dartos bears the weight of the testis and is reflexly controlled by temperature changes and acts as a kind of thermostat for efficient spermatogenesis at some 2·5° C. lower than rectal temperature. On exposure to cold it raises the testis to the body so conserving heat, while a too warm environment causes relaxation of the dartos. Hanley and Harrison, who have reawakened interest in the effects and treatment of varicocele, explain the characteristic elongation of the scrotum in this condition on the grounds that venous engorgement in the varicosities reduces the temperature differential (scrotum/rectum) to about 0·1° C. which may seriously depress spermatogenesis. The dartos relaxes in a vain attempt to maintain the temperature differential. It also follows that the modern tendency to wear tight and poorly ventilated pants and scrotal supports is to be deprecated.

Sir Eric William Riches, Contemporary. Consulting Surgeon Middlesex Hospital, London.

Treatment.—Operation for varicocele is not indicated unless there is (1): pain; (2) serious depression of spermatogenesis (oligospermia).

Technique.—The testis and varices are best exposed by a scrotal incision. The operating table is tilted downwards to distend the varicosities. Tortuous and varicose veins are divided and ligated individually. If there are any distended testicular veins of the pampiniform plexus, the enclosing glistening capsule is incised and each affected vein divided and ligated. Sufficient veins must be left to maintain venous return. Some maintain that these veins are more easily ligated within the inguinal canal, or even within the abdomen.

Hæmatoma formation after operation on the scrotal contents is usually due to bleeding from the dartos muscle. This should be sutured meticulously with a continuous everting catgut stitch; the scrotum should not be drained. The skin edges will lie together and need not be stitched. The scrotum should be supported on a bridge of 'Elastoplast' (fig. 1518) across the thighs, and the patient should be kept in bed for forty-eight hours.

As a result of this operation the testis becomes cooler, and the dartos contracts, supports the testis, and relieves pain, while cases of oligospermia show a 70 to 80 per cent. improvement with a conception rate of about 30 per cent.

The older operations employing mass ligation, transfixion, and wide resection, are no longer advocated.

HYDROCELE

- Congenital (fig. 1510).
- Acquired
  - Primary, or idiopathic.
  - Secondary, due to disease of testis
    - Acute.
    - Chronic.

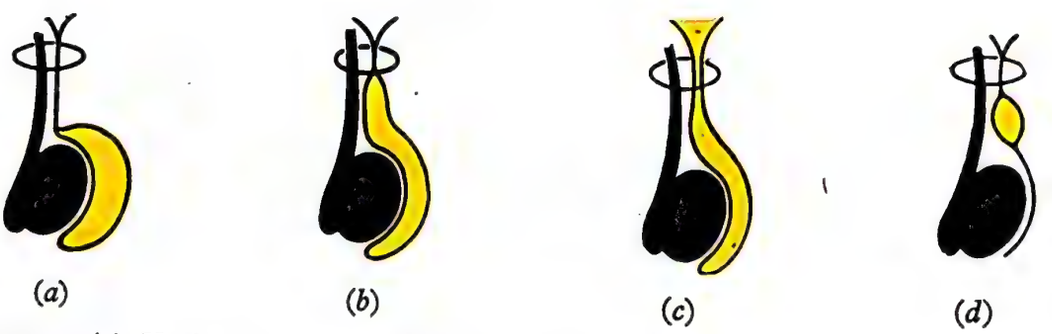

FIG. 1510.—(*a*) Vaginal hydrocele (very common); (*b*) 'infantile' hydrocele (unusual); (*c*) congenital hydrocele; (*d*) encysted hydrocele of the cord.

A hydrocele is a collection of serous fluid in some part of the processus vaginalis, usually in the tunica. Four anatomical varieties of congenital hydrocele are encountered.

Ætiology.—A hydrocele can be produced in four ways:

1. By excessive production of fluid within the sac, e.g. secondary hydrocele.
2. By defective absorption of hydrocele fluid by the tunica vaginalis.

Defective absorption appears to be the most common cause of the common variety of primary hydrocele, but the reason for the defective absorption is obscure. Damage to the endothelial wall by low-grade infection seems to be the probable explanation.

3. By interference with the drainage of fluid by the lymphatic vessels of the cord.
4. By connection with the peritoneal cavity, as in the congenital variety.

Hydrocele fluid is amber coloured, and registers a specific gravity of 1·022 to 1·024. It contains water, inorganic salts, 6 per cent. of albumin, and a quantity of fibrinogen. The last constituent confers upon the fluid a characteristic feature. If the contents of a hydrocele are allowed to run through a cannula into a receptacle, the fluid does *not* clot, but if a few drops of blood which have come into contact with cut tissues are stirred into even a large quantity of hydrocele fluid, the whole clots firmly. In old-standing cases the fluid sometimes contains so much cholesterol that it is irridescent, and occasionally tyrosine crystals are found.

FIG. 1511.—Right vaginal hydrocele in an infant. It is possible to get above the swelling which is brilliantly translucent.

DIAGNOSTIC RULES FOR ALL HYDROCELES

Ninety-nine out of every 100 *hydroceles are translucent. On examination it is possible ' to get above the swelling '.*

(*a*) **Primary vaginal hydrocele** most often appears in middle-aged or elderly men, but it is not uncommon in early childhood (fig. 1511). The condition is particularly common in tropical countries. The only complaint of the patient is the swelling, and occasionally he does not seek relief until the sac has attained enormous dimensions.

About 5 per cent. of inguinal herniæ are associated with a vaginal hydrocele of the same side.[1] Often a large hydrocele obscures a small inguinal hernia, even if the latter has been especially looked for.

(*b*) **Infantile hydrocele** does not necessarily appear in infants. The tunica and the processus vaginalis are distended up to the internal abdominal ring, but the sac has no connection with the general peritoneal cavity.

(*c*) **Congenital Hydrocele.**—The processus vaginalis communicates with the peritoneal cavity. Usually the communicating orifice is too small for the development of a hernia. When the patient is horizontal, e.g. at night, the fluid in the pouch disappears within the abdominal cavity, but it returns when the erect posture is resumed. The hydrocele cannot be emptied by digital pressure, as this results in an ' inverted ink bottle ' effect at the internal ring. Especially in bilateral cases, ascites or ascitic tuberculous peritonitis should be suspected.

(*d*) **Encysted Hydrocele of the Cord.**—There is a smooth, oval swelling associated with the spermatic cord, which is liable to be mistaken for an irreducible inguinal hernia. If, with gentle traction upon the testis, the swelling moves downwards and becomes less mobile, the diagnosis of hydrocele of the cord is confirmed.

Hydrocele of the canal of Nuck is a condition comparable to the foregoing. It occurs in females, the cyst being in relationship to the round ligament. Unlike a hydrocele of the cord, a hydrocele of the canal of Nuck is always wholly, or partially, in the inguinal canal.

---

[1] Edward Gibbon, 1737–1794, the English historian, who is best known for his ' History of the Decline and Fall of the Roman Empire ', was greatly embarrassed by a large hydrocele. The second time this was tapped the hydrocele became infected, and Gibbon died a few days after the operation. The hydrocele was associated with a large scrotal hernia which, probably, was punctured.

Anton Nuck, 1650–1692. Professor of Anatomy and Medicine, Leiden, Netherlands.

Hydrocele en Bisac.—A rare condition where the hydrocele has two intercommunicating sacs, one above and one below the neck of the scrotum. The upper lies superficial to or partly within the inguinal canal and it may insinuate itself in between the muscle layers.

Complications of a Hydrocele

1. *Rupture* is usually traumatic, but may possibly be spontaneous. On rare occasions a cure results after absorption of the fluid.

2. *Hernia of the hydrocele sac* sometimes occurs in old-standing cases. Tension of fluid within the tunica causes herniation through the dartos muscle (fig. 1512).

3. *Transformation into a hæmatocele* occurs both spontaneously and as the result of trauma (p. 1301).

4. *Calcification* of the sac wall sometimes occurs in long-standing cases.

FIG. 1512.—A hernia of a hydrocele.

Treatment of a Hydrocele.—*Tapping.*—After transillumination, the swelling is made tense by manual compression. A fine trocar and cannula is inserted into an unquestionably translucent area and the fluid evacuated. After a varying interval of weeks or months the sac usually refills. Many patients are content to be relieved at regular intervals in this way. Repeated tapping is liable to be followed by a little oozing into the sac. Deposits of blood on the walls of the sac in time increase its thickness, and so diminish its translucency. After tapping, the testis should always be examined.

Lord's Operation.—This procedure has replaced subtotal excision when the tunica is not thickened. No tissue dissection is performed, no reactionary œdema occurs, bleeding is minimised and recurrence is unlikely as the tunica cannot surround the testis again.

FIG. 1513.—Tapping a hydrocele.

A small incision in between the lines of scrotal blood vessels is made through all layers, including the tunica, well away from the testis. The testis is allowed to prolapse through the wound so that the tunica is totally everted. A series of 10–12 catgut or Dexon sutures are woven radially from the cut edge of the tunica to the reflection of the tunica from the testis and epididymis. When these are tied the whole tunica is bunched into a 'ruff' at the edge of the testis (fig. 1514).

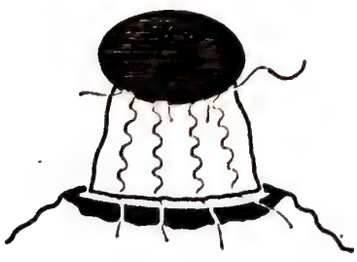

FIG. 1514.—Lord's operation. *(Peter Lord, F.R.C.S., High Wycombe, England and Karger Verlag, Basel, Switzerland.)*

Peter Herent Lord, Contemporary. Surgeon, High Wycombe General Hospital, High Wycombe, Bucks, England.

Subtotal excision necessitates a larger incision, complete delivery of the hydrocele through the wound, excision of the major part of the tunica and the most scrupulous attention to hæmostasis.

Secondary hydrocele is an effusion into the tunica vaginalis that accompanies certain affections of the testis. It is frequently associated with

acute and chronic epididymo-orchitis. It is nearly always present in the syphilitic affections of the testis, and occasionally complicates malignant disease of the organ. A secondary hydrocele rarely attains a large size, and in most instances is lax and does not interfere unduly with the palpation of the testis and its epididymis. Occasionally the question as to whether a hydrocele is or is not secondary to some underlying disease of the testis can be settled only after the contents of the hydrocele have been aspirated.

In the case of acute epididymo-orchitis usually a secondary hydrocele subsides *pari passu* with the primary lesion.

Post-herniorrhaphy hydrocele is a secondary hydrocele that appears after an operation for inguinal hernia in 0·2 per cent. of cases in which there was no evidence of a hydrocele pre-operatively. Possibly this is due to damage of the lymphatic vessels of the tunica vaginalis, which pass with those of the testis, along the spermatic cord, mostly superficial to the blood-vessels.

Hydrocele of a Hernial Sac.—The neck of a hernial sac becomes plugged with omentum or occluded by adhesions, and a hydrocele results.

Filarial Hydroceles and Chyloceles.—As one proceeds from temperate climates towards the Equator, the incidence of vaginal hydrocele increases. Filariasis (p. 44) accounts for 80 per cent. of hydroceles in some tropical countries. In most instances neither are microfilariæ discovered in nocturnal samples of blood, nor is a history of filariasis elicited. Usually filarial hydroceles follow repeated attacks of filarial epididymitis, and develop rapidly or gradually and can be large or small: frequently they are bilateral. In early cases the hydrocele fluid is similar to that found in the idiopathic variety. In cases of some standing, if the fluid is placed in a tall glass, after a few hours a film of liquid fat (chyle) will be floating on the surface. This is rich in cholesterol, and is derived from rupture of a lymph varix into the tunica. The presence of chyle is proof-positive of the filarial origin of a hydrocele. Adult worms of the *Wuchereria bancrofti* have been found in the epididymis removed by operation, or at necropsy on these cases. In long-standing chyloceles dense adhesions form between the scrotum and its contents. Filarial elephantiasis of the scrotum (p. 1313) supervenes in a small proportion of cases.

Treatment.—Acute cases should be treated by rest and aspiration. The more usual chronic cases can be cured by excision of the sac.

Hæmatocele can be either recent, or present as the clinical entity ' old clotted hæmatocele ' (see below).

Recent hæmatocele is usually the result of injury of a small blood-vessel during tapping or aspiration of a hydrocele. Prompt refilling of the sac with considerable pain and tenderness, and poor or absent transillumination, leave no doubt as to the diagnosis. The treatment should be urgent operation, with evacuation of blood and excision or eversion of the sac. If this course is not followed a clotted hæmatocele will almost certainly result.

Acute hæmorrhage into a previously normal tunica vaginalis can result from a blow on the testis. The treatment should be similar to the above for the reasons given, and also because without exploration it is impossible to tell whether or not the testicle is ruptured. Furthermore, a neoplasm can sometimes present in this way.

Old Clotted Hæmatocele.—Curiously, slow hæmorrhage into the tunica vaginalis can occur spontaneously, and apparently painlessly, for most of the patients presenting with an old clotted hæmatocele give neither a history of trauma to the testis nor of pain in the organ. An old clotted hæmatocele simulates a neoplasm of the testis so closely that pre-operative differential diagnosis is sometimes impossible.

Treatment.—Unless exposure of the organ leaves no doubt as to the innocent nature of the swelling, unquestionably orchiectomy should be performed. As a rule it is impossible to be certain of the diagnosis until the mass has been bisected. As

Otto Eduard Heinrich Wucherer, 1820–1873. German Physician who practised in Brazil.
Joseph Bancroft, 1836–1894. Surgeon, General Hospital, Brisbane, Australia.

FIG. 1515.—An old clotted hæmatocele. The long-standing pressure has flattened the testis.

can be seen in fig. 1515, the testicle is often so compressed as to be virtually functionless, so the responsibilities of removing it unnecessarily are not great. Russell Howard, renowned in his day as a surgical diagnostician and teacher, was wont to recount how he had performed orchiectomy for old clotted hæmatocele on the mistaken diagnosis of malignant testis on three consecutive occasions.

CYSTS CONNECTED WITH THE EPIDIDYMIS

1. Cysts of the Epididymis.—A cyst of the epididymis, filled with crystal-clear fluid (as opposed to the barley-water-like fluid of a spermatocele or the amber-coloured fluid of a vaginal hydrocele), is a common condition.

Ætiology.—A cyst of the epididymis is due to cystic degeneration of:

(*a*) The paradidymis (or organ of Giraldes), which is the most likely cause.

(*b*) The appendix of the epididymis (pedunculated hydatid of Morgagni) (fig. 1516).

(*c*) The appendix of the testis (sessile hydatid of Morgagni).

(*d*) The vas aberrans (of Haller).

Clinical Features.—Cysts of the epididymis usually are found during middle life and, due no doubt to their congenital origin, they are often bilateral. They are tense, as opposed to the softness of a spermatocele, and they consist of an aggregation of a number of small cysts which on careful palpation feel like a bunch of tiny grapes. Cysts of the epididymis are situated *behind* the body of the testis, and on transillumination, because of the numerous septa, their brilliant translucency is finely tesselated, giving an appearance like that of a Chinese lantern.

Treatment.—As epididymeal cysts are multilocular, aspiration is useless. If causing discomfort, which is unusual, they must be excised. They should not be operated on without considering the fact that excision will almost certainly cause infertility from blockage.

Cyst of an appendage of the testis is a separate clinical entity. It forms a small globular swelling at the superior pole of the testis; it is usually unilateral, and when pedunculated (fig. 1516) it is liable to undergo axial rotation (p. 1295). The treatment of this variety of cyst is removal by ligation and severance of its pedicle.

FIG. 1516.—Cyst of the pedunculated hydatid of Morgagni.

2. Spermatocele is a unilocular retention cyst derived from some portion of the sperm-conducting mechanism of the epididymis.

Clinical Features.—A spermatocele is nearly always situated in the head of the epididymis, and is therefore above and behind the body of the testis. Filled with fluid resembling barley water and containing spermatozoa, the swelling is typically softer than other cysts occurring within the scrotum but, like them, is translucent. Spermatoceles

Russell John Howard, 1875–1942. Surgeon, The London Hospital.
Joachim Albin Cardazo Cazado Giraldes, 1808–1875. Professor of Surgery, Paris.
Albrecht von Haller, 1708–1777. Professor of Anatomy, Physiology, Surgery, and Botany, Göttingen, Germany.

give rise to few symptoms, and are usually small and unobtrusive. Less frequently they are large enough to attract notice.[1]

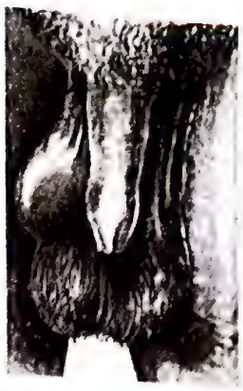

FIG. 1517.—A large spermatocele.

Treatment.—Small spermatoceles can be ignored. Larger ones, if causing symptoms, can be aspirated or excised via a scrotal incision. The thin coverings of the cyst are carefully peeled off, layer by layer, and any residual attachments are ligated and divided.

ACUTE EPIDIDYMO-ORCHITIS

In many instances inflammation remains confined to the epididymis, in which case it is referred to as epididymitis; when the infection spreads to the body of the testis the condition is known as epididymo-orchitis.

Mode of Infection.—As a rule infection reaches the epididymis via the lumen of the vas, and affects the globus minor first. It is secondary to infection of the urethra, prostate and seminal vesicles. Blood-borne infections affect the globus major of the testis primarily.

Clinical Features.—The initial symptoms are those of acute prostatitis (p. 1251). Some days later an ache in the groin with some increase in fever heralds the onset of epididymitis. Severe pain and swelling of the testis occurs rapidly: the scrotal wall becomes red, œdematous and shiny. The epididymis may become adherent to the scrotal skin and may soften and, later, discharge. Resolution is heralded by scaling of the scrotal skin. Complete resolution of the swelling in the epididymis may take 6–8 weeks.

Acute epididymitis due to *Esch. coli*, streptococcus, staphylococcus or proteus is a not uncommon clinical entity. As a rule there is no evidence of urethritis. Especially in *Esch. coli* infection, it is sometimes unaccompanied by infection of the urine (an initial specimen should be sent for bacteriological examination). In the absence of any local cause, the infection is assumed to be blood-borne.

Acute epididymitis can follow any form of urethral instrumentation. It usually occurs when there is an associated infection in the prostate. Indwelling catheters encourage organisms normally found in the distal urethra to migrate upwards.

Epididymitis complicating non-gonococcal urethritis is more frequent than it is in gonorrhœa, and unless correct antibiotic therapy (p. 1267) is given early, suppuration is usual.

Acute gonococcal epididymitis is much less common than formerly, as a result of the antibiotic treatment of acute gonorrhœa. Epididymitis usually commences during the second or third week of gonococcal posterior urethritis. In 90 per cent. of cases the infection is unilateral. When the epididymis becomes involved the urethral discharge lessens and pain commences in the testis. On the following day the urethral discharge ceases, but the urine is hazy with pus cells. The temperature rises to 38·9° to 39·5° C, and the patient feels so ill that he goes to bed. About the third day the skin of the scrotum often becomes reddened and adherent to the globus minor, but in cases where the gonococcus is the sole infecting organism suppuration does not occur. After the fifth day the symptoms commence to abate, and by the eighth to tenth day the condition subsides. Induration of the globus minor some-

[1] Sometimes the patient may believe that he has a third testicle (fig. 1517). It is recorded that in the fourteenth century the Pope granted a petition from a gentleman to marry two wives because he possessed three testicles.

times persists for months. In cases of persistent infection of the corresponding vesicle, subacute attacks of recurrent epididymitis are not infrequent.

Epididymitis from Retrograde Passage of Urine.—Epididymitis can develop during an unusual exertion or violent strain while the bladder is full, and it is caused by the urine being forced along the vas deferens. The degree of inflammation that results depends upon whether the urine is infected, or if there is an active or latent infection in the prostate or seminal vesicles. This 'reflux' epididymitis can also occur due to the presence of a stricture in the urethra.

Acute Tuberculous Epididymitis.—In cases where the vas is thickened and there is little response to the usual treatment, the possibility of the infection being due to tuberculosis of the epididymis, which is not rare, must receive due consideration.

Acute epididymo-orchitis of mumps develop in about 18 per cent of males suffering from mumps, usually as the parotid inflammation is waning. The testis becomes swollen and painful. Rarely, the testicular precede the salivary manifestations. Resolution or fibrosis, as opposed to suppuration, nearly always occurs, but in 55 per cent. of cases atrophy of the testis follows. It often takes many months for signs of testicular atrophy to become apparent. A small incision into the tunica vaginalis and drainage, if undertaken early in the attack, prevents this atrophy and relieves the intense pain. It is often stated that the body of the testis is alone involved, but the epididymis is also acutely inflamed, as has been witnessed at operation. Especially in infants, epididymo-orchitis of mumps can occur without parotitis.[1] Partial atrophy is commonly associated with a tendency to recurrent pain in the testis.

Acute post-operative epididymitis was a serious and frequent complication of prostatectomy. It can be abolished by prophylactic division of the vasa deferentia (p. 1241), and has been greatly reduced by closed drainage and catheter care which have reduced the rate of post-operative urinary infection.

Other causes include Bornholm disease,[2] Brucellosis, and Lympho-granuloma venereum.

FIG. 1518.—Treatment of acute epididymo-orchitis. Broad adhesive strapping is applied to the thighs to support the testicles.

Treatment.—The patient must be kept in bed until the acute symptoms have abated. A broad spectrum antibiotic such as tetracycline should be given (500 mg. q.d.s.) until the result of the urine culture is available. The scrotum is supported on a sling formed by broad adhesive plaster attached across the thighs (fig. 1518). Upon the sling is placed a nest of cotton wool, and in this the inflamed organ rests and cooling lotions are applied. The urine is rendered alkaline, and a high fluid intake is necessary. Antibiotic treatment should be continued for two weeks or until the inflammation has subsided. If suppuration occurs, drainage is necessary. Atrophy of the testis may follow as a sequela in any case of epididymo-orchitis.

CHRONIC EPIDIDYMO-ORCHITIS

Chronic Tuberculous Epididymitis.—Nearly 90 per cent. of cases of chronic epididymo-orchitis are tuberculous, and the great majority commence insidiously.

Ætiology.—The frequency with which the globus minor is first attacked indicates that infection is commonly retrograde along the vas deferens from

[1] A complement fixation test for the virus of mumps is sometimes positive.
[2] Epidemic myalgia. Bornholm is a Danish island in the Baltic sea.

Sir David Bruce, 1855–1931. Major-General, Royal Army Medical Service.

an infected seminal vesicle. Blood-borne infection commences in the globus major.

FIG. 1519.—Tuberculous epididymitis.

Clinical Features.—A slight ache in the testis or a trivial injury, calls the patient's attention to the swelling in relation to the testis. An early manifestation is a discrete, indurated, slightly tender nodule in the globus minor—rarely in the globus major. As the disease progresses other nodules appear, and eventually the entire epididymis becomes involved, and is felt as a firm, craggy, often painless, mass situated behind the testis, which feels normal. In 30 per cent. of cases a lax secondary hydrocele is present. When the testis is anteverted, these changes are found in front of the testis. The vas on the affected side sometimes becomes 'beaded' due to submucous tubercles. Rectal examination reveals a thickened, and later an irregular, indurated seminal vesicle of the corresponding side, and sometimes of the contralateral vesicle as well. The prostate in advanced cases contains one or more discrete nodules. In 20 per cent. of cases the patient first presents himself with a 'cold' abscess in the lower and posterior aspect of the scrotum or with a discharging sinus, which may have healed and reopened several times. Untreated, after a varying time (from a few months to a year or so), the contralateral epididymis becomes similarly diseased. The body of the testis remains uninvolved for a long period, often years.

In two-thirds of the cases there is either active tuberculosis in the renal tract or evidence of previous disease. In the remainder the patient is apparently healthy.

In all cases of chronic epididymitis the urine is examined for tubercle bacilli, if necessary on several occasions, and pyelography should be undertaken. The chest is X-rayed (evidence of disease in about 50 per cent.). Culture of the semen can also be a useful means of confirming the tuberculous nature of an epididymitis.

Treatment.—When tuberculous epididymitis is secondary, the primary lesion should receive priority. The epididymitis may well resolve during the treatment.

When renal tuberculosis is present, the renal lesion is treated as detailed on p. 1184. Rarely active pulmonary tuberculosis will be present.

Treatment with streptomycin and associated anti-tuberculous drugs (p. 32) is less effective in genital tuberculosis than in urinary tuberculosis. If there is no sign of resolution within two months, epididymectomy or orchiectomy is advisable. Subsequently, in the absence of evidence of active tuberculosis elsewhere, a further three months' course of suitable and anti-tuberculous drugs is all that is necessary. Care of the patient in a sanatorium is an insurance that he will adhere to the treatment.

Chronic non-tuberculous epididymitis either follows an acute attack or is chronic from the commencement. The condition is difficult to dis-

tinguish from tuberculosis, but as a rule the epididymis in non-specific epididymitis is larger and smoother. It is essential to exclude a urethral stricture.

Treatment.—In most cases associated posterior urethritis, vesiculitis, or prostatitis must be eradicated. If the condition fails to resolve after six to eight weeks of conservative treatment and antibiotic therapy, epididymectomy or orchiectomy may be needed.

ORCHITIS

Syphilitic Orchitis.—Syphilis attacks the body of the testis, and like other late manifestations of the disease, all three varieties have become uncommon, interstitial fibrosis the least so. The three varieties of syphilitic orchitis are:

(*a*) *Bilateral orchitis* occurs in congenital syphilis (p. 42).

(*b*) *Interstitial fibrosis* is bilateral, symptomless, and leads to gradual destruction of the seminiferous tubules. The testes are not enlarged. They are firmer than normal, and there is a gradual loss of testicular sensation. In bisecting the testis, irregularly distributed streaks of fibrosis are seen traversing the parenchyma.

(*c*) *Gumma.*—The condition is nearly always unilateral. The body of the testis enlarges slowly and painlessly. At this stage it feels extremely hard. Testicular sensation is lost, and there is nearly always an associated secondary hydrocele. Later there is softening anteriorly and the skin of the scrotum becomes involved, and a gummatous ulcer forms. If the response to treatment is not rapid it is better to perform orchiectomy than risk the possibility of overlooking a neoplasm with purely coincidental positive serological tests.

Leprous Orchitis.—Over 25 per cent. of male lepers have testicular atrophy due to fibrosis engendered by the direct action of the *Mycobacterium lepræ*, and in 20 per cent. of those so affected the orchitis is associated with gynæcomazia.

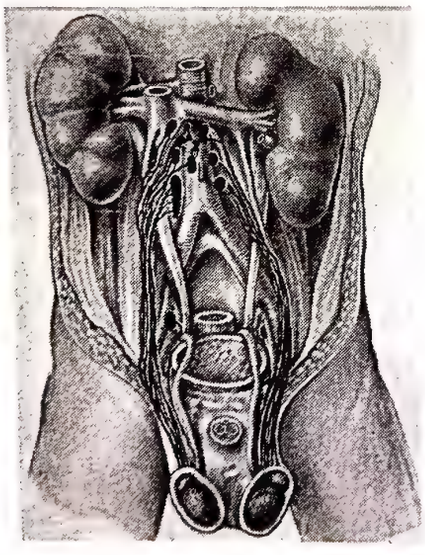

FIG. 1520.—The lymphatics of the testes. (*After Rouvier.*)

NEOPLASMS OF THE TESTIS

The lymphatics of the testis run upwards in the spermatic cord, and, passing through the internal inguinal ring, they branch fountain-wise (behind and adherent to the posterior peritoneum) towards the para-aortic lymph nodes in the region of the origin of the spermatic vessels. Above this level the lymph drains into the thoracic duct which extends through the mediastinum to the left supraclavicular fossa, where it drains into the left innominate vein. Lymphatics from the medial side of the testis may run with the artery to the vas and drain into a lymph node at the bifurcation of the common iliac artery.

When lymphatic spread of a neoplasm occurs, contralateral lymph nodes can be affected. Inguinal lymph nodes are only affected if the scrotum is involved.

MALIGNANT NEOPLASMS OF THE TESTIS

About 99 per cent. of neoplasms of the testis are malignant, and though they only constitute about 1–2 per cent. of malignant tumours in the male, they are one of the commonest forms of cancer in young adult males. Maldescent undoubtedly predisposes to malignancy (p. 1292). It is curious that a testicle bearing such a tumour, contained as it is in a bag of skin bereft of fat, and thus more readily accessible to the examining fingers than a tumour of

any other organ in the body, only too often escapes detection until it has metastasised. In this connection, perhaps the worst error is to plunge a trocar and cannula into the enlarged testis in the belief that it is a hydrocele, for want of applying the test of translucency. This has been done more often than the reader may be inclined to believe.

Types of Tumour.—Tumours of the testis are classified as follows:

(1) Seminoma	40 per cent.
(2) Teratoma	32 per cent.
(3) Combined Seminoma and Teratoma	14 per cent.
(4) Interstitial tumours	1·5 per cent.
(5) Lymphoma	7 per cent.
(6) Other tumours	5·5 per cent.

The percentage of the first two subdivisions varies in different series. Those series emanating from hospitals for Service personnel show a higher percentage of teratomata. The reason for this is that patients in such hospitals are likely to be of a younger age-group than found in the community at large; **the peak incidence** of teratoma being between twenty and twenty-five years of age, while that of seminoma is between thirty and thirty-five. Seminoma has only once been recorded before puberty.

Seminoma commences in the mediastinum of the testis, and as it increases in size the neighbouring testicular tissue is compressed (fig. 1521). Macroscopically the enlarged testis is firm and smooth, and on section homogeneous and pink or cream in colour. Occasionally fibrous septa give it a lobulated appearance. In rapidly growing tumours areas of necrosis are sometimes present, in which case the consistency is variable.

FIG. 1521.—Seminoma of the testis.

Histologically it is composed of rounded, slightly oval cells with clear protoplasm and large rounded nuclei containing acidophile nucleoli. The cells are arranged in sheets separated by a fine fibrous stroma. Derived from the seminiferous tubules, the cells resemble spermatocytes. Stromal and tumour infiltration by lymphocytes suggest a good host reaction (? autoimmune reaction) and tends to improve the prognosis.

A seminoma metastasises almost exclusively by the lymph vessels to lymph nodes; only occasionally does it disseminate by the blood-stream and give rise to secondary deposits in other situations.

Teratoma arises in the rete testis from toti-potent cells; accordingly, elements of ectoderm, mesoderm, or endoderm are often represented. Usually one of these predominates and attains malignancy. The tumour varies in size from that of a peanut to that of a coconut, and even when large, as it is moulded by the tunica vaginalis, the shape of the testis is more

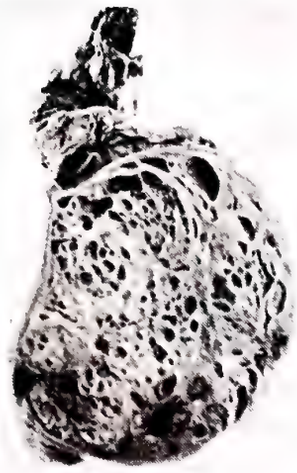

FIG. 1522.—Teratoma of the testis containing solid and cystic areas. (*Dr. Keith Simpson, London.*)

or less retained but the surface is usually slightly irregular.

The most usual variety[1] is yellowish in colour and shows cystic spaces (fig. 1522) containing gelatinous fluid. Cartilaginous nodules are often present.

Histology.—The Testicular Tumour Panel have classified teratomas as follows:

(1) **Teratoma Differentiated (T.D.)** (1 per cent.[2]).—The best-known variety of this type of tumour is a dermoid cyst. If a teratoma has no histologically recognisable malignant components, it is termed differentiated, but it cannot be considered to be benign, because such growths may have metastasised. Many patients have been cured following simple orchiectomy. With radical orchiectomy the outlook is improved, the five-year survival rate being over 80 per cent.

(2) **Malignant Teratoma Intermediate (M.T.I.—A and B)** (30 per cent.), consisting of definitely malignant and incompletely differentiated tissues. In type A some mature tissue will be seen. Type B is more malignant and no fully differentiated tissue can be found. The tumours are mostly radio-resistant (see prognosis, p. 1312).

(3) **Malignant Teratoma Anaplastic (M.T.A.)** (1·5 per cent.) is composed of quite undifferentiated cells, which are radio-resistant.

(4) **Malignant Teratoma Trophoblastic (M.T.T.)** (1 per cent.) contains within the other tissue types a syncytial cell mass with malignant villous or papillary cytotrophoblast (choriocarcinoma). In some cases it is associated with the production of chorionic gonadotrophin and gynæcomazia. Spread is by the blood-stream as well as by lymphatics while the primary tumour is small, and it is often described as the most malignant tumour known. It is usually radio-resistant. Methotrexate may produce a temporary regression but death results within months. However, a choriocarcinoma is frequently associated with teratoid tissue in the form of a teratochoriocarcinoma, and patients with this hybrid choriocarcinoma have survived five years following *radical* orchiectomy (p. 1311).

Interstitial Cell Tumour.—A tumour of the testis arising in the interstitial cells of Leydig occurs at an early age or the prime of life, and arises either in the cells of Leydig or those of Sertoli.

A Leydig cell tumour masculinises; a Sertoli cell tumour feminises. For clinical reasons these tumours are classified as those occurring before or after puberty.

Prepubertal tumour is characterised by an excessive output of androgen, which is responsible for sexual precocity and extreme muscular development. This results in an infant Hercules, in all respects similar to the condition produced by an adrenal cortical tumour (see p. 626), except that on palpation a swelling of the testis can be elicited. Exceptionally the tumour is bilateral, but it must be noted that in this condition the contralateral normal testis frequently becomes hypertrophied. In so far as the neoplasm is concerned, removal of the testis is curative; in some cases the symptoms regress, in others (where the contralateral testis is hypertrophied) the regression is incomplete.

Post-Pubertal Tumour.—In a high percentage of cases the tumour arises in the cells of Sertoli, and consequently the output of feminising hormone becomes excessive. Gynæcomazia, loss of libido, and aspermia result; in such cases the Aschheim-Zondek test is positive. As a rule the tumour is innocent, and orchiectomy is curative.

Human Chorionic Gonadotrophin in a 12-hour collection of urine, may be estimated by a radio-immuno assay technique. It is likely to be very high in cases containing chorionic elements (T.T.). Normal levels are up to 100 iu HCG.

---

[1] Formerly known as 'fibro-cystic' disease.
[2] The percentages given refer to all cases of testicular neoplasm.

Franz von Leydig, 1821–1908. Professor of Histology, Bonn, Germany.
Enrico Sertoli, 1842–1910. Professor of Experimental Physiology, Milan, Italy.
Selmar Aschheim, 1878–1965. Formerly Honorary Professor of Gynæcology, University of Berlin.
Bernhard Zondek, 1891–1966. Professor of Obstetrics and Gynæcology, Hadassah Medical School, Hebrew University, Jerusalem, Israel.

Clinical Features of Testicular Tumours.—Various clinical types are met with.

1. **Typical.**—The patient may not seek advice until four to six months after the first symptom, which is enlargement of the testicle. A sensation of heaviness is complained of when the testis has reached two to three times its normal size. Pain is complained of in only about 30 per cent. of cases (Fergusson). There is a history of trauma to the affected side in over 10 per cent. It is generally conceded that injury merely calls attention to the testicular enlargement and in no way initiates the neoplasm.

On examination the body of the testis is found to be enlarged, firm, smooth, and heavy. Later one or more softer bosses may be palpable. In no other disease is testicular sensation lost so early or so completely, but the greatest gentleness must be exercised in eliciting this sign for fear of disseminating the neoplasm. A secondary hydrocele is present in 10 per cent. of cases; it is usually lax, and seldom obscures the enlarged testis. The epididymis is normal at first; later it becomes so flattened or incorporated in the growth that it is imperceptible. The spermatic cord remains normal for a considerable time. It then becomes thickened, due to cremasteric hypertrophy and enlargement of testicular vessels. The vas is never thickened. Rectal examination reveals no abnormality in the prostate or seminal vesicles.

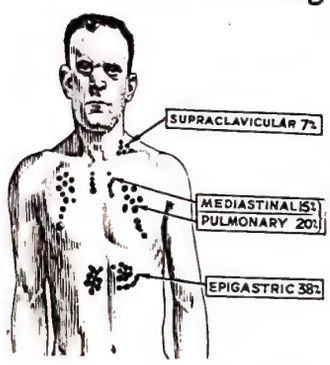

FIG. 1523.—Distribution of metastases in teratoma of the testis.

Next, the sites of possible metastases (fig. 1523) should be examined. The abdomen is palpated for secondary retroperitoneal deposits, their most usual situation being just *above the umbilicus* on the same side, the opposite side, or both sides. The left supraclavicular region is examined, and occasionally the first presenting sign is an enlarged supra clavicular lymph node. An X-ray of the chest may show metastases in the lungs, particularly in cases of teratoma (fig. 1524).

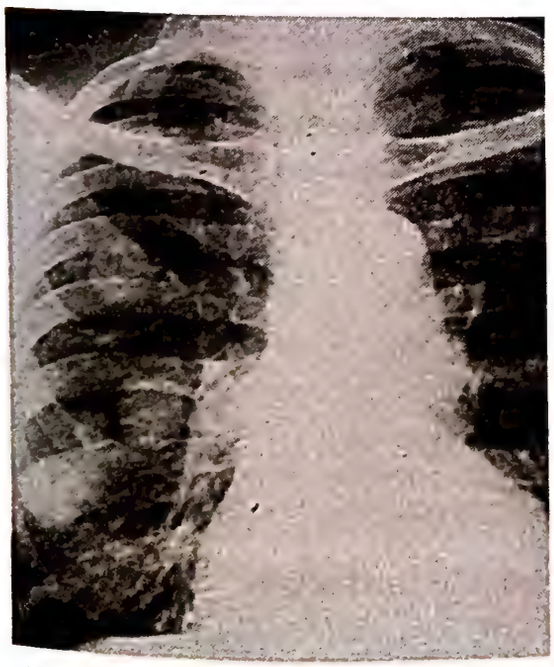

FIG. 1524.—'Cannon ball' metastases from a testicular tumour.

2. **When the predominant symptoms are due to metastases:** (*a*) with a seminoma the patient complains of abdominal or lumbar pain, and on examination a mass is discovered in the epigastrium. (*b*) Pulmonary metastases from a teratoma of the testis give rise to few, if any, early symptoms. Later the patient may complain of pain in the chest, dyspnœa, and perhaps hæmoptysis.

In either case the enlargement of the

John Douglas Fergusson, Contemporary. Surgeon, St. Paul's Hospital, London.

testis may not have been noticed by the patient, and is discovered only by a thoughtful clinician. Sometimes the primary growth is tiny and will only be discovered by operative exploration.

3. **Atypical Cases.**—The variations are:

(*a*) Some cases (7 per cent.) simulate *epididymo-orchitis*; there may even be organisms in the urine. Failure to respond to a short sharp course of antibiotics should make one say ' this could be a tumour ' and action must be taken. Rarely, patients will present with severe pain and acute swelling due to a hæmorrhage. Between 1 to 5 per cent. of cases have gynæcomastia (mainly the teratomas).

(*b*) *The Hurricane Type.*—Metastases from a highly malignant tumour bring about a fatal termination in a matter of weeks (Gordon-Taylor).

(*c*) *The Slowly Growing Type.*—In a few cases of teratomas, the patient notices an increasing enlargement of the testis for two or three years.

Management of a Suspected Case of Neoplasm

The action to be taken when the clinical diagnosis is made is:

(1) Collect a 12-hour sample of urine for gonadotropin estimation by radio-immune assay (normal= < 100 iu HCG).
(2) Take a chest X-ray to exclude secondary deposits.
(3) Orchiectomy (or exploration).
(4) Confirmation of pathology by serial histology.
(5) Radiography (I.V.P. and Lymphangiography).
(6) Radiotherapy.

Orchiectomy (retrograde simple[1] orchiectomy).—This should be done at once. Through an inguino-scrotal incision the inguinal canal is opened to display the spermatic cord, which is divided and ligated at the level of the internal inguinal ring. The spermatic cord and the testis are then removed from above downwards by separating them from their attachments. The wound is closed, and radiotherapy starts as soon as the pathology is confirmed and the sutures have been removed.

Exploration.—On occasion when the clinical diagnosis is in doubt, delay is still dangerous, and nothing is lost by exposing the testis first, providing a ' soft ' clamp is placed across the cord above to prevent dissemination. The testis may have to be split open and any doubtful material subjected to immediate frozen section. Wedge biopsy without frozen section and needling should not be attempted for fear of involving the scrotum and opening up an alternative way of lymphatic spread (to inguinal lymph nodes) (p. 1306).

Confirmation of Pathology.—The pathologist will report the type and grade of the tumour (p. 1308).

Radiography should be used as follows:

(*a*) Pre-operative X-ray of the chest to exclude metastases.

(*b*) Excretory urography (I.V.P.). This has two purposes: (1) Protection of kidney from radiotherapy, for besides ascertaining the function of the

[1] *Simple,* as opposed to the radical operation p. 1311.

Sir Gordon Gordon-Taylor, 1878–1960. Surgeon, Middlesex Hospital, London.

kidneys, their position must be marked out so that they may be shielded during irradiation in order to prevent radiation nephritis and hypertension. (2) Detecting the presence and extent of retroperitoneal metastases by the displacement of the ureters or deformity of a renal pelvis. Changes in radiographs after irradiation may indicate the radio-sensitivity of the tumour.

(c) Lymphangiography can demonstrate secondary deposits in para-aortic lymph-nodes. Its greatest value lies in outlining enlarged nodes which can be observed during radiation for shrinkage.

Radiotherapy.—Radiotherapy has made an enormous difference to the prognosis in testicular tumours. Most, but not all, seminomas are highly radio-sensitive. Teratomas are less sensitive. Well over 80% of patients suffering from seminoma of the testis without pulmonary metastases survive more than five years after simple orchiectomy followed by radiotherapy.

From its inception, radiotherapy of tumours of the testis has been based on the assumption that retroperitoneal lymphatic metastases have occurred whether or not they are palpable. Such irradiation should be given by a cobalt or linear accelerator X-ray unit to permit the desired deep dose to be given in shorter time, with greater certainty, with less injury to superficial tissues, and with less general reaction than is possible with machines of lower voltage. When there is no clinical or radiological evidence of metastases the radiation is confined to the area between the scrotum and the 10th dorsal vertebra, with suitable screening of the remaining testis. In patients who are eager to have more children the remaining testis is shielded by lead blocks and moulds. Even so there is some danger of mutations. Only careful follow-up of descendants will show whether this procedure is the correct one. The average dose is 3,000 rad for a seminoma, and 4,500 rad for a teratoma, given over some five or six weeks. It may take longer if interrupted by an excessive fall in the platelet count.

In more advanced cases radiotherapy is given through one inguinal, four abdominal, two mediastinal and two left supraclavicular portals. Chlorpromazine may be given to control the vomiting of radiation sickness, so common in patients receiving radiotherapy in high dosage.

Pulmonary Metastases.—Sometimes irradiation results in regression, but almost invariably this is followed by fresh deposits. Frequently the dose of X-rays converts a condition that was symptomless into one accompanied by severe pulmonitis, discomfort and respiratory deterioration, and it is doubtful if the X-ray treatment of pulmonary metastases is worth while (Cox).

Block Dissection of Retroperitoneal Lymph Nodes (radical operation).—With improvements in radiotherapeutic apparatus and techniques this operation is not often employed. When it is attempted, in up to 25% of cases some nodes are inoperable; 50–60% show no node involvement.

Principles of Technique.—An extensive retrograde exposure is required to allow the removal of spermatic vessels and lymphatics from the internal ring up to the region of the renal vessels (Lymphatics, p. 1306). The vas is transected above the bladder. Only part of the incision is made to start with, for through this the peritoneum is opened and the upper abdomen is explored to exclude very high fixed lymph nodes which would make the case inoperable.

Robert Cox, Contemporary. Surgeon, Westminster Hospital, London.

Chemotherapy.—In disseminated seminoma and teratoma, chemotherapy may be given a trial and perhaps in 20% of cases some benefit may be achieved. Methylhydrazine 100 mg b.d. orally has produced some good results in anaplastic teratoma. Mithramycin given intravenously to a dose of 600 μg is also being used with some hopeful reports, while methotroxate, or a combination of this drug with Actinomycin D and chlorambucil, is most useful in chorionic teratoma.

Prognosis of Testicular Tumours.—The histological appearance of the tumour and the presence or absence of metastases at the time of operation are the two main factors in assessing prognosis:—

Seminoma.—No evidence of metastases; with orchiectomy and radiotherapy 85 per cent. survive five years. If metastases are present, only 25 per cent. survive five years.

Teratoma.—The histological appearances are very important (p. 1308). Excluding Teratoma Differentiated, if no metastases are present, up to 40 per cent. survive five years. If metastases are present only 1 to 5 per cent. survive three years.

Testicular tumours in children most commonly appear during the first year of life and are exceedingly rare after the third birthday. The tumours at this time of life are teratomas, many of these being anaplastic (T.A.) in which event, in spite of treatment, the patient dies within a few months. Now and then the tumour proves to be differentiated (T.D.) when, following orchiectomy alone, the prognosis is exceptionally good. On rarer occasions still, the tumour proves to be an interstitial cell tumour (p. 1308), in which case, following orchiectomy, the prognosis is also excellent.

Tumours of the Epididymis.—Mesothelioma is a unique innocent tumour that usually springs from the globus minor: most examples have been about the size of a cherry. Sarcoma, and very rarely carcinoma, arise in the epididymis, and those who put their trust in the aphorism that swellings of the epididymis are invariably inflammatory may one day rue it. If the swelling in question does not respond to rest and antibiotic therapy quickly, it should be treated by epididymectomy or, if obviously malignant, by orchiectomy.

THE SCROTUM

Prepenile scrotum is an exceedingly rare congenital condition. The scrotum, suspended from the mons pubis, is situated anterior to the penis.

Idiopathic Scrotal Œdema is described on page 1296.

FIG. 1525.—Fournier's gangrene.
(Max Pemberton, F.R.C.S., London.)

Idiopathic gangrene of the scrotum (*syn.* Fournier's gangrene) is uncommon but fearful in effect. It is a vascular disaster of infective origin. The three cardinal characteristics of this disease are: (1) sudden appearance of scrotal inflammation in the midst of apparently good health; (2) rapid onset of gangrene (fig. 1525); (3) absence of any cause in over half the cases. It has been known to follow minor injuries or procedures in the perineum, such as a bruise, scratch, dilatation of stricture, injection of anal fissure or opening a periurethral abscess.

The hæmolytic streptococcus (sometimes micro-ærophilic) associated with other organisms (staphylococci, *E. coli*, *Cl. Welchii*) set up a fulminating inflammation within the scrotal subcutaneous tissues that results in obliterative arteritis of the arterioles supplying the overlying skin (cf. gangrene of the abdominal wall, p. 1102).

Jean Alfred Fournier, 1832–1914. Founder of the Venereal and Dermatological Clinic, Hôpital St. Louis, Paris.

The clinical features are: sudden pain in the scrotum, prostration, pallor, and pyrexia. At first only the scrotum is involved: still unchecked, if the patient survives, the cellulitis spreads along those planes so well known in superficial extravasation of urine (p. 1264). Sometimes the entire scrotal coverings slough, leaving the testes hanging exposed, bared to their tunica, though, remarkably, free from gangrene.

Treatment.—Pending the bacteriological report, chloramphenicol or Gentamycin and Ceporin are the antibiotics of choice as the organisms are usually sensitive.

The scrotum should be incised. If gangrene has commenced, wide excision of all sloughing areas saves time, rids the patient of scrotal tissue that is doomed, provides the freest possible drainage, and stops the spread of gangrene.

Filarial elephantiasis of the scrotum is confined to those who dwell, or have dwelt, in tropical and subtropical countries, and is due to obstruction of the lymphatic vessels of the pelvis by *Wuchereria bancrofti* (p. 1301), with superadded infection and lymphangitis. The earliest manifestation is an attack of funiculitis with the development of a secondary hydrocele. Repeated attacks cause the scrotum to remain œdematous and the scrotal skin and subcutaneous tissue greatly thicken. In long-standing cases the scrotum becomes immense, and the penis is buried within it (fig. 1526).

FIG. 1526.—Elephantiasis of the scrotum, burying the penis. *(Professor M. Bahadur Khan, Hyderabad, India.)*

Treatment.—There is no medical treatment for the condition. The principle of operative treatment is the construction of new lymphatic pathways. This can be achieved by constructing cellular-cutaneous bridges of generous size uniting the scrotum to the thigh, for the purpose of permitting the scrotal lymph to be absorbed via the uninvolved thighs. In very advanced cases excision of all involved skin together with implantation of the testes into the thighs and skin grafting of the bared shaft of the penis, if necessary, is the only curative treatment. It should be especially noted that the *inner layer* of the prepuce is rarely involved: it should therefore be spared and in many instances it can be utilised to cover the bare shaft of the penis (Bowesman). In all cases concomitant hydroceles are dealt with by excision of the sac at the time of the operation.

Non-filarial elephantiasis can be acquired in non-tropical as well as tropical climates, and it is consequent upon fibrosis of lymphatic vessels due to lymphogranuloma venereum. Non-filarial elephantiasis never reaches the extravagant proportions of tropical elephantiasis. There is no effective medical treatment: the scrotum-thigh cutaneous tunnel operation described above is recommended.

FIG. 1527.—Sebaceous cysts of the scrotum.

Sebaceous cysts are common in the skin of the scrotum. They are usually small and multiple (fig. 1527). Sometimes a large sebaceous cyst suppurates, and when it does so the odour emitted is particularly obnoxious. A suppurating scrotal sebaceous cyst may be mistaken for a carcinoma of the scrotum, which calls to mind Cock's peculiar tumour (p. 104).

Carcinoma of the Scrotum.—In the last century squamous epithelioma of the scrotum was rife amongst chimney sweeps.[1] With improved working

[1] This disease was first described in 1775 by Percivall Pott (1714–1788), Surgeon, St. Bartholomew's Hospital, London. In those days the chimney sweep's apprentice climbed up and down the chimney.

Charles Bowesman, Contemporary. Formerly Surgical Specialist, Colonial Medical Service, Kumasi, Ghana.
Edward Cock, 1805–1892. Surgeon, Guy's Hospital, London.

conditions, this occupational disease ceased to exist in as far as chimney sweeps were concerned, but with the mechanisation of the cotton industry, lubricating oil from the spinning jenny soaked the crutch of the mule spinners' trousers, and proved more carcinogenic than soot. Now that a lubricating oil free from impurities has been substituted it is hoped that carcinoma of the scrotum will no longer attack[1] mule spinners in particular. A few cases still occur in tar and shale oil workers, but in the majority of cases encountered at the present time there is no known ætiological factor. It is remarkable that, in contradistinction to carcinoma of the penis, carcinoma of the scrotum is almost unknown in India and Asiatic countries.

FIG. 1528.—Carcinoma of the scrotum with bilateral metastases in the inguinal nodes. (*Department of Medical Photography, Cardiff Royal Infirmary.*)

Clinical Features.—The growth commences in a wart or an ulcer (fig. 1528). As it extends it may involve the underlying testis.

Treatment.—The growth, together with a considerable margin of healthy tissue, is excised by diathermy. If, as is often the case, the inguinal lymph nodes are enlarged and do not subside with antibiotic treatment, a block dissection of these nodes, and of the external iliac nodes, should be carried out, usually on both sides.

MALE INFERTILITY

Causes.—These are as follows:

1. *Impotence* due to (*a*) malformations or loss of the penis; (*b*) psychic causes; (*c*) chromosome defects.

2. *Oligospermia or aspermia* due to small (fibrotic) or soft (partially atrophic) testes resulting from mumps (quarter of cases), varicocele (p. 1296), cryptorchism, over-exposure to X-rays, and occasionally other varieties of bilateral epididymo-orchitis.

3. *Aspermia Due to a Faulty Sperm-conducting Mechanism.*—Leading examples are (*a*) urethral fistula, (*b*) tight urethral stricture, (*c*) obliteration by scar tissue of both common ejaculatory ducts or both vasa deferentia. Fifteen per cent. of all cases of infertility are due to gonorrhœa, (*d*) absent vasa and vesicles.

Investigation includes: (*a*) three sperm counts at weekly intervals, and an adjudication of the average; (*b*) testicular biopsy; (*c*) plasma or urinary gonadotrophin estimations, plasma testosterone; (*d*) search for sperm antibodies in cases of infertility with normal counts; (*e*) chromosome studies.

Treatment.—(1) Avoid wearing tight pants (see p. 1297). (2) Cold bathing of the scrotum. (3) Clomiphene in cases of low FSH levels and maturation defect. (4) Oral testosterone (mesterolone 100 mg daily) in patients with a low count, relatively normal semen and low plasma testosterone. Or fluoxymesterone (5 mg daily) where motility is reduced. (5) Vitamin B_{12} has been reported to improve semen morphology. (6) Operation for varicocele, if present, and if there is a low count and low motility (p. 1297). (7) Epididymo-vasotomy in cases of obstruction, when vas is proved patent and testicular biopsy is normal:

Operation.—The vas is divided at least 2·5 cm above the portion considered to be obliterated, and in order to make certain of its patency, the proximal end is catheterised with a suitably-sized piece of silkworm gut, and patency down to the urethra proved by the injection of a weak solution of methylene blue while observing the verumontanem with a urethroscope. The silkworm gut is removed and the free end of

[1] As it may take up to twenty years for the result of exposure to carcinogens to become manifest, the outcome as yet is uncertain.

the vas is split for a short distance. The silkworm gut is then reinserted. End-to-side anastomosis is carried out with 4/0 silk, the flaps resulting from the bifurcation being carried into the lumen of the epididymis (fig. 1529A). The silkworm gut splint

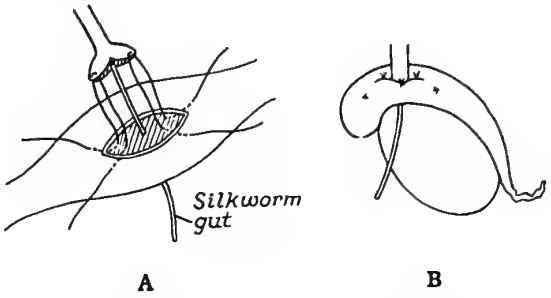

FIG. 1529.—End-to-side vaso-epididymal anastomosis. (*After S. Popelka* et al.)

is brought out between the epididymis and the body of the testis (fig. 1529B), and it is also well to pass this through a minute puncture in the scrotum and withdraw it after several days, when the anastomosis can be presumed to have united.

CHAPTER 59

ORGAN TRANSPLANTATION

THE transplantation of tissues and organs has a venerable history. Skin transplantation dates back to about 1500 B.C. Corneal and bone transplantation came more to the front in the second half of the nineteenth century and were followed in the early years of this century by whole organ transplantation after the work of Alexis Carrell.

Most tissue and organ transplants are rejected when the donor and recipient are genetically dissimilar. This rejection is an immunological phenomenon in which the recipient produces antibodies to antigens which the donor possesses but the recipient does not. Classically this rejection takes between 10–14 days to develop and to become fully effective. The result of this rejection is widespread infiltration of the transplant with lymphocytes, and microvascular changes which result in failure of the blood supply to the transplant.

Many potential recipients may previously have received sensitising challenges such as blood transfusions or previous transplantations. In these circumstances the recipient patient may show a modified response, resulting in an accelerated rejection in some, while 'enhancing' the effect in others.

Any attempt, therefore, to make organ transplantation a clinically acceptable procedure, must modify this rejection process. Much of the work on this subject has been done with kidney transplants following the pioneering work of Murray, Calne, Hume and Starzl.

KIDNEY TRANSPLANTATION

The Recipient.—It is usually better if the prospective patient is prepared for transplantation by hæmodialysis.

Access to Circulation—External Fistulæ.—This is achieved by the insertion of *Teflon* cannulæ either at the ankle or the wrist. The artery at the ankle is usually the posterior tibial artery while the vein may be the long or short saphenous vein. At the forearm, the radial artery and basilic or cephalic veins are used. These procedures can often be performed under local anæsthesia. The two Teflon cannulæ are connected with a *Silastic* loop which is used for linkage to the dialysis unit. Thrombosis and infection of these external fistulæ are frequent.

Internal Fistulæ.—For most patients, a *Cimino* fistula is made at the wrist, anastomosing the radial artery to the cephalic vein. Surprisingly, distal gangrene as a result of such a shunt is rare. If the cephalic vein has

Alexis Carrell, 1873–1944. Surgeon, Member of the Staff of the Rockefeller Institute for Medical Research, New York, U.S.A.
Joseph Edward Murray, Contemporary. Director of the Laboratory for Surgical Research, Harvard University, Boston, Massachusetts, U.S.A.
Roy Yorke Calne, F.R.S., Contemporary. Professor of Surgery, Cambridge, England.
David Milford Hulme, 1917–1973. Professor of Surgery, Harvard University, Boston, Massachusetts, U.S.A.
Thomas Earl Starzl, Contemporary. Professor of Surgery, University of Colorado, Denver, Colorado, U.S.A.
James E. Cimino, Contemporary. Chief, Renal Service Dialysis Unit, Veterans Administration Hospital, Bronx, N.Y., U.S.A.

been obliterated by previous intravenous infusion then an internal fistula can be made in the thigh by mobilising the long saphenous vein into a subcutaneous position and anastomosing its distal end to the femoral artery above the popliteal fossa.

It is important to place any fistula in a position which is accessible to the patient, i.e. a right-handed patient needs a fistula in the left arm.

If a patient is in incipient renal failure *never* place an intravenous infusion into a vessel likely to be used for an internal arteriovenous fistula.

While undergoing hæmodialysis, problems of congestive cardiac failure, tuberculosis, hypersecretion of gastric acid, secondary hyperparathyroidism, uræmic peripheral neuropathy and uræmic pericarditis can be corrected.

Donor Selection.—Most kidneys for transplantation come from people who may soon die as a result of a severe irreversible brain injury (cadaver kidneys). An alternative source is the living related donor (see below).

The dying head-injury victim must be cared for on a ventilator, and during this time of emergency care the blood group and the tissue-type will have been ascertained, and a suitable recipient found.

Any prospective donor must be free of infection or extracranial malignant disease and should preferably not be hypertensive. A patient maintained on a ventilator for more than two days will seldom be available as a donor because infection frequently supervenes. In addition the urine output should preferably be above 30 ml per hour. Normal blood urea and serum creatinine levels are desirable.

Compatibility.—The principle histocompatibility antigens in man include the ABO blood group antigens and the Human Leucocyte Antigens (HLA).

HL Antigens are detected on the membrane of peripheral blood lymphocytes by serological methods. Four principal genetic loci have been identified which code for antigen specificities inherited in simple Mendelian fashion from mother and father. Tissue typing refers to the serological techniques used to identify HL Antigens of donor and recipient in preparation for transplantation (fig. 1530).

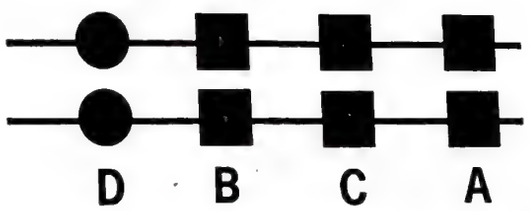

FIG. 1530.—Chromosome pair showing the arrangement of the four loci of the HLA gene complex—A, B, C, and D. Twenty antigen specificities are recognised both at the major A and B loci with a further five at the C locus, and six at the D locus.

Mixed Lymphocyte Culture (MLC) measures direct cell-to-cell reactions of lymphocytes from donor and recipient. The HLD locus Antigens are important in these reactions and matching for MLC reactivity may be better correlated with graft survival.

The sensitisation of the recipient to previous antigens, such as multiple blood transfusions may mask the role of the HLA matching. Such presensitisation may produce accelerated rejection or the exact opposite, by producing a blocking antibody giving extremely good transplant results.

Cadaver Unrelated Donors.—Successful transplantation of cadaveric, i.e. unrelated, donor kidneys depends on matching the HL Antigens of

Gregor Johann Mendel, 1822–1884. Austrian Monk and naturalist, who became Abbot of the Augustinian Monastery at Brunn (Brno), Czechoslovakia.

donor and recipient. Festenstein has discovered that optimal kidney graft survival depends on matching as close as possible the HL Antigens of donor and recipient.

Living Related Donors.—Care must be taken to ensure that these donors are really voluntary. Donors from psychiatrically unstable relatives should be avoided. Unrelated living donors may rarely be considered.

Once ABO compatibility between donor and recipient is established, then an IVP, urine culture and blood urea should establish that the donor is urologically normal.

There is seldom concern about HLA compatibility with the related living donors. In a parent-to-child donation there will always be two out of four antigens compatible and if a sibling donor is used there may even be a more compatible HLA configuration. A 'cross-match' between donor lymphocytes and recipient serum is performed. If a positive cytotoxic result is obtained then such a transplant would be unlikely to function. If the cross-match is negative, the donor should have an aortogram to select which kidney should be used.

Diagnosis of Death (brief guide lines—there being no accepted definition).—The prospective donor, who must be normothermic and free of all types of sedative and anæsthetic drugs is declared dead if:

1. There is a total unreceptivity and unresponsiveness to all external stimuli.
2. There is no spontaneous respiratory movement for 3 minutes when the patient's pCO_2 is normal (this test should be repeated at regular intervals).
3. There are no reflexes.
4. There are bilateral fixed dilated pupils.
5. The electroencephalogram is flat on all channels.

Where possible all these tests should be repeated over a period of 24 hours.

The diagnosis of death must be made by physicians of some standing and who are not in any way involved in the transplantation.

Ownership of the Body.—Permission for the use of organs must be obtained from the person who owns the body. This is usually the next of kin. If a 'reasonable search' fails to find a next of kin, then the hospital administration (in the U.K.) own the body and may give permission for the removal of organs. The finding of a 'donor card' does not over-rule the instructions of the owners of the body, but should guide them.

The Donor Operation.—The living donor operation is a routine nephrectomy taking as much artery and vein as possible, conserving the perireteric fat to protect the blood supply of the ureter.

The cadaveric donor operation is also a fully sterile operation, but the two kidneys are usually removed *en bloc* with the piece of aorta and vena cava between them, conserving any accessory vessels. Cadaveric kidneys must be removed within 100 minutes of cardiac arrest. This is called the warm ischæmic time. The kidneys must then be cooled to 8–12°C. This cooling gives a cold ischæmic time and may safely extend up to 24 hours if the kidney is cooled by gravity wash through with ice-cold solutions resembling

Hilliard Festenstein, Contemporary. Professor of Transplant Immunology, The London Hospital, London, England.

intra-cellular fluid. Following this the kidney is put into a sterile plastic bag, which is put into ice in a suitable insulating box.

Organ Preservation.—If the excised kidney is put on a preserving machine, it can be perfused at 8–12°C. with albumin or plasma and kept viable for as long as 72 hours while a suitable recipient is found.

A kidney on a preservation machine (*Belzer*) can be studied physiologically, in order to exclude irreversible hypoxic or acidotic damage which often accompanies death. These irreversibly damaged kidneys are then discarded; it is better to do this than give the recipient a useless kidney.

The Recipient Operation.—While the donor kidney is being excised, the recipient is anæsthetised, and a lower quadrant incision made above and parallel to the inguinal ligament. The internal and external iliac vessels are cleared of lymph nodes and adipose tissue, and then clamped superiorly with bulldog clamps. The renal artery may be anastomosed end to end with the internal iliac artery (fig. 1531) or end to side with the external iliac arteries.

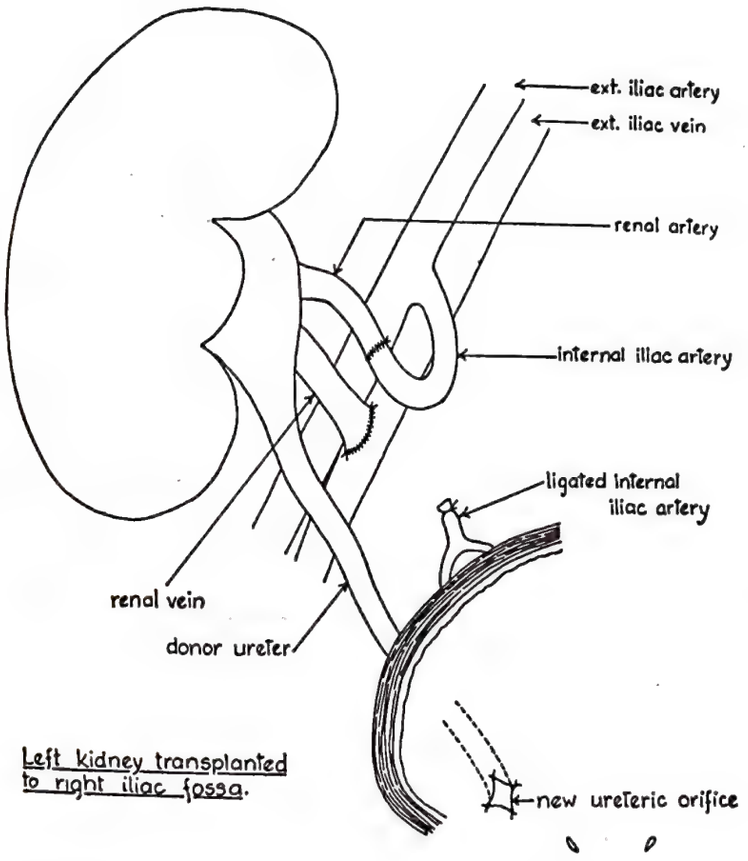

FIG. 1531.—Renal transplantation (recipient operation).

Post-Operative Management

1. *Immunosuppression.*—This is usually achieved with combinations of Azathioprine and Prednisone. Antilymphocyte serum, purified to IgG has improved the results considerably in cadaveric transplants. Azathioprine is used with various treatment regimes, the best results being with a dose of 3 mg/kg throughout the operation and subsequent days.

2. *Steroids.*—Steroids are usually administered as Prednisone starting at a dose of 1·5 mg/kg at the operation. The dose of steroid is gradually reduced over three months to a maintenance dose of 15 mg/day.

Folkert Belzer, Contemporary. Professor of Surgery, University of California, San Francisco, Cal., U.S.A.

Actinomycin C, external irradiation of the kidney with 600 rad, extracorporeal irradiation of circulating blood, and thoracic duct fistula also have an occasional use.

3. *Fluid Balance.*—Urinary output is measured hourly and replaced ml. for ml. with dextrose saline up to a urinary output of 200 ml/hour. It should not be forgotten that an anephric patient needs 500 ml. of fluid per day to replace insensible loss. This can be replaced at 20 ml/hour of normal saline at the same time as the dextrose-saline replacement of urinary output. It is convenient to add the immunosuppressive drugs into the normal saline for 24 hours, so that a steady administration of drugs is achieved.

Management of Post-Operative Oliguria.—Many cadaveric renal transplants are followed by a period of anuria due to acute tubular necrosis which recovers spontaneously while the patient is maintained on hæmodialysis. However, the transplant kidney may stop secreting urine after an initially satisfactory output. The causes of this may be:

1. *Hypovolæmia.*—This can be tested by administering normal saline in 200 ml. aliquots and using a central venous pressure line (p. 69), and sometimes supplemented with 150 mg of Frusemide.

2. *Mechanical Obstruction or Extravasation.*—An intravenous pyelogram should be obtained and cystoscopy and ureteric catheterisation should usually follow it. Isotope renography and gamma camera visualisation gives more information. Obstruction or extravasation of urine should be corrected immediately, and a nephrostomy is a wise adjunct to such a procedure.

3. *Acute Tubular Necrosis.*—This is the commonest cause of post-operative anuria. Tubular casts may be seen in the urine if there is any. A period of hæmodialysis for up to 4 weeks may be necessary.

4. *Rejection.*—All allotransplants have some degree of rejection. The severest form is termed hyperacute rejection, and may occur within minutes of completion of the operation. This phenomenon is seen in A.B.O. incompatibility, or in some recipients sensitised by multiple blood transfusions; little can be done to reverse this hyperacute rejection, which is associated with intrarenal coagulopathy and gross platelet aggregations in the kidney. The commoner acute form of rejection may occur even in H.L.A.-compatible transplants and may be seen during the three months after the transplantation. Rejection is associated with the excretion of fibrinogen degradation products and microglobulins in the urine. The kidney becomes tense and tender, with pyrexia, hypertension and leucocytosis being frequently noted. Chronic rejection noted many months after transplantation is associated with arterial damage in the kidney.

If hypovolæmia and mechanical disasters have been excluded, a biopsy of the kidney should be performed. This should be arranged at a time when fresh tissue can be obtained for immunofluorescence and electron microscopy as well as conventional light microscopy studies.

Treatment of Rejection.—The usual treatment is to increase the daily dose of Prednisone to 1000 mg on three successive days and then reduce to 1·5 mg/kg. Sometimes the patient may have marrow suppression from

Azothioprine, or viræmia, when large doses of steroids can be lethal. In these circumstances the rejection may be reversed with 600 rad of external irradiation restricted to the transplant, or the spleen may be removed as leucopænia can be caused by cytomegalovirus incarceration in the spleen.

Hazards of Immunosuppression.—High doses of steroids not only delay healing but mask classical physical signs of disease, such as pneumonia or an acute abdomen. Gastrointestinal bleeding may be exacerbated in recipients who also have achlorhydria or hyperchlorhydria. Patients also succumb to many other micro-organisms such as monilia, cytomegalovirus, or *staph. albus*, in addition to normal pathogens. Patients should avoid contact with normal childhood virus infections.

Azathioprine.—This can only be excreted by the kidney. During anuria the dose of azathioprine may be reduced, or it will accumulate, with associated marrow suppression. Many other alleged toxic affects of azathioprine such as pancreatitis and hepatitis are probably due to viral infection of these organs. There is probably a higher incidence of malignant disease in patients receiving immunosuppressant drugs.

Anti-lymphocyte serum is made by injecting cells of the lymphoid series into animals such as horses or rabbits. It is usually purified to IgG and can be a potent immunosuppressant agent, which may open the way for the induction of specific tolerance.

Results of Kidney Transplantation

It is important to differentiate between patient survival and transplant survival. When a kidney ceases to function the kidney can be removed and the patient returned to hæmodialysis. The international survival figures for the years following 1969 are in the era of modern tissue typing, organ preservation, and immunological screening of recipients. Patient survival is always better than graft survival.

By September 1975, nearly 23,000 renal transplants had been reported in the literature and the results have not changed over the last three years. The one year survival figure for patients is 91% for sibling donors, 87% for parental donors and 72% for cadaver sources. These figures drop by 5% per year to a plateau at five years.

LIVER TRANSPLANTATION

By April 1976, the world total of liver transplants was 265; of these 31 were still alive. The commonest indication for liver transplants has been biliary atresia and shows the best results. The longest survival was 74 months, but most liver transplants have not lived beyond one year. There are so many other complications in recipients with cirrhosis or malignancy, that these results are discouraging.

The liver is particularly sensitive to hypoxia. It is only recently that the period of ischæmia between donor death and transplantation could exceed 6 hours. The liver transplant is also very sensitive to azathioprine. It may be better managed with cyclophosphamide or anti-lymphocyte serum.

The liver is best transplanted into the normal subdiaphragmatic position. This requires recipient hepatectomy, but these orthotopic transplants show better results than heterotopic transplants where the liver transplant is used as an auxiliary to the recipient's own liver.

HEART TRANSPLANTATION[1]

Of the 305 cardiac transplants performed between 1967–1976, 40% had a one year survival and 36% had a two year survival. The longest survival was 89 months. The technique standardised by Shumway, involved leaving the posterior walls of the

[1] The first human heart transplant was performed in December 1967 at the Groote Schuur Hospital, Cape Town, South Africa, by Christiaan Neethling Barnard, Professor of Cardiothoracic Surgery, University of Cape Town.

Norman Edward Shumway, Contemporary. Professor of Surgery, Stanford University, Palo Alto, California, U.S.A.

recipient's atria *in situ*, to which the donor atria are anastomosed, for venous return. The pulmonary artery and aorta of the donor are anastomosed end to end to the recipient's great vessels. Despite this technique autonomic re-innervation of the donor heart does not occur.

Many recipients are far from ideal, with pulmonary infection and pulmonary hypertension. Amongst these patients are seen the worst results. Rejection of the heart occurs, as in any organ, and the classical arteriolar lesions of rejection limit long term success. Recipient coronary arteries show accelerated atherosclerosis, and some recipients have benefited from coronary revascularisation procedures.

BONE MARROW

Over one hundred bone marrow transplants have been reported since 1968, for leukæmia, aplastic anæmia or immune deficiency diseases. HLA identity is probably more important in marrow transplants than in other organs. The success rate is low, but when engraftment succeeded 50% of the patients survived 3 months.

OTHER VISCERA

Pancreas.—Forty-nine pancreatic transplants have been performed, the longest survivor (by 1976) being for 45 months.

Lung.—Very few of these have survived 6 weeks. Although 37 cases have been reported, currently none are functioning (p. 727).

CHAPTER 60

THE SURGICAL PATIENT

THE PATIENT comes to the surgeon with an affliction of some part of the body. To plan the most effective treatment the surgeon needs to know something about the patient beyond the disease itself in order to:

1. Understand the patient as a whole person. 2. Discover any factors in the patient's life situation which might have a bearing on the ætiology. 3. Assess the kind of treatment best suited to the particular patient (according to their personality and their general economic circumstances), and the timing of any operative intervention. 4. Help make an accurate estimate of prognosis.

Psychosocial Background

The patient lying quietly in a hospital bed has as many responsibilities, anxieties, personal concerns as the doctors looking after him, plus all the problems associated with being ill, away from home or not earning, and there may also be social problems and psychiatric symptoms. These can all be grouped together as Psychosocial Factors and they can be assessed under the following headings:

1. *Bereavement*, from the death of any member of the family or close friend within the past 12 months. 2. *Serious illness or Disability* in anyone living with the patient or having to be cared for by the patient. 3. *Previous Psychiatric History*, G.P. or specialist care, or use of psychotropic drugs. 4. *Problems with the children* (*if any*), dependant or adult. 5. *Work Problems* actual or threatened, no sick pay, bad working conditions, difficult relations with superiors or subordinates, retirement. 6. *Home Problems*. The building itself, the local environment, personal relationships in the home and with neighbours. 7. *Other Problems* in the patient's life situation.

Pre-operative Preparation

Levels of Anxiety.—A surgical operation is a major event in anyone's life, and so a level of anxiety is expected in any patient who has an accurate grasp of what is going on. Some patients may display high anxiety and will benefit from repeated explanation and reassurance, and also from tranquillising medication. Others will appear as relaxed and uncomplaining 'good patients' but they may in fact be denying ostrich-fashion the realities of the operation. They too require explanation because they can become resentful and uncooperative in the postoperative period if they have not been made to realise that at least some discomfort is ahead of them.

Special Organs and Procedures.—Any operation may be of particular importance to a patient if, for example, a relative died after one quite similar, or indeed died from some totally different cause in the same hospital or even the same ward.

Operations on the heart, the eye, the uterus, the breast, are followed by a disproportionate number of psychological and social problems, as they pose a threat to life itself, the individual's independence, or to personal or sexual identity. Furthermore, some of these patients will spend time in intensive care units or be blindfolded for a period. Dangerous levels of anxiety can develop which can lead to acute psychiatric emergencies.

Colostomy, ileostomy, amputation and organ transplant have a special place because of the drastic effect they have on the individual's life and self-image. Specialised technical advice about appliances and facilities is available, but patients need the opportunity to discuss their fears, the future function of their bodies (especially sexual function), and they need a period of personal support while they adapt to their new life style.

Postoperative Phase

Careful pre-operative explanation is the best way to reduce post-operative distress. The patient with an accurate knowledge of what to expect—drains, dressings, intravenous infusions, how to breathe, how to move in bed, how much pain to expect and how long it will last—will require less post-operative analgesia and spend less time in hospital than the patient who has no idea of what to expect. The tense postoperative patient lies rigid, holds muscles tight, does not breathe freely or move his legs and predisposes himself to postoperative complications.

Recovery

The self-employed man is the soonest back to work. Delayed recovery, however good may be the clinical reasons, calls for a psychosocial inquiry. There may be outstanding claims for compensation, difficulties at home or at work, or if there has been prolonged disability, the resumption of full health—with all the demands that are made on the healthy—may be a mixed blessing.

What to Tell the Patient

'I knew I was done for when the doctors didn't stop at the bed any more.' Patients lying in bed all day are minutely sensitive to every aspect of the doctor's behaviour. Surveys of patients with incurable diseases show that the great majority want to know what is wrong with them, however bad the prognosis.

When someone is told they have cancer or an incurable illness they are bound to react. How would you react? People take time to adjust to the realities, and may go through periods of denial of the truth, depression, anger, and resentment against the staff. But with warm support with plenty of opportunity for frank expression of feelings, and involving family, chaplain, general practitioner and social worker as the case may be, most people

can be brought through to a state where they can accept peacefully that there is no more that the doctors can do for them.

There will, of course, be a small number who really should not be confronted with the realities of fatal illness. The doctor who is sensitive to his patients (and who has overcome his own antipathies in dealing with the dying) will recognise who these are, but no one should ever be left in ignorance by default. All members of the team and the general practitioner must agree about what to tell the patient, but the most experienced member should be the one to do the telling.

Those Who Cannot be Cured

The surgeon has many skills that can be used to help those for whom there can be no cure. For example, procedures to relieve vomiting, appliances to lessen the distress of incontinence, measures to control diarrhœa and constipation. The patient should not automatically be confined to bed. Sympathetic and practical physiotherapy can do wonders. Most important of all is the control of chronic pain, of which most doctors, used only to brief acute pain, can have no conception. Ideas of standard dosages can be cast aside. The correct dose of an analgesic for someone with painful terminal illness is that dose which the patient says relieves the pain. The drug is titrated against the patient, and the dose is repeated before the effects of the previous one have worn off.

Anxiety is greatly relieved by frank discussion but there is also a definite place for tranquillisers such as the benzodiazepines or chlorpromazine, and they can enhance the effects of analgesics and avoid excessive sedation. When the pain is severe there should never be any hesitation in using morphine or related alkaloids, questions of addiction or escalating dosage are irrelevant in terminal care. These drugs, and cocaine also, can bring a consoling sense of calm and wellbeing in the final stages.

Special Medication.—The formula used at The Royal Marsden (formerly Cancer) Hospital, London, is—morph. hydrochlor 15 mg, cocaine hydrochlor 10 mg, gin 4 ml, honey 4 g, aq. chlor ad 15 ml. This formula can be varied, e.g. if pain is not severe the morphia can be omitted or substituted by heroin, which is less likely to cause nausea and flatulence. Honey disguises the bitterness of cocaine. The mixture is similar to the ' Brompton cocktail ', London.
